|                                    | additional metrics, rather than being surprised when they are permanently removed in the release after that. Default: ""                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
| systemReservedCgroup<br>string     | systemReservedCgroup helps the kubelet identify absolute name of top level CGroup used to enforce systemReserved compute resource reservation for OS system daemons. Refer to <a href="#">Node Allocatable</a> doc for more information. Default: ""                                                                                                                                                                                                                                                                                                                     |
| kubeReservedCgroup<br>string       | kubeReservedCgroup helps the kubelet identify absolute name of top level CGroup used to enforce KubeReserved compute resource reservation for Kubernetes node system daemons. Refer to <a href="#">Node Allocatable</a> doc for more information. Default: ""                                                                                                                                                                                                                                                                                                            |
| enforceNodeAllocatable<br>[]string | This flag specifies the various Node Allocatable enforcements that Kubelet needs to perform. This flag accepts a list of options. Acceptable options are none, pods, system-reserved and kube-reserved. If none is specified, no other options may be specified. When system-reserved is in the list, systemReservedCgroup must be specified. When kube-reserved is in the list, kubeReservedCgroup must be specified. This field is supported only when cgroupsPerQOS is set to true. Refer to <a href="#">Node Allocatable</a> for more information. Default: ["pods"] |
| allowedUnsafeSysctls<br>[]string   | A comma separated whitelist of unsafe sysctls or sysctl patterns (ending in *). Unsafe sysctl groups are kernel.shm*, kernel.msg*, kernel.sem, fs.mqueue.*, and net.*. For example: "kernel.msg*,net.ipv4.route.min_pmtu" Default: []                                                                                                                                                                                                                                                                                                                                    |
| volumePluginDir<br>string          | volumePluginDir is the full path of the directory in which to search for additional third party volume plugins. Default: "/usr/libexec/kubernetes/kubelet-plugins/volume/exec/"                                                                                                                                                                                                                                                                                                                                                                                          |
| providerID<br>string               | providerID, if set, sets the unique ID of the instance that an external provider (i.e. cloudprovider) can use to identify a specific node. Default: ""                                                                                                                                                                                                                                                                                                                                                                                                                   |

| enableSystemLogHandler<br>bool                                                         | enableSystemLogHandler enables system logs via web interface host:port/logs/ Default: true                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
| enableSystemLogQuery<br>bool                                                           | enableSystemLogQuery enables the node log query feature on the /logs endpoint. EnableSystemLogHandler has to be enabled in addition for this feature to work. Default: false                                                                                                                                                                                                                                                                                                                                                                          |
| shutdownGracePeriod<br><a href="#">meta/v1.Duration</a>                                | shutdownGracePeriod specifies the total duration that the node should delay the shutdown and total grace period for pod termination during a node shutdown. Default: "0s"                                                                                                                                                                                                                                                                                                                                                                             |
| shutdownGracePeriodCriticalPods<br><a href="#">meta/v1.Duration</a>                    | shutdownGracePeriodCriticalPods specifies the duration used to terminate critical pods during a node shutdown. This should be less than shutdownGracePeriod. For example, if shutdownGracePeriod=30s, and shutdownGracePeriodCriticalPods=10s, during a node shutdown the first 20 seconds would be reserved for gracefully terminating normal pods, and the last 10 seconds would be reserved for terminating critical pods. Default: "0s"                                                                                                           |
| shutdownGracePeriodByPodPriority<br><a href="#">[]ShutdownGracePeriodByPodPriority</a> | shutdownGracePeriodByPodPriority specifies the shutdown grace period for Pods based on their associated priority class value. When a shutdown request is received, the Kubelet will initiate shutdown on all pods running on the node with a grace period that depends on the priority of the pod, and then wait for all pods to exit. Each entry in the array represents the graceful shutdown time a pod with a priority class value that lies in the range of that value and the next higher entry in the list when the node is shutting down. |                                                                  | <p>example, to allow critical pods 10s to shutdown, priority&gt;=10000 pods 20s to shutdown, and all remaining pods 30s to shutdown.</p> <p>shutdownGracePeriodByPodPriority:</p> <ul style="list-style-type: none"> <li>• priority: 2000000000<br/>shutdownGracePeriodSeconds: 10</li> <li>• priority: 10000<br/>shutdownGracePeriodSeconds: 20</li> <li>• priority: 0 shutdownGracePeriodSeconds: 30</li> </ul> <p>The time the Kubelet will wait before exiting will at most be the maximum of all shutdownGracePeriodSeconds for each priority class range represented on the node. When all pods have exited or reached their grace periods, the Kubelet will release the shutdown inhibit lock. Requires the GracefulNodeShutdown feature gate to be enabled. This configuration must be empty if either ShutdownGracePeriod or ShutdownGracePeriodCriticalPods is set. Default: nil</p>                                                                                                                                                                                                                                                                                                                  |
| <p>reservedMemory</p> <p><a href="#">[]MemoryReservation</a></p> | <p>reservedMemory specifies a comma-separated list of memory reservations for NUMA nodes. The parameter makes sense only in the context of the memory manager feature. The memory manager will not allocate reserved memory for container workloads. For example, if you have a NUMA0 with 10Gi of memory and the reservedMemory was specified to reserve 1Gi of memory at NUMA0, the memory manager will assume that only 9Gi is available for allocation. You can specify a different amount of NUMA node and memory types. You can omit this parameter at all, but you should be aware that the amount of reserved memory from all NUMA nodes should be equal to the amount of memory specified by the <a href="#">node allocatable</a>. If at least one node allocatable parameter has a non-zero value, you will need to specify at least one NUMA node. Also, avoid specifying:</p> <ol style="list-style-type: none"> <li>1. Duplicates, the same NUMA node, and memory type, but with a different value.</li> <li>2. zero limits for any memory type.</li> <li>3. NUMAs nodes IDs that do not exist under the machine.</li> <li>4. memory types except for memory and hugepages-&lt;size&gt;</li> </ol> |

| Field                                                 | Description                                                                                                                                                                                                                                                                                                                                                                                                                       |

|                                                       | Default: nil                                                                                                                                                                                                                                                                                                                                                                                                                      |
| enableProfilingHandler<br>bool                        | enableProfilingHandler enables profiling via web interface host:port/debug/pprof/ Default: true                                                                                                                                                                                                                                                                                                                                   |
| enableDebugFlagsHandler<br>bool                       | enableDebugFlagsHandler enables flags endpoint via web interface host:port/debug/flags/v Default: true                                                                                                                                                                                                                                                                                                                            |
| seccompDefault<br>bool                                | SeccompDefault enables the use of RuntimeDefault as the default seccomp profile for all workloads. Default: false                                                                                                                                                                                                                                                                                                                 |
| memoryThrottlingFactor<br>float64                     | MemoryThrottlingFactor specifies the factor multiplied by the memory limit or node allocatable memory when setting the cgroupv2 memory.high value to enforce MemoryQoS. Decreasing this factor will set lower high limit for container cgroups and put heavier reclaim pressure while increasing will put less reclaim pressure. See <a href="https://kep.k8s.io/2570">https://kep.k8s.io/2570</a> for more details. Default: 0.9 |
| registerWithTaints<br><a href="#">[]core/v1.Taint</a> | registerWithTaints are an array of taints to add to a node object when the kubelet registers itself. This only takes effect when registerNode is true and upon the initial registration of the node. Default: nil                                                                                                                                                                                                                 |
| registerNode<br>bool                                  | registerNode enables automatic registration with the apiserver. Default: true                                                                                                                                                                                                                                                                                                                                                     |
| tracing<br><a href="#">TracingConfiguration</a>       | Tracing specifies the versioned configuration for OpenTelemetry tracing clients. See <a href="https://kep.k8s.io/2832">https://kep.k8s.io/2832</a> for more details. Default: nil                                                                                                                                                                                                                                                 |
| localStorageCapacityIsolation<br>bool                 | LocalStorageCapacityIsolation enables local ephemeral storage isolation feature. The default setting is true. This feature allows users to set request/limit for container's ephemeral storage and manage it in a similar way as cpu and memory. It also allows setting sizeLimit for emptyDir volume, which will trigger pod eviction if disk usage from                                                                         |

| Field                                                | Description                                                                                                                                                                                                                                                                                                                                                                                           |
|------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                                                      | the volume exceeds the limit. This feature depends on the capability of detecting correct root file system disk usage. For certain systems, such as kind rootless, if this capability cannot be supported, the feature LocalStorageCapacityIsolation should be disabled. Once disabled, user should not set request/limit for container's ephemeral storage, or sizeLimit for emptyDir. Default: true |
| containerRuntimeEndpoint <b>[Required]</b><br>string | ContainerRuntimeEndpoint is the endpoint of container runtime. Unix Domain Sockets are supported on Linux, while npipe and tcp endpoints are supported on Windows. Examples:'unix:///path/to/runtime.sock', 'npipe:////./pipe/runtime'                                                                                                                                                                |
| imageServiceEndpoint<br>string                       | ImageServiceEndpoint is the endpoint of container image service. Unix Domain Socket are supported on Linux, while npipe and tcp endpoints are supported on Windows. Examples:'unix:///path/to/runtime.sock', 'npipe:////./pipe/runtime'. If not specified, the value in containerRuntimeEndpoint is used.                                                                                             |

## SerializedNodeConfigSource

SerializedNodeConfigSource allows us to serialize v1.NodeConfigSource. This type is used internally by the Kubelet for tracking checkpointed dynamic configs. It exists in the kubeletconfig API group because it is classified as a versioned input to the Kubelet.

| Field                                              | Description                                   |
|----------------------------------------------------|-----------------------------------------------|
| apiVersion<br>string                               | kubelet.config.k8s.io/v1beta1                 |
| kind<br>string                                     | SerializedNodeConfigSource                    |
| source<br><a href="#">core/v1.NodeConfigSource</a> | source is the source that we are serializing. |

## CredentialProvider

Appears in:

- [CredentialProviderConfig](#)

CredentialProvider represents an exec plugin to be invoked by the kubelet. The plugin is only invoked when an image being pulled matches the images handled by the plugin (see `matchImages`).

| Field                                                                                   | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
|-----------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>name</code> <b>[Required]</b><br>string                                           | <code>name</code> is the required name of the credential provider. It must match the name of the provider executable as seen by the kubelet. The executable must be in the kubelet's bin directory (set by the <code>--image-credential-provider-bin-dir</code> flag).                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| <code>matchImages</code> <b>[Required]</b><br>[]string                                  | <p><code>matchImages</code> is a required list of strings used to match against images in order to determine if this provider should be invoked. If one of the strings matches the requested image from the kubelet, the plugin will be invoked and given a chance to provide credentials. Images are expected to contain the registry domain and URL path.</p> <p>Each entry in <code>matchImages</code> is a pattern which can optionally contain a port and a path. Globs can be used in the domain, but not in the port or the path. Globs are supported as subdomains like <code>*.k8s.io</code> or <code>k8s.*.io</code>, and top-level-domains such as <code>k8s.*</code>. Matching partial subdomains like <code>app*.k8s.io</code> is also supported. Each glob can only match a single subdomain segment, so <code>*.io</code> does not match <code>*.k8s.io</code>.</p> <p>A match exists between an image and a <code>matchImage</code> when all of the below are true:</p> <ul style="list-style-type: none"><li>• Both contain the same number of domain parts and each part matches.</li><li>• The URL path of an <code>imageMatch</code> must be a prefix of the target image URL path.</li><li>• If the <code>imageMatch</code> contains a port, then the port must match in the image as well.</li></ul> <p>Example values of <code>matchImages</code>:</p> <ul style="list-style-type: none"><li>• <code>123456789.dkr.ecr.us-east-1.amazonaws.com</code></li><li>• <code>*.azurecr.io</code></li><li>• <code>gcr.io</code></li><li>• <code>*.*.registry.io</code></li><li>• <code>registry.io:8080/path</code></li></ul> |
| <code>defaultCacheDuration</code> <b>[Required]</b><br><a href="#">meta/v1.Duration</a> | <code>defaultCacheDuration</code> is the default duration the plugin will cache credentials in-memory if a cache duration is not provided in the plugin response. This field is required.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |

| Field                              | Description                                                                                                                                                                                                                                                                      |
|------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| apiVersion<br>[Required]<br>string | Required input version of the exec CredentialProviderRequest. The returned CredentialProviderResponse MUST use the same encoding version as the input. Current supported values are: <ul style="list-style-type: none"> <li>credentialprovider.kubelet.k8s.io/v1beta1</li> </ul> |
| args<br>[]string                   | Arguments to pass to the command when executing it.                                                                                                                                                                                                                              |
| env<br>[]ExecEnvVar                | Env defines additional environment variables to expose to the process. These are unioned with the host's environment, as well as variables client-go uses to pass argument to the plugin.                                                                                        |

## ExecEnvVar

Appears in:

- [CredentialProvider](#)

ExecEnvVar is used for setting environment variables when executing an exec-based credential plugin.

| shutdownGracePeriodSeconds <b>[Required]</b><br>int64 | shutdownGracePeriodSeconds is the shutdown grace period in seconds       |

## Kubelet CredentialProvider (v1)

### Resource Types

- [CredentialProviderRequest](#)
- [CredentialProviderResponse](#)

## CredentialProviderRequest

CredentialProviderRequest includes the image that the kubelet requires authentication for. Kubelet will pass this request object to the plugin via stdin. In general, plugins should prefer responding with the same apiVersion they were sent.

| Field                                | Description                                                                                                                                                                                           |
|--------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| apiVersion<br>string                 | credentialprovider.kubelet.k8s.io/v1                                                                                                                                                                  |
| kind<br>string                       | CredentialProviderRequest                                                                                                                                                                             |
| image<br><b>[Required]</b><br>string | image is the container image that is being pulled as part of the credential provider plugin request. Plugins may optionally parse the image to extract any information required to fetch credentials. |

## CredentialProviderResponse

CredentialProviderResponse holds credentials that the kubelet should use for the specified image provided in the original request. Kubelet will read the response from the plugin via stdout. This response should be set to the same apiVersion as CredentialProviderRequest.

| Field                                                                   | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |

| kind<br>string                                                          | CredentialProviderResponse                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| cacheKeyType<br><b>[Required]</b><br><a href="#">PluginCacheKeyType</a> | cacheKeyType indicates the type of caching key to use based on the image provided in the request. There are three valid values for the cache key type: Image, Registry, and Global. If an invalid value is specified, the response will NOT be used by the kubelet.                                                                                                                                                                                                                                                                                                              |
| cacheDuration<br><a href="#">meta/v1.Duration</a>                       | cacheDuration indicates the duration the provided credentials should be cached for. The kubelet will use this field to set the in-memory cache duration for credentials in the AuthConfig. If null, the kubelet will use defaultCacheDuration provided in CredentialProviderConfig. If set to 0, the kubelet will not cache the provided AuthConfig.                                                                                                                                                                                                                             |
| auth<br><a href="#">map[string]AuthConfig</a>                           | <p>auth is a map containing authentication information passed into the kubelet. Each key is a match image string (more on this below). The corresponding authConfig value should be valid for all images that match against this key. A plugin should set this field to null if no valid credentials can be returned for the requested image.</p> <p>Each key in the map is a pattern which can optionally contain a port and a path. Globs can be used in the domain, but not in the port or the path. Globs are supported as subdomains like '*.k8s.io' or 'k8s.*.io', and</p> |

| Field | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
|-------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|       | <p>top-level-domains such as 'k8s.*'. Matching partial subdomains like 'app*.k8s.io' is also supported. Each glob can only match a single subdomain segment, so '*.io' does not match '*.k8s.io'.</p> <p>The kubelet will match images against the key when all of the below are true:</p> <ul style="list-style-type: none"> <li>• Both contain the same number of domain parts and each part matches.</li> <li>• The URL path of an imageMatch must be a prefix of the target image URL path.</li> <li>• If the imageMatch contains a port, then the port must match in the image as well.</li> </ul> <p>When multiple keys are returned, the kubelet will traverse all keys in reverse order so that:</p> <ul style="list-style-type: none"> <li>• longer keys come before shorter keys with the same prefix</li> <li>• non-wildcard keys come before wildcard keys with the same prefix.</li> </ul> <p>For any given match, the kubelet will attempt an image pull with the provided credentials, stopping after the first successfully authenticated pull.</p> <p>Example keys:</p> <ul style="list-style-type: none"> <li>• 123456789.dkr.ecr.us-east-1.amazonaws.com</li> <li>• *.azurecr.io</li> <li>• gcr.io</li> <li>• *.registry.io</li> <li>• registry.io:8080/path</li> </ul> |

## AuthConfig

Appears in:

- [CredentialProviderResponse](#)

AuthConfig contains authentication information for a container registry. Only username/password based authentication is supported today, but more authentication mechanisms may be added in the future.

| Field                                   | Description                                                                                               |
|-----------------------------------------|-----------------------------------------------------------------------------------------------------------|
| username<br><b>[Required]</b><br>string | username is the username used for authenticating to the container registry<br>An empty username is valid. |

| Field                            | Description                                                                                               |
|----------------------------------|-----------------------------------------------------------------------------------------------------------|
| password<br>[Required]<br>string | password is the password used for authenticating to the container registry<br>An empty password is valid. |

## MetricValueList

MetricValueList is a list of values for a given metric for some set of objects

| Field                                                                                            | Description                                          |
|--------------------------------------------------------------------------------------------------|------------------------------------------------------|
| apiVersion<br>string                                                                             | custom.metrics.k8s.io/v1beta2                        |
| kind<br>string                                                                                   | MetricValueList                                      |
| metadata <b>[Required]</b><br><a href="https://k8s.io/api/meta/v1.ListMeta">meta/v1.ListMeta</a> | No description provided.                             |
| items <b>[Required]</b><br><a href="#">[]MetricValue</a>                                         | the value of the metric across the described objects |

## MetricIdentifier

Appears in:

- [MetricValue](#)

MetricIdentifier identifies a metric by name and, optionally, selector

| Field                                                                                    | Description                                                                                                                                                                                                                                        |
|------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| name<br><b>[Required]</b><br>string                                                      | name is the name of the given metric                                                                                                                                                                                                               |
| selector<br><a href="https://k8s.io/api/meta/v1.LabelSelector">meta/v1.LabelSelector</a> | selector represents the label selector that could be used to select this metric, and will generally just be the selector passed in to the query used to fetch this metric. When left blank, only the metric's Name will be used to gather metrics. |

# Kubernetes External Metrics (v1beta1)

## Scheduling

---

[Scheduler Configuration](#)

[Scheduling Policies](#)

## Scheduler Configuration

FEATURE STATE: Kubernetes v1.25 [stable]

You can customize the behavior of the kube-scheduler by writing a configuration file and passing its path as a command line argument.

A scheduling Profile allows you to configure the different stages of scheduling in the [kube-scheduler](#). Each stage is exposed in an extension point. Plugins provide scheduling behaviors by implementing one or more of these extension points.

You can specify scheduling profiles by running kube-scheduler --config <filename>, using the KubeSchedulerConfiguration [v1](#) struct.

A minimal configuration looks as follows:

```
apiVersion: kubescheduler.config.k8s.io/v1
kind: KubeSchedulerConfiguration
clientConnection:
 kubeconfig: /etc/srv/kubernetes/kube-scheduler/kubeconfig
```

**Note:**

KubeSchedulerConfiguration v1beta3 is deprecated in v1.26 and is removed in v1.29. Please migrate KubeSchedulerConfiguration to [v1](#).

## Profiles

A scheduling Profile allows you to configure the different stages of scheduling in the [kube-scheduler](#). Each stage is exposed in an [extension point](#). [Plugins](#) provide scheduling behaviors by implementing one or more of these extension points.

You can configure a single instance of kube-scheduler to run [multiple profiles](#).

## Extension points

Scheduling happens in a series of stages that are exposed through the following extension points:

1. **queueSort**: These plugins provide an ordering function that is used to sort pending Pods in the scheduling queue. Exactly one queue sort plugin may be enabled at a time.
2. **preFilter**: These plugins are used to pre-process or check information about a Pod or the cluster before filtering. They can mark a pod as unschedulable.
3. **filter**: These plugins are the equivalent of Predicates in a scheduling Policy and are used to filter out nodes that can not run the Pod. Filters are called in the configured order. A pod is marked as unschedulable if no nodes pass all the filters.
4. **postFilter**: These plugins are called in their configured order when no feasible nodes were found for the pod. If any postFilter plugin marks the Pod *schedulable*, the remaining plugins are not called.
5. **preScore**: This is an informational extension point that can be used for doing pre-scoring work.
6. **score**: These plugins provide a score to each node that has passed the filtering phase. The scheduler will then select the node with the highest weighted scores sum.
7. **reserve**: This is an informational extension point that notifies plugins when resources have been reserved for a given Pod. Plugins also implement an Unreserve call that gets called in the case of failure during or after Reserve.
8. **permit**: These plugins can prevent or delay the binding of a Pod.
9. **preBind**: These plugins perform any work required before a Pod is bound.
10. **bind**: The plugins bind a Pod to a Node. bind plugins are called in order and once one has done the binding, the remaining plugins are skipped. At least one bind plugin is required.
11. **postBind**: This is an informational extension point that is called after a Pod has been bound.
12. **multiPoint**: This is a config-only field that allows plugins to be enabled or disabled for all of their applicable extension points simultaneously.

For each extension point, you could disable specific [default plugins](#) or enable your own. For example:

```
apiVersion: kubescheduler.config.k8s.io/v1
kind: KubeSchedulerConfiguration
profiles:
- plugins:
 score:
 disabled:
 - name: PodTopologySpread
 enabled:
 - name: MyCustomPluginA
 weight: 2
 - name: MyCustomPluginB
 weight: 1
```

You can use \* as name in the disabled array to disable all default plugins for that extension point. This can also be used to rearrange plugins order, if desired.

## Scheduling plugins

The following plugins, enabled by default, implement one or more of these extension points:

- **ImageLocality**: Favors nodes that already have the container images that the Pod runs. Extension points: score.
- **TaintToleration**: Implements [taints and tolerations](#). Implements extension points: filter, preScore, score.
- **NodeName**: Checks if a Pod spec node name matches the current node. Extension points: filter.
- **NodePorts**: Checks if a node has free ports for the requested Pod ports. Extension points: preFilter, filter.
- **NodeAffinity**: Implements [node selectors](#) and [node affinity](#). Extension points: filter, score.
- **PodTopologySpread**: Implements [Pod topology spread](#). Extension points: preFilter, filter, preScore, score.
- **NodeUnschedulable**: Filters out nodes that have .spec.unschedulable set to true. Extension points: filter.
- **NodeResourcesFit**: Checks if the node has all the resources that the Pod is requesting. The score can use one of three strategies: LeastAllocated (default), MostAllocated and RequestedToCapacityRatio. Extension points: preFilter, filter, score.
- **NodeResourcesBalancedAllocation**: Favors nodes that would obtain a more balanced resource usage if the Pod is scheduled there. Extension points: score.
- **VolumeBinding**: Checks if the node has or if it can bind the requested [volumes](#). Extension points: preFilter, filter, reserve, preBind, score.

### Note:

score extension point is enabled when VolumeCapacityPriority feature is enabled. It prioritizes the smallest PVs that can fit the requested volume size.

- **VolumeRestrictions**: Checks that volumes mounted in the node satisfy restrictions that are specific to the volume provider. Extension points: filter.
- **VolumeZone**: Checks that volumes requested satisfy any zone requirements they might have. Extension points: filter.

- **NodeVolumeLimits**: Checks that CSI volume limits can be satisfied for the node. Extension points: filter.
- **EBSLimits**: Checks that AWS EBS volume limits can be satisfied for the node. Extension points: filter.
- **GCEPDLimits**: Checks that GCP-PD volume limits can be satisfied for the node. Extension points: filter.
- **AzureDiskLimits**: Checks that Azure disk volume limits can be satisfied for the node. Extension points: filter.
- **InterPodAffinity**: Implements [inter-Pod affinity and anti-affinity](#). Extension points: preFilter, filter, preScore, score.
- **PrioritySort**: Provides the default priority based sorting. Extension points: queueSort.
- **DefaultBinder**: Provides the default binding mechanism. Extension points: bind.
- **DefaultPreemption**: Provides the default preemption mechanism. Extension points: postFilter.

You can also enable the following plugins, through the component config APIs, that are not enabled by default:

- **CinderLimits**: Checks that [OpenStack Cinder](#) volume limits can be satisfied for the node. Extension points: filter.

## Multiple profiles

You can configure kube-scheduler to run more than one profile. Each profile has an associated scheduler name and can have a different set of plugins configured in its [extension points](#).

With the following sample configuration, the scheduler will run with two profiles: one with the default plugins and one with all scoring plugins disabled.

```
apiVersion: kubescheduler.config.k8s.io/v1
kind: KubeSchedulerConfiguration
profiles:
- schedulerName: default-scheduler
- schedulerName: no-scoring-scheduler
plugins:
 preScore:
 disabled:
 - name: '*'
 score:
 disabled:
 - name: '*'
```

Pods that want to be scheduled according to a specific profile can include the corresponding scheduler name in its `.spec.schedulerName`.

By default, one profile with the scheduler name `default-scheduler` is created. This profile includes the default plugins described above. When declaring more than one profile, a unique scheduler name for each of them is required.

If a Pod doesn't specify a scheduler name, kube-apiserver will set it to `default-scheduler`. Therefore, a profile with this scheduler name should exist to get those pods scheduled.

**Note:**

Pod's scheduling events have `.spec.schedulerName` as their `reportingController`. Events for leader election use the scheduler name of the first profile in the list.

For more information, please refer to the `reportingController` section under [Event API Reference](#).

**Note:**

All profiles must use the same plugin in the `queueSort` extension point and have the same configuration parameters (if applicable). This is because the scheduler only has one pending pods queue.

## Plugins that apply to multiple extension points

Starting from `kubescheduler.config.k8s.io/v1beta3`, there is an additional field in the profile config, `multiPoint`, which allows for easily enabling or disabling a plugin across several extension points. The intent of `multiPoint` config is to simplify the configuration needed for users and administrators when using custom profiles.

Consider a plugin, `MyPlugin`, which implements the `preScore`, `score`, `preFilter`, and `filter` extension points. To enable `MyPlugin` for all its available extension points, the profile config looks like:

```
apiVersion: kubescheduler.config.k8s.io/v1
kind: KubeSchedulerConfiguration
profiles:
- schedulerName: multipoint-scheduler
 plugins:
 multiPoint:
 enabled:
 - name: MyPlugin
```

This would equate to manually enabling `MyPlugin` for all of its extension points, like so:

```
apiVersion: kubescheduler.config.k8s.io/v1
kind: KubeSchedulerConfiguration
profiles:
- schedulerName: non-multipoint-scheduler
 plugins:
 preScore:
 enabled:
 - name: MyPlugin
 score:
 enabled:
 - name: MyPlugin
 preFilter:
 enabled:
 - name: MyPlugin
 filter:
 enabled:
 - name: MyPlugin
```

One benefit of using `multiPoint` here is that if `MyPlugin` implements another extension point in the future, the `multiPoint` config will automatically enable it for the new extension.

Specific extension points can be excluded from `MultiPoint` expansion using the `disabled` field for that extension point. This works with disabling default plugins, non-default plugins, or with the wildcard (`*`) to disable all plugins. An example of this, disabling `Score` and `PreScore`, would be:

```
apiVersion: kubescheduler.config.k8s.io/v1
kind: KubeSchedulerConfiguration
profiles:
- schedulerName: non-multipoint-scheduler
 plugins:
 multiPoint:
 enabled:
 - name: 'MyPlugin'
 preScore:
 disabled:
 - name: '*'
 score:
 disabled:
 - name: '*'
```

Starting from `kubescheduler.config.k8s.io/v1beta3`, all [default plugins](#) are enabled internally through `MultiPoint`. However, individual extension points are still available to allow flexible reconfiguration of the default values (such as ordering and `Score` weights). For example, consider two `Score` plugins `DefaultScore1` and `DefaultScore2`, each with a weight of 1. They can be reordered with different weights like so:

```
apiVersion: kubescheduler.config.k8s.io/v1
kind: KubeSchedulerConfiguration
profiles:
- schedulerName: multipoint-scheduler
 plugins:
 score:
 enabled:
 - name: 'DefaultScore2'
 weight: 5
```

In this example, it's unnecessary to specify the plugins in `MultiPoint` explicitly because they are default plugins. And the only plugin specified in `Score` is `DefaultScore2`. This is because plugins set through specific extension points will always take precedence over `MultiPoint` plugins. So, this snippet essentially re-orders the two plugins without needing to specify both of them.

The general hierarchy for precedence when configuring `MultiPoint` plugins is as follows:

1. Specific extension points run first, and their settings override whatever is set elsewhere
2. Plugins manually configured through `MultiPoint` and their settings
3. Default plugins and their default settings

To demonstrate the above hierarchy, the following example is based on these plugins:

| Plugin           | Extension Points |
|------------------|------------------|
| DefaultQueueSort | QueueSort        |

| Plugin          | Extension Points |
|-----------------|------------------|
| CustomQueueSort | QueueSort        |
| DefaultPlugin1  | Score, Filter    |
| DefaultPlugin2  | Score            |
| CustomPlugin1   | Score, Filter    |
| CustomPlugin2   | Score, Filter    |

A valid sample configuration for these plugins would be:

```
apiVersion: kubescheduler.config.k8s.io/v1
kind: KubeSchedulerConfiguration
profiles:
- schedulerName: multipoint-scheduler
 plugins:
 multiPoint:
 enabled:
 - name: 'CustomQueueSort'
 - name: 'CustomPlugin1'
 weight: 3
 disabled:
 - name: 'DefaultQueueSort'
 filter:
 disabled:
 - name: 'DefaultPlugin1'
 score:
 enabled:
 - name: 'DefaultPlugin2'
```

Note that there is no error for re-declaring a MultiPoint plugin in a specific extension point. The re-declaration is ignored (and logged), as specific extension points take precedence.

Besides keeping most of the config in one spot, this sample does a few things:

- Enables the custom queueSort plugin and disables the default one
- Enables CustomPlugin1 and CustomPlugin2, which will run first for all of their extension points
- Disables DefaultPlugin1, but only for filter
- Reorders DefaultPlugin2 to run first in score (even before the custom plugins)

In versions of the config before v1beta3, without multiPoint, the above snippet would equate to this:

```
apiVersion: kubescheduler.config.k8s.io/v1beta2
kind: KubeSchedulerConfiguration
profiles:
- schedulerName: multipoint-scheduler
 plugins:

 # Disable the default QueueSort plugin
 queueSort:
 enabled:
 - name: 'CustomQueueSort'
```

```

disabled:
- name: 'DefaultQueueSort'

Enable custom Filter plugins
filter:
 enabled:
 - name: 'CustomPlugin1'
 - name: 'CustomPlugin2'
 - name: 'DefaultPlugin2'
 disabled:
 - name: 'DefaultPlugin1'

Enable and reorder custom score plugins
score:
 enabled:
 - name: 'DefaultPlugin2'
 weight: 1
 - name: 'DefaultPlugin1'
 weight: 3

```

While this is a complicated example, it demonstrates the flexibility of MultiPoint config as well as its seamless integration with the existing methods for configuring extension points.

## Scheduler configuration migrations

- [v1beta1 → v1beta2](#)
- [v1beta2 → v1beta3](#)
- [v1beta3 → v1](#)
- With the v1beta2 configuration version, you can use a new score extension for the NodeResourcesFit plugin. The new extension combines the functionalities of the NodeResourcesLeastAllocated, NodeResourcesMostAllocated and RequestedToCapacityRatio plugins. For example, if you previously used the NodeResourcesMostAllocated plugin, you would instead use NodeResourcesFit (enabled by default) and add a pluginConfig with a scoreStrategy that is similar to:

```

apiVersion: kubescheduler.config.k8s.io/v1beta2
kind: KubeSchedulerConfiguration
profiles:
- pluginConfig:
 - args:
 scoringStrategy:
 resources:
 - name: cpu
 weight: 1
 type: MostAllocated
 name: NodeResourcesFit

```

- The scheduler plugin NodeLabel is deprecated; instead, use the [NodeAffinity](#) plugin (enabled by default) to achieve similar behavior.
- The scheduler plugin ServiceAffinity is deprecated; instead, use the [InterPodAffinity](#) plugin (enabled by default) to achieve similar behavior.

- The scheduler plugin `NodePreferAvoidPods` is deprecated; instead, use [node taints](#) to achieve similar behavior.
- A plugin enabled in a `v1beta2` configuration file takes precedence over the default configuration for that plugin.
- Invalid host or port configured for scheduler healthz and metrics bind address will cause validation failure.
- Three plugins' weight are increased by default:
  - `InterPodAffinity` from 1 to 2
  - `NodeAffinity` from 1 to 2
  - `TaintToleration` from 1 to 3
- The scheduler plugin `SelectorSpread` is removed, instead, use the `PodTopologySpread` plugin (enabled by default) to achieve similar behavior.

## What's next

- Read the [kube-scheduler reference](#)
- Learn about [scheduling](#)
- Read the [kube-scheduler configuration \(v1\)](#) reference

# Scheduling Policies

In Kubernetes versions before `v1.23`, a scheduling policy can be used to specify the *predicates* and *priorities* process. For example, you can set a scheduling policy by running `kube-scheduler --policy-config-file <filename>` or `kube-scheduler --policy-configmap <ConfigMap>`.

This scheduling policy is not supported since Kubernetes `v1.23`. Associated flags `policy-config-file`, `policy-configmap`, `policy-configmap-namespace` and `use-legacy-policy-config` are also not supported. Instead, use the [Scheduler Configuration](#) to achieve similar behavior.

## What's next

- Learn about [scheduling](#)
- Learn about [kube-scheduler Configuration](#)
- Read the [kube-scheduler configuration reference \(v1\)](#)

# Other Tools

Kubernetes contains several tools to help you work with the Kubernetes system.

## crictl

[crictl](#) is a command-line interface for inspecting and debugging [CRI](#)-compatible container runtimes.

# Dashboard

[Dashboard](#), the web-based user interface of Kubernetes, allows you to deploy containerized applications to a Kubernetes cluster, troubleshoot them, and manage the cluster and its resources itself.

## Helm

This item links to a third party project or product that is not part of Kubernetes itself. [More information](#)

[Helm](#) is a tool for managing packages of pre-configured Kubernetes resources. These packages are known as *Helm charts*.

Use Helm to:

- Find and use popular software packaged as Kubernetes charts
- Share your own applications as Kubernetes charts
- Create reproducible builds of your Kubernetes applications
- Intelligently manage your Kubernetes manifest files
- Manage releases of Helm packages

## Kompose

[Kompose](#) is a tool to help Docker Compose users move to Kubernetes.

Use Kompose to:

- Translate a Docker Compose file into Kubernetes objects
- Go from local Docker development to managing your application via Kubernetes
- Convert v1 or v2 Docker Compose yaml files or [Distributed Application Bundles](#)

## Kui

[Kui](#) is a GUI tool that takes your normal kubectl command line requests and responds with graphics.

Kui takes the normal kubectl command line requests and responds with graphics. Instead of ASCII tables, Kui provides a GUI rendering with tables that you can sort.

Kui lets you:

- Directly click on long, auto-generated resource names instead of copying and pasting
- Type in kubectl commands and see them execute, even sometimes faster than kubectl itself
- Query a [Job](#) and see its execution rendered as a waterfall diagram
- Click through resources in your cluster using a tabbed UI

# Minikube

[minikube](#) is a tool that runs a single-node Kubernetes cluster locally on your workstation for development and testing purposes.

## Mapping from dockercli to crictl

### Note:

This page is being directed to <https://v1-24.docs.kubernetes.io/docs/reference/tools/map-crictl-dockercli/> because of the [removal of dockershim from crictl in v1.24](#). As per our community policy, deprecated documents are not maintained beyond next three versions. The reason for deprecation is explained in [Dockershim-FAQ](#).

This section lists the different ways to set up and run Kubernetes. When you install Kubernetes, choose an installation type based on: ease of maintenance, security, control, available resources, and expertise required to operate and manage a cluster.

You can [download Kubernetes](#) to deploy a Kubernetes cluster on a local machine, into the cloud, or for your own datacenter.

Several [Kubernetes components](#) such as [kube-apiserver](#) or [kube-proxy](#) can also be deployed as [container images](#) within the cluster.

It is **recommended** to run Kubernetes components as container images wherever that is possible, and to have Kubernetes manage those components. Components that run containers - notably, the kubelet - can't be included in this category.

If you don't want to manage a Kubernetes cluster yourself, you could pick a managed service, including [certified platforms](#). There are also other standardized and custom solutions across a wide range of cloud and bare metal environments.

## Learning environment

If you're learning Kubernetes, use the tools supported by the Kubernetes community, or tools in the ecosystem to set up a Kubernetes cluster on a local machine. See [Install tools](#).

## Production environment

When evaluating a solution for a [production environment](#), consider which aspects of operating a Kubernetes cluster (or *abstractions*) you want to manage yourself and which you prefer to hand off to a provider.

For a cluster you're managing yourself, the officially supported tool for deploying Kubernetes is [kubeadm](#).

## What's next

- [Download Kubernetes](#)
- Download and [install tools](#) including kubect1
- Select a [container runtime](#) for your new cluster
- Learn about [best practices](#) for cluster setup

Kubernetes is designed for its [control plane](#) to run on Linux. Within your cluster you can run applications on Linux or other operating systems, including Windows.

- Learn to [set up clusters with Windows nodes](#)

## Install Tools

Set up Kubernetes tools on your computer.

# kubectl

The Kubernetes command-line tool, [kubectl](#), allows you to run commands against Kubernetes clusters. You can use kubectl to deploy applications, inspect and manage cluster resources, and view logs. For more information including a complete list of kubectl operations, see the [kubectl reference documentation](#).

kubectl is installable on a variety of Linux platforms, macOS and Windows. Find your preferred operating system below.

- [Install kubectl on Linux](#)
- [Install kubectl on macOS](#)
- [Install kubectl on Windows](#)

# kind

[kind](#) lets you run Kubernetes on your local computer. This tool requires that you have either [Docker](#) or [Podman](#) installed.

The kind [Quick Start](#) page shows you what you need to do to get up and running with kind.

[View kind Quick Start Guide](#)

# minikube

Like kind, [minikube](#) is a tool that lets you run Kubernetes locally. minikube runs an all-in-one or a multi-node local Kubernetes cluster on your personal computer (including Windows, macOS and Linux PCs) so that you can try out Kubernetes, or for daily development work.

You can follow the official [Get Started!](#) guide if your focus is on getting the tool installed.

[View minikube Get Started! Guide](#)

Once you have minikube working, you can use it to [run a sample application](#).

# kubeadm

You can use the [kubeadm](#) tool to create and manage Kubernetes clusters. It performs the actions necessary to get a minimum viable, secure cluster up and running in a user friendly way.

[Installing kubeadm](#) shows you how to install kubeadm. Once installed, you can use it to [create a cluster](#).

[View kubeadm Install Guide](#)

# Production environment

Create a production-quality Kubernetes cluster

A production-quality Kubernetes cluster requires planning and preparation. If your Kubernetes cluster is to run critical workloads, it must be configured to be resilient. This page explains steps you can take to set up a production-ready cluster, or to promote an existing cluster for production use. If you're already familiar with production setup and want the links, skip to [What's next](#).

## Production considerations

Typically, a production Kubernetes cluster environment has more requirements than a personal learning, development, or test environment Kubernetes. A production environment may require secure access by many users, consistent availability, and the resources to adapt to changing demands.

As you decide where you want your production Kubernetes environment to live (on premises or in a cloud) and the amount of management you want to take on or hand to others, consider how your requirements for a Kubernetes cluster are influenced by the following issues:

- *Availability:* A single-machine Kubernetes [learning environment](#) has a single point of failure. Creating a highly available cluster means considering:
  - Separating the control plane from the worker nodes.
  - Replicating the control plane components on multiple nodes.
  - Load balancing traffic to the cluster's [API server](#).
  - Having enough worker nodes available, or able to quickly become available, as changing workloads warrant it.
- *Scale:* If you expect your production Kubernetes environment to receive a stable amount of demand, you might be able to set up for the capacity you need and be done. However, if you expect demand to grow over time or change dramatically based on things like season or special events, you need to plan how to scale to relieve increased pressure from more requests to the control plane and worker nodes or scale down to reduce unused resources.
- *Security and access management:* You have full admin privileges on your own Kubernetes learning cluster. But shared clusters with important workloads, and more than one or two users, require a more refined approach to who and what can access cluster resources. You can use role-based access control ([RBAC](#)) and other security mechanisms to make sure that users and workloads can get access to the resources they need, while keeping workloads, and the cluster itself, secure. You can set limits on the resources that users and workloads can access by managing [policies](#) and [container resources](#).

Before building a Kubernetes production environment on your own, consider handing off some or all of this job to [Turnkey Cloud Solutions](#) providers or other [Kubernetes Partners](#). Options include:

- *Serverless:* Just run workloads on third-party equipment without managing a cluster at all. You will be charged for things like CPU usage, memory, and disk requests.
- *Managed control plane:* Let the provider manage the scale and availability of the cluster's control plane, as well as handle patches and upgrades.
- *Managed worker nodes:* Configure pools of nodes to meet your needs, then the provider makes sure those nodes are available and ready to implement upgrades when needed.

- *Integration:* There are providers that integrate Kubernetes with other services you may need, such as storage, container registries, authentication methods, and development tools.

Whether you build a production Kubernetes cluster yourself or work with partners, review the following sections to evaluate your needs as they relate to your cluster's *control plane*, *worker nodes*, *user access*, and *workload resources*.

## Production cluster setup

In a production-quality Kubernetes cluster, the control plane manages the cluster from services that can be spread across multiple computers in different ways. Each worker node, however, represents a single entity that is configured to run Kubernetes pods.

### Production control plane

The simplest Kubernetes cluster has the entire control plane and worker node services running on the same machine. You can grow that environment by adding worker nodes, as reflected in the diagram illustrated in [Kubernetes Components](#). If the cluster is meant to be available for a short period of time, or can be discarded if something goes seriously wrong, this might meet your needs.

If you need a more permanent, highly available cluster, however, you should consider ways of extending the control plane. By design, one-machine control plane services running on a single machine are not highly available. If keeping the cluster up and running and ensuring that it can be repaired if something goes wrong is important, consider these steps:

- *Choose deployment tools:* You can deploy a control plane using tools such as kubeadm, kops, and kubespray. See [Installing Kubernetes with deployment tools](#) to learn tips for production-quality deployments using each of those deployment methods. Different [Container Runtimes](#) are available to use with your deployments.
- *Manage certificates:* Secure communications between control plane services are implemented using certificates. Certificates are automatically generated during deployment or you can generate them using your own certificate authority. See [PKI certificates and requirements](#) for details.
- *Configure load balancer for apiserver:* Configure a load balancer to distribute external API requests to the apiserver service instances running on different nodes. See [Create an External Load Balancer](#) for details.
- *Separate and backup etcd service:* The etcd services can either run on the same machines as other control plane services or run on separate machines, for extra security and availability. Because etcd stores cluster configuration data, backing up the etcd database should be done regularly to ensure that you can repair that database if needed. See the [etcd FAQ](#) for details on configuring and using etcd. See [Operating etcd clusters for Kubernetes](#) and [Set up a High Availability etcd cluster with kubeadm](#) for details.
- *Create multiple control plane systems:* For high availability, the control plane should not be limited to a single machine. If the control plane services are run by an init service (such as systemd), each service should run on at least three machines. However, running control plane services as pods in Kubernetes ensures that the replicated number of services that you request will always be available. The scheduler should be fault tolerant, but not highly available. Some deployment tools set up [Raft](#) consensus algorithm to do leader election of Kubernetes services. If the primary goes away, another service elects itself and take over.

- *Span multiple zones:* If keeping your cluster available at all times is critical, consider creating a cluster that runs across multiple data centers, referred to as zones in cloud environments. Groups of zones are referred to as regions. By spreading a cluster across multiple zones in the same region, it can improve the chances that your cluster will continue to function even if one zone becomes unavailable. See [Running in multiple zones](#) for details.
- *Manage on-going features:* If you plan to keep your cluster over time, there are tasks you need to do to maintain its health and security. For example, if you installed with kubeadm, there are instructions to help you with [Certificate Management](#) and [Upgrading kubeadm clusters](#). See [Administer a Cluster](#) for a longer list of Kubernetes administrative tasks.

To learn about available options when you run control plane services, see [kube-apiserver](#), [kube-controller-manager](#), and [kube-scheduler](#) component pages. For highly available control plane examples, see [Options for Highly Available topology](#), [Creating Highly Available clusters with kubeadm](#), and [Operating etcd clusters for Kubernetes](#). See [Backing up an etcd cluster](#) for information on making an etcd backup plan.

## Production worker nodes

Production-quality workloads need to be resilient and anything they rely on needs to be resilient (such as CoreDNS). Whether you manage your own control plane or have a cloud provider do it for you, you still need to consider how you want to manage your worker nodes (also referred to simply as *nodes*).

- *Configure nodes:* Nodes can be physical or virtual machines. If you want to create and manage your own nodes, you can install a supported operating system, then add and run the appropriate [Node services](#). Consider:
  - The demands of your workloads when you set up nodes by having appropriate memory, CPU, and disk speed and storage capacity available.
  - Whether generic computer systems will do or you have workloads that need GPU processors, Windows nodes, or VM isolation.
- *Validate nodes:* See [Valid node setup](#) for information on how to ensure that a node meets the requirements to join a Kubernetes cluster.
- *Add nodes to the cluster:* If you are managing your own cluster you can add nodes by setting up your own machines and either adding them manually or having them register themselves to the cluster's apiserver. See the [Nodes](#) section for information on how to set up Kubernetes to add nodes in these ways.
- *Scale nodes:* Have a plan for expanding the capacity your cluster will eventually need. See [Considerations for large clusters](#) to help determine how many nodes you need, based on the number of pods and containers you need to run. If you are managing nodes yourself, this can mean purchasing and installing your own physical equipment.
- *Autoscale nodes:* Read [Cluster Autoscaling](#) to learn about the tools available to automatically manage your nodes and the capacity they provide.
- *Set up node health checks:* For important workloads, you want to make sure that the nodes and pods running on those nodes are healthy. Using the [Node Problem Detector](#) daemon, you can ensure your nodes are healthy.

## Production user management

In production, you may be moving from a model where you or a small group of people are accessing the cluster to where there may potentially be dozens or hundreds of people. In a

learning environment or platform prototype, you might have a single administrative account for everything you do. In production, you will want more accounts with different levels of access to different namespaces.

Taking on a production-quality cluster means deciding how you want to selectively allow access by other users. In particular, you need to select strategies for validating the identities of those who try to access your cluster (authentication) and deciding if they have permissions to do what they are asking (authorization):

- *Authentication*: The apiserver can authenticate users using client certificates, bearer tokens, an authenticating proxy, or HTTP basic auth. You can choose which authentication methods you want to use. Using plugins, the apiserver can leverage your organization's existing authentication methods, such as LDAP or Kerberos. See [Authentication](#) for a description of these different methods of authenticating Kubernetes users.
- *Authorization*: When you set out to authorize your regular users, you will probably choose between RBAC and ABAC authorization. See [Authorization Overview](#) to review different modes for authorizing user accounts (as well as service account access to your cluster):
  - *Role-based access control (RBAC)*: Lets you assign access to your cluster by allowing specific sets of permissions to authenticated users. Permissions can be assigned for a specific namespace (Role) or across the entire cluster (ClusterRole). Then using RoleBindings and ClusterRoleBindings, those permissions can be attached to particular users.
  - *Attribute-based access control (ABAC)*: Lets you create policies based on resource attributes in the cluster and will allow or deny access based on those attributes. Each line of a policy file identifies versioning properties (apiVersion and kind) and a map of spec properties to match the subject (user or group), resource property, non-resource property (/version or /apis), and readonly. See [Examples](#) for details.

As someone setting up authentication and authorization on your production Kubernetes cluster, here are some things to consider:

- *Set the authorization mode*: When the Kubernetes API server ([kube-apiserver](#)) starts, the supported authentication modes must be set using the `--authorization-mode` flag. For example, that flag in the `kube-adminserver.yaml` file (in `/etc/kubernetes/manifests`) could be set to `Node,RBAC`. This would allow Node and RBAC authorization for authenticated requests.
- *Create user certificates and role bindings (RBAC)*: If you are using RBAC authorization, users can create a CertificateSigningRequest (CSR) that can be signed by the cluster CA. Then you can bind Roles and ClusterRoles to each user. See [Certificate Signing Requests](#) for details.
- *Create policies that combine attributes (ABAC)*: If you are using ABAC authorization, you can assign combinations of attributes to form policies to authorize selected users or groups to access particular resources (such as a pod), namespace, or apiGroup. For more information, see [Examples](#).
- *Consider Admission Controllers*: Additional forms of authorization for requests that can come in through the API server include [Webhook Token Authentication](#). Webhooks and other special authorization types need to be enabled by adding [Admission Controllers](#) to the API server.

# Set limits on workload resources

Demands from production workloads can cause pressure both inside and outside of the Kubernetes control plane. Consider these items when setting up for the needs of your cluster's workloads:

- *Set namespace limits:* Set per-namespace quotas on things like memory and CPU. See [Manage Memory, CPU, and API Resources](#) for details. You can also set [Hierarchical Namespaces](#) for inheriting limits.
- *Prepare for DNS demand:* If you expect workloads to massively scale up, your DNS service must be ready to scale up as well. See [Autoscale the DNS service in a Cluster](#).
- *Create additional service accounts:* User accounts determine what users can do on a cluster, while a service account defines pod access within a particular namespace. By default, a pod takes on the default service account from its namespace. See [Managing Service Accounts](#) for information on creating a new service account. For example, you might want to:
  - Add secrets that a pod could use to pull images from a particular container registry. See [Configure Service Accounts for Pods](#) for an example.
  - Assign RBAC permissions to a service account. See [ServiceAccount permissions](#) for details.

## What's next

- Decide if you want to build your own production Kubernetes or obtain one from available [Turnkey Cloud Solutions](#) or [Kubernetes Partners](#).
- If you choose to build your own cluster, plan how you want to handle [certificates](#) and set up high availability for features such as [etcd](#) and the [API server](#).
- Choose from [kubeadm](#), [kops](#) or [Kubespray](#) deployment methods.
- Configure user management by determining your [Authentication](#) and [Authorization](#) methods.
- Prepare for application workloads by setting up [resource limits](#), [DNS autoscaling](#) and [service accounts](#).

# Container Runtimes

**Note:** Dockershim has been removed from the Kubernetes project as of release 1.24. Read the [Dockershim Removal FAQ](#) for further details.

You need to install a [container runtime](#) into each node in the cluster so that Pods can run there. This page outlines what is involved and describes related tasks for setting up nodes.

Kubernetes 1.30 requires that you use a runtime that conforms with the [Container Runtime Interface](#) (CRI).

See [CRI version support](#) for more information.

This page provides an outline of how to use several common container runtimes with Kubernetes.

- [containerd](#)
- [CRI-O](#)

- [Docker Engine](#)
- [Mirantis Container Runtime](#)

**Note:**

Kubernetes releases before v1.24 included a direct integration with Docker Engine, using a component named *dockershim*. That special direct integration is no longer part of Kubernetes (this removal was [announced](#) as part of the v1.20 release). You can read [Check whether Dockershim removal affects you](#) to understand how this removal might affect you. To learn about migrating from using dockershim, see [Migrating from dockershim](#).

If you are running a version of Kubernetes other than v1.30, check the documentation for that version.

## Install and configure prerequisites

### Network configuration

By default, the Linux kernel does not allow IPv4 packets to be routed between interfaces. Most Kubernetes cluster networking implementations will change this setting (if needed), but some might expect the administrator to do it for them. (Some might also expect other `sysctl` parameters to be set, kernel modules to be loaded, etc; consult the documentation for your specific network implementation.)

### Enable IPv4 packet forwarding

To manually enable IPv4 packet forwarding:

```
sysctl params required by setup, params persist across reboots
cat <<EOF | sudo tee /etc/sysctl.d/k8s.conf
net.ipv4.ip_forward = 1
EOF

Apply sysctl params without reboot
sudo sysctl --system
```

Verify that `net.ipv4.ip_forward` is set to 1 with:

```
sysctl net.ipv4.ip_forward
```

## cgroup drivers

On Linux, [control groups](#) are used to constrain resources that are allocated to processes.

Both the [kubelet](#) and the underlying container runtime need to interface with control groups to enforce [resource management for pods and containers](#) and set resources such as cpu/memory requests and limits. To interface with control groups, the kubelet and the container runtime need to use a *cgroup driver*. It's critical that the kubelet and the container runtime use the same cgroup driver and are configured the same.

There are two cgroup drivers available:

- [cgroupfs](#)
- [systemd](#)

## cgroupfs driver

The cgroupfs driver is the [default cgroup driver in the kubelet](#). When the cgroupfs driver is used, the kubelet and the container runtime directly interface with the cgroup filesystem to configure cgroups.

The cgroupfs driver is **not** recommended when [systemd](#) is the init system because systemd expects a single cgroup manager on the system. Additionally, if you use [cgroup v2](#), use the systemd cgroup driver instead of cgroupfs.

## systemd cgroup driver

When [systemd](#) is chosen as the init system for a Linux distribution, the init process generates and consumes a root control group (cgroup) and acts as a cgroup manager.

systemd has a tight integration with cgroups and allocates a cgroup per systemd unit. As a result, if you use systemd as the init system with the cgroupfs driver, the system gets two different cgroup managers.

Two cgroup managers result in two views of the available and in-use resources in the system. In some cases, nodes that are configured to use cgroupfs for the kubelet and container runtime, but use systemd for the rest of the processes become unstable under resource pressure.

The approach to mitigate this instability is to use systemd as the cgroup driver for the kubelet and the container runtime when systemd is the selected init system.

To set systemd as the cgroup driver, edit the [KubeletConfiguration](#) option of cgroupDriver and set it to systemd. For example:

```
apiVersion: kubelet.config.k8s.io/v1beta1
kind: KubeletConfiguration
...
cgroupDriver: systemd
```

### Note:

Starting with v1.22 and later, when creating a cluster with kubeadm, if the user does not set the cgroupDriver field under KubeletConfiguration, kubeadm defaults it to systemd.

In Kubernetes v1.28, with the KubeletCgroupDriverFromCRI [feature gate](#) enabled and a container runtime that supports the RuntimeConfig CRI RPC, the kubelet automatically detects the appropriate cgroup driver from the runtime, and ignores the cgroupDriver setting within the kubelet configuration.

If you configure `systemd` as the cgroup driver for the kubelet, you must also configure `systemd` as the cgroup driver for the container runtime. Refer to the documentation for your container runtime for instructions. For example:

- [containerd](#)
- [CRI-O](#)

### Caution:

Changing the cgroup driver of a Node that has joined a cluster is a sensitive operation. If the kubelet has created Pods using the semantics of one cgroup driver, changing the container runtime to another cgroup driver can cause errors when trying to re-create the Pod sandbox for such existing Pods. Restarting the kubelet may not solve such errors.

If you have automation that makes it feasible, replace the node with another using the updated configuration, or reinstall it using automation.

## Migrating to the `systemd` driver in kubeadm managed clusters

If you wish to migrate to the `systemd` cgroup driver in existing kubeadm managed clusters, follow [configuring a cgroup driver](#).

## CRI version support

Your container runtime must support at least v1alpha2 of the container runtime interface.

Kubernetes [starting v1.26](#) *only works* with v1 of the CRI API. Earlier versions default to v1 version, however if a container runtime does not support the v1 API, the kubelet falls back to using the (deprecated) v1alpha2 API instead.

## Container runtimes

**Note:** This section links to third party projects that provide functionality required by Kubernetes. The Kubernetes project authors aren't responsible for these projects, which are listed alphabetically. To add a project to this list, read the [content guide](#) before submitting a change. [More information](#).

### containerd

This section outlines the necessary steps to use containerd as CRI runtime.

To install containerd on your system, follow the instructions on [getting started with containerd](#). Return to this step once you've created a valid `config.toml` configuration file.

- [Linux](#)
- [Windows](#)

You can find this file under the path `/etc/containerd/config.toml`.

You can find this file under the path `C:\Program Files\containerd\config.toml`.

On Linux the default CRI socket for containerd is `/run/containerd/containerd.sock`. On Windows the default CRI endpoint is `npip://./pipe/containerd-containerd`.

## Configuring the systemd cgroup driver

To use the systemd cgroup driver in `/etc/containerd/config.toml` with runc, set

```
[plugins."io.containerd.grpc.v1.cri".containerd.runtimes.runc]
...
[plugins."io.containerd.grpc.v1.cri".containerd.runtimes.runc.options]
 SystemdCgroup = true
```

The systemd cgroup driver is recommended if you use [cgroup v2](#).

### Note:

If you installed containerd from a package (for example, RPM or .deb), you may find that the CRI integration plugin is disabled by default.

You need CRI support enabled to use containerd with Kubernetes. Make sure that `cri` is not included in the `disabled_plugins` list within `/etc/containerd/config.toml`; if you made changes to that file, also restart containerd.

If you experience container crash loops after the initial cluster installation or after installing a CNI, the containerd configuration provided with the package might contain incompatible configuration parameters. Consider resetting the containerd configuration with `containerd config default > /etc/containerd/config.toml` as specified in [getting-started.md](#) and then set the configuration parameters specified above accordingly.

If you apply this change, make sure to restart containerd:

```
sudo systemctl restart containerd
```

When using kubeadm, manually configure the [cgroup driver for kubelet](#).

In Kubernetes v1.28, you can enable automatic detection of the cgroup driver as an alpha feature. See [systemd cgroup driver](#) for more details.

## Overriding the sandbox (pause) image

In your [containerd config](#) you can overwrite the sandbox image by setting the following config:

```
[plugins."io.containerd.grpc.v1.cri"]
 sandbox_image = "registry.k8s.io/pause:3.2"
```

You might need to restart containerd as well once you've updated the config file: `systemctl restart containerd`.

Please note, that it is a best practice for kubelet to declare the matching `pod-infra-container-image`. If not configured, kubelet may attempt to garbage collect the pause image. There is ongoing work in [containerd to pin the pause image](#) and not require this setting on kubelet any longer.

## CRI-O

This section contains the necessary steps to install CRI-O as a container runtime.

To install CRI-O, follow [CRI-O Install Instructions](#).

### cgroup driver

CRI-O uses the systemd cgroup driver per default, which is likely to work fine for you. To switch to the cgroupfs cgroup driver, either edit `/etc/crio/crio.conf` or place a drop-in configuration in `/etc/crio/crio.conf.d/02-cgroup-manager.conf`, for example:

```
[crio.runtime]
common_cgroup = "pod"
cgroup_manager = "cgroupfs"
```

You should also note the changed `common_cgroup`, which has to be set to the value `pod` when using CRI-O with `cgroupfs`. It is generally necessary to keep the cgroup driver configuration of the kubelet (usually done via `kubeadm`) and CRI-O in sync.

In Kubernetes v1.28, you can enable automatic detection of the cgroup driver as an alpha feature. See [systemd cgroup driver](#) for more details.

For CRI-O, the CRI socket is `/var/run/crio/crio.sock` by default.

### Overriding the sandbox (pause) image

In your [CRI-O config](#) you can set the following config value:

```
[crio.image]
pause_image="registry.k8s.io/pause:3.6"
```

This config option supports live configuration reload to apply this change: `systemctl reload crio` or by sending `SIGHUP` to the `crio` process.

## Docker Engine

### Note:

These instructions assume that you are using the [cri-dockerd](#) adapter to integrate Docker Engine with Kubernetes.

1. On each of your nodes, install Docker for your Linux distribution as per [Install Docker Engine](#).
2. Install [cri-dockerd](#), following the directions in the install section of the documentation.

For `cri-dockerd`, the CRI socket is `/run/cri-dockerd.sock` by default.

## Mirantis Container Runtime

[Mirantis Container Runtime](#) (MCR) is a commercially available container runtime that was formerly known as Docker Enterprise Edition.

You can use Mirantis Container Runtime with Kubernetes using the open source [cri-dockerd](#) component, included with MCR.

To learn more about how to install Mirantis Container Runtime, visit [MCR Deployment Guide](#).

Check the systemd unit named `cri-docker.socket` to find out the path to the CRI socket.

### Overriding the sandbox (pause) image

The `cri-dockerd` adapter accepts a command line argument for specifying which container image to use as the Pod infrastructure container (“pause image”). The command line argument to use is `--pod-infra-container-image`.

## What's next

As well as a container runtime, your cluster will need a working [network plugin](#).

# Installing Kubernetes with deployment tools

There are many methods and tools for setting up your own production Kubernetes cluster. For example:

- [kubeadm](#)
- [kops](#): An automated cluster provisioning tool. For tutorials, best practices, configuration options and information on reaching out to the community, please check the [kOps website](#) for details.
- [kubespray](#): A composition of [Ansible](#) playbooks, [inventory](#), provisioning tools, and domain knowledge for generic OS/Kubernetes clusters configuration management tasks. You can reach out to the community on Slack channel [#kubespray](#).

[Dual-stack support with kubeadm](#)

# Installing kubeadm

This page shows how to install the kubeadm toolbox. For information on how to create a cluster with kubeadm once you have performed this installation process, see the [Creating a cluster with kubeadm](#) page.

This installation guide is for Kubernetes v1.30. If you want to use a different Kubernetes version, please refer to the following pages instead:

- [Installing kubeadm \(Kubernetes v1.29\)](#)
- [Installing kubeadm \(Kubernetes v1.28\)](#)
- [Installing kubeadm \(Kubernetes v1.27\)](#)
- [Installing kubeadm \(Kubernetes v1.26\)](#)

## Before you begin

- A compatible Linux host. The Kubernetes project provides generic instructions for Linux distributions based on Debian and Red Hat, and those distributions without a package manager.
- 2 GB or more of RAM per machine (any less will leave little room for your apps).
- 2 CPUs or more.
- Full network connectivity between all machines in the cluster (public or private network is fine).
- Unique hostname, MAC address, and product\_uuid for every node. See [here](#) for more details.
- Certain ports are open on your machines. See [here](#) for more details.
- Swap configuration. The default behavior of a kubelet was to fail to start if swap memory was detected on a node. Swap has been supported since v1.22. And since v1.28, Swap is supported for cgroup v2 only; the NodeSwap feature gate of the kubelet is beta but disabled by default.
  - You **MUST** disable swap if the kubelet is not properly configured to use swap. For example, `sudo swapoff -a` will disable swapping temporarily. To make this change persistent across reboots, make sure swap is disabled in config files like `/etc/fstab`, `systemd.swap`, depending how it was configured on your system.

### Note:

The kubeadm installation is done via binaries that use dynamic linking and assumes that your target system provides glibc. This is a reasonable assumption on many Linux distributions (including Debian, Ubuntu, Fedora, CentOS, etc.) but it is not always the case with custom and lightweight distributions which don't include glibc by default, such as Alpine Linux. The

expectation is that the distribution either includes glibc or a [compatibility layer](#) that provides the expected symbols.

## Verify the MAC address and product\_uuid are unique for every node

- You can get the MAC address of the network interfaces using the command `ip link` or `ifconfig -a`
- The `product_uuid` can be checked by using the command `sudo cat /sys/class/dmi/id/product_uuid`

It is very likely that hardware devices will have unique addresses, although some virtual machines may have identical values. Kubernetes uses these values to uniquely identify the nodes in the cluster. If these values are not unique to each node, the installation process may [fail](#).

## Check network adapters

If you have more than one network adapter, and your Kubernetes components are not reachable on the default route, we recommend you add IP route(s) so Kubernetes cluster addresses go via the appropriate adapter.

## Check required ports

These [required ports](#) need to be open in order for Kubernetes components to communicate with each other. You can use tools like [netcat](#) to check if a port is open. For example:

```
nc 127.0.0.1 6443 -v
```

The pod network plugin you use may also require certain ports to be open. Since this differs with each pod network plugin, please see the documentation for the plugins about what port(s) those need.

## Installing a container runtime

To run containers in Pods, Kubernetes uses a [container runtime](#).

By default, Kubernetes uses the [Container Runtime Interface](#) (CRI) to interface with your chosen container runtime.

If you don't specify a runtime, kubeadm automatically tries to detect an installed container runtime by scanning through a list of known endpoints.

If multiple or no container runtimes are detected kubeadm will throw an error and will request that you specify which one you want to use.

See [container runtimes](#) for more information.

## Note:

Docker Engine does not implement the [CRI](#) which is a requirement for a container runtime to work with Kubernetes. For that reason, an additional service [cri-dockerd](#) has to be installed. cri-dockerd is a project based on the legacy built-in Docker Engine support that was [removed](#) from the kubelet in version 1.24.

The tables below include the known endpoints for supported operating systems:

- [Linux](#)
- [Windows](#)

### Linux container runtimes

| Runtime                           | Path to Unix domain socket                 |
|-----------------------------------|--------------------------------------------|
| containerd                        | unix:///var/run/containerd/containerd.sock |
| CRI-O                             | unix:///var/run/crio/crio.sock             |
| Docker Engine (using cri-dockerd) | unix:///var/run/cri-dockerd.sock           |

### Windows container runtimes

| Runtime                           | Path to Windows named pipe             |
|-----------------------------------|----------------------------------------|
| containerd                        | npipes:///./pipe/containerd-containerd |
| Docker Engine (using cri-dockerd) | npipes:///./pipe/cri-dockerd           |

## Installing kubeadm, kubelet and kubectl

You will install these packages on all of your machines:

- kubeadm: the command to bootstrap the cluster.
- kubelet: the component that runs on all of the machines in your cluster and does things like starting pods and containers.
- kubectl: the command line util to talk to your cluster.

kubeadm **will not** install or manage kubelet or kubectl for you, so you will need to ensure they match the version of the Kubernetes control plane you want kubeadm to install for you. If you do not, there is a risk of a version skew occurring that can lead to unexpected, buggy behaviour. However, *one* minor version skew between the kubelet and the control plane is supported, but the kubelet version may never exceed the API server version. For example, the kubelet running 1.7.0 should be fully compatible with a 1.8.0 API server, but not vice versa.

For information about installing kubectl, see [Install and set up kubectl](#).

## Warning:

These instructions exclude all Kubernetes packages from any system upgrades. This is because kubeadm and Kubernetes require [special attention to upgrade](#).

For more information on version skews, see:

- Kubernetes [version and version-skew policy](#)
- Kubeadm-specific [version skew policy](#)

**Note:** The legacy package repositories ([apt.kubernetes.io](https://apt.kubernetes.io) and [yum.kubernetes.io](https://yum.kubernetes.io)) have been [deprecated and frozen starting from September 13, 2023](#). **Using the [new package repositories hosted at pkgs.k8s.io](https://pkgs.k8s.io) is strongly recommended and required in order to install Kubernetes versions released after September 13, 2023.** The deprecated legacy repositories, and their contents, might be removed at any time in the future and without a further notice period. The new package repositories provide downloads for Kubernetes versions starting with v1.24.0.

**Note:**

There's a dedicated package repository for each Kubernetes minor version. If you want to install a minor version other than v1.30, please see the installation guide for your desired minor version.

- [Debian-based distributions](#)
- [Red Hat-based distributions](#)
- [Without a package manager](#)

These instructions are for Kubernetes v1.30.

1. Update the apt package index and install packages needed to use the Kubernetes apt repository:

```
sudo apt-get update
apt-transport-https may be a dummy package; if so, you can skip that package
sudo apt-get install -y apt-transport-https ca-certificates curl gpg
```

2. Download the public signing key for the Kubernetes package repositories. The same signing key is used for all repositories so you can disregard the version in the URL:

```
If the directory `/etc/apt/keyrings` does not exist, it should be created before the curl
command, read the note below.
sudo mkdir -p -m 755 /etc/apt/keyrings
curl -fsSL https://pkgs.k8s.io/core:/stable:/v1.30/deb/Release.key | sudo gpg --dearmor -o /
etc/apt/keyrings/kubernetes-apt-keyring.gpg
```

**Note:**

In releases older than Debian 12 and Ubuntu 22.04, directory `/etc/apt/keyrings` does not exist by default, and it should be created before the curl command.

1. Add the appropriate Kubernetes apt repository. Please note that this repository have packages only for Kubernetes 1.30; for other Kubernetes minor versions, you need to change the Kubernetes minor version in the URL to match your desired minor version (you should also check that you are reading the documentation for the version of Kubernetes that you plan to install).

```
This overwrites any existing configuration in /etc/apt/sources.list.d/kubernetes.list
echo 'deb [signed-by=/etc/apt/keyrings/kubernetes-apt-keyring.gpg] https://pkgs.k8s.io/
core:/stable:/v1.30/deb/ ' | sudo tee /etc/apt/sources.list.d/kubernetes.list
```

2. Update the apt package index, install kubelet, kubeadm and kubectl, and pin their version:

```
sudo apt-get update
sudo apt-get install -y kubelet kubeadm kubectl
sudo apt-mark hold kubelet kubeadm kubectl
```

3. (Optional) Enable the kubelet service before running kubeadm:

```
sudo systemctl enable --now kubelet
```

1. Set SELinux to permissive mode:

These instructions are for Kubernetes 1.30.

```
Set SELinux in permissive mode (effectively disabling it)
sudo setenforce 0
sudo sed -i 's/^SELINUX=enforcing$/SELINUX=permissive/' /etc/selinux/config
```

### Caution:

- Setting SELinux in permissive mode by running `setenforce 0` and `sed ...` effectively disables it. This is required to allow containers to access the host filesystem; for example, some cluster network plugins require that. You have to do this until SELinux support is improved in the kubelet.
  - You can leave SELinux enabled if you know how to configure it but it may require settings that are not supported by kubeadm.
1. Add the Kubernetes yum repository. The `exclude` parameter in the repository definition ensures that the packages related to Kubernetes are not upgraded upon running `yum update` as there's a special procedure that must be followed for upgrading Kubernetes. Please note that this repository has packages only for Kubernetes 1.30; for other Kubernetes minor versions, you need to change the Kubernetes minor version in the URL to match your desired minor version (you should also check that you are reading the documentation for the version of Kubernetes that you plan to install).

```
This overwrites any existing configuration in /etc/yum.repos.d/kubernetes.repo
cat <<EOF | sudo tee /etc/yum.repos.d/kubernetes.repo
[kubernetes]
name=Kubernetes
baseurl=https://pkgs.k8s.io/core:/stable:/v1.30/rpm/
enabled=1
gpgcheck=1
gpgkey=https://pkgs.k8s.io/core:/stable:/v1.30/rpm/repodata/repomd.xml.key
exclude=kubelet kubeadm kubectl cri-tools kubernetes-cni
EOF
```

2. Install kubelet, kubeadm and kubectl:

```
sudo yum install -y kubelet kubeadm kubectl --disableexcludes=kubernetes
```

3. (Optional) Enable the kubelet service before running kubeadm:

```
sudo systemctl enable --now kubelet
```

Install CNI plugins (required for most pod network):

```
CNI_PLUGINS_VERSION="v1.3.0"
ARCH="amd64"
DEST="/opt/cni/bin"
sudo mkdir -p "$DEST"
curl -L "https://github.com/containernetworking/plugins/releases/download/${CNI_PLUGINS_VERSION}/cni-plugins-linux-${ARCH}-${CNI_PLUGINS_VERSION}.tgz" | sudo tar -C "$DEST" -xz
```

Define the directory to download command files:

**Note:**

The DOWNLOAD\_DIR variable must be set to a writable directory. If you are running Flatcar Container Linux, set DOWNLOAD\_DIR="/opt/bin".

```
DOWNLOAD_DIR="/usr/local/bin"
sudo mkdir -p "$DOWNLOAD_DIR"
```

Install crictl (required for kubeadm / Kubelet Container Runtime Interface (CRI)):

```
CRICTL_VERSION="v1.28.0"
ARCH="amd64"
curl -L "https://github.com/kubernetes-sigs/cri-tools/releases/download/${CRICTL_VERSION}/crictl-${CRICTL_VERSION}-linux-${ARCH}.tar.gz" | sudo tar -C $DOWNLOAD_DIR -xz
```

Install kubeadm, kubelet and add a kubelet systemd service:

```
RELEASE="$(curl -sSL https://dl.k8s.io/release/stable.txt)"
ARCH="amd64"
cd $DOWNLOAD_DIR
sudo curl -L --remote-name-all https://dl.k8s.io/release/${RELEASE}/bin/linux/${ARCH}/{kubeadm,kubelet}
sudo chmod +x {kubeadm,kubelet}
```

```
RELEASE_VERSION="v0.16.2"
curl -sSL "https://raw.githubusercontent.com/kubernetes/release/${RELEASE_VERSION}/cmd/krel/templates/latest/kubelet/kubelet.service" | sed "s:/usr/bin:${DOWNLOAD_DIR}:g" | sudo tee /usr/lib/systemd/system/kubelet.service
sudo mkdir -p /usr/lib/systemd/system/kubelet.service.d
curl -sSL "https://raw.githubusercontent.com/kubernetes/release/${RELEASE_VERSION}/cmd/krel/templates/latest/kubeadm/10-kubeadm.conf" | sed "s:/usr/bin:${DOWNLOAD_DIR}:g" | sudo tee /usr/lib/systemd/system/kubelet.service.d/10-kubeadm.conf
```

**Note:**

Please refer to the note in the [Before you begin](#) section for Linux distributions that do not include glibc by default.

Install kubectl by following the instructions on [Install Tools page](#).

Optionally, enable the kubelet service before running kubeadm:

```
sudo systemctl enable --now kubelet
```

**Note:**

The Flatcar Container Linux distribution mounts the `/usr` directory as a read-only filesystem. Before bootstrapping your cluster, you need to take additional steps to configure a writable directory. See the [Kubeadm Troubleshooting guide](#) to learn how to set up a writable directory.

The kubelet is now restarting every few seconds, as it waits in a crashloop for kubeadm to tell it what to do.

## Configuring a cgroup driver

Both the container runtime and the kubelet have a property called "[cgroup driver](#)", which is important for the management of cgroups on Linux machines.

**Warning:**

Matching the container runtime and kubelet cgroup drivers is required or otherwise the kubelet process will fail.

See [Configuring a cgroup driver](#) for more details.

## Troubleshooting

If you are running into difficulties with kubeadm, please consult our [troubleshooting docs](#).

## What's next

- [Using kubeadm to Create a Cluster](#)

## Troubleshooting kubeadm

As with any program, you might run into an error installing or running kubeadm. This page lists some common failure scenarios and have provided steps that can help you understand and fix the problem.

If your problem is not listed below, please follow the following steps:

- If you think your problem is a bug with kubeadm:
  - Go to [github.com/kubernetes/kubeadm](https://github.com/kubernetes/kubeadm) and search for existing issues.
  - If no issue exists, please [open one](#) and follow the issue template.
- If you are unsure about how kubeadm works, you can ask on [Slack](#) in #kubeadm, or open a question on [StackOverflow](#). Please include relevant tags like #kubernetes and #kubeadm so folks can help you.

# Not possible to join a v1.18 Node to a v1.17 cluster due to missing RBAC

In v1.18 kubeadm added prevention for joining a Node in the cluster if a Node with the same name already exists. This required adding RBAC for the bootstrap-token user to be able to GET a Node object.

However this causes an issue where kubeadm join from v1.18 cannot join a cluster created by kubeadm v1.17.

To workaround the issue you have two options:

Execute kubeadm init phase bootstrap-token on a control-plane node using kubeadm v1.18. Note that this enables the rest of the bootstrap-token permissions as well.

or

Apply the following RBAC manually using kubectl apply -f ...:

```
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
 name: kubeadm:get-nodes
rules:
- apiGroups:
 - ""
 resources:
 - nodes
 verbs:
 - get

apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
 name: kubeadm:get-nodes
roleRef:
 apiGroup: rbac.authorization.k8s.io
 kind: ClusterRole
 name: kubeadm:get-nodes
subjects:
- apiGroup: rbac.authorization.k8s.io
 kind: Group
 name: system:bootstrappers:kubeadm:default-node-token
```

## ebtables or some similar executable not found during installation

If you see the following warnings while running kubeadm init

```
[preflight] WARNING: ebtables not found in system path
[preflight] WARNING: ethtool not found in system path
```

Then you may be missing `ebtables`, `ethtool` or a similar executable on your node. You can install them with the following commands:

- For Ubuntu/Debian users, run `apt install ebtables ethtool`.
- For CentOS/Fedora users, run `yum install ebtables ethtool`.

## kubeadm blocks waiting for control plane during installation

If you notice that `kubeadm init` hangs after printing out the following line:

```
[apiclient] Created API client, waiting for the control plane to become ready
```

This may be caused by a number of problems. The most common are:

- network connection problems. Check that your machine has full network connectivity before continuing.
- the cgroup driver of the container runtime differs from that of the kubelet. To understand how to configure it properly, see [Configuring a cgroup driver](#).
- control plane containers are crashlooping or hanging. You can check this by running `docker ps` and investigating each container by running `docker logs`. For other container runtime, see [Debugging Kubernetes nodes with crictl](#).

## kubeadm blocks when removing managed containers

The following could happen if the container runtime halts and does not remove any Kubernetes-managed containers:

```
sudo kubeadm reset
```

```
[preflight] Running pre-flight checks
[reset] Stopping the kubelet service
[reset] Unmounting mounted directories in "/var/lib/kubelet"
[reset] Removing kubernetes-managed containers
(block)
```

A possible solution is to restart the container runtime and then re-run `kubeadm reset`. You can also use `crictl` to debug the state of the container runtime. See [Debugging Kubernetes nodes with crictl](#).

## Pods in RunContainerError, CrashLoopBackOff or Error state

Right after `kubeadm init` there should not be any pods in these states.

- If there are pods in one of these states *right after* `kubeadm init`, please open an issue in the `kubeadm` repo. `coredns` (or `kube-dns`) should be in the Pending state until you have deployed the network add-on.
- If you see Pods in the `RunContainerError`, `CrashLoopBackOff` or `Error` state after deploying the network add-on and nothing happens to `coredns` (or `kube-dns`), it's very likely that the Pod Network add-on that you installed is somehow broken. You might

have to grant it more RBAC privileges or use a newer version. Please file an issue in the Pod Network providers' issue tracker and get the issue triaged there.

## coredns is stuck in the Pending state

This is **expected** and part of the design. kubeadm is network provider-agnostic, so the admin should [install the pod network add-on](#) of choice. You have to install a Pod Network before CoreDNS may be deployed fully. Hence the Pending state before the network is set up.

## HostPort services do not work

The HostPort and HostIP functionality is available depending on your Pod Network provider. Please contact the author of the Pod Network add-on to find out whether HostPort and HostIP functionality are available.

Calico, Canal, and Flannel CNI providers are verified to support HostPort.

For more information, see the [CNI portmap documentation](#).

If your network provider does not support the portmap CNI plugin, you may need to use the [NodePort feature of services](#) or use HostNetwork=true.

## Pods are not accessible via their Service IP

- Many network add-ons do not yet enable [hairpin mode](#) which allows pods to access themselves via their Service IP. This is an issue related to [CNI](#). Please contact the network add-on provider to get the latest status of their support for hairpin mode.
- If you are using VirtualBox (directly or via Vagrant), you will need to ensure that `hostname -i` returns a routable IP address. By default, the first interface is connected to a non-routable host-only network. A work around is to modify `/etc/hosts`, see this [Vagrantfile](#) for an example.

## TLS certificate errors

The following error indicates a possible certificate mismatch.

```
kubectl get pods
```

```
Unable to connect to the server: x509: certificate signed by unknown authority (possibly because of "crypto/rsa: verification error" while trying to verify candidate authority certificate "kubernetes")
```

- Verify that the `$HOME/.kube/config` file contains a valid certificate, and regenerate a certificate if necessary. The certificates in a kubeconfig file are base64 encoded. The `base64 --decode` command can be used to decode the certificate and `openssl x509 -text -noout` can be used for viewing the certificate information.
- Unset the KUBECONFIG environment variable using:

```
unset KUBECONFIG
```

Or set it to the default KUBECONFIG location:

```
export KUBECONFIG=/etc/kubernetes/admin.conf
```

- Another workaround is to overwrite the existing kubeconfig for the "admin" user:

```
mv $HOME/.kube $HOME/.kube.bak
mkdir $HOME/.kube
sudo cp -i /etc/kubernetes/admin.conf $HOME/.kube/config
sudo chown $(id -u):$(id -g) $HOME/.kube/config
```

## Kubelet client certificate rotation fails

By default, kubeadm configures a kubelet with automatic rotation of client certificates by using the `/var/lib/kubelet/pki/kubelet-client-current.pem` symlink specified in `/etc/kubernetes/kubelet.conf`. If this rotation process fails you might see errors such as `x509: certificate has expired or is not yet valid` in kube-apiserver logs. To fix the issue you must follow these steps:

1. Backup and delete `/etc/kubernetes/kubelet.conf` and `/var/lib/kubelet/pki/kubelet-client*` from the failed node.
2. From a working control plane node in the cluster that has `/etc/kubernetes/pki/ca.key` execute `kubeadm kubeconfig user --org system:nodes --client-name system:node:$NODE > kubelet.conf`. `$NODE` must be set to the name of the existing failed node in the cluster. Modify the resulted `kubelet.conf` manually to adjust the cluster name and server endpoint, or pass `kubeconfig user --config` (see [Generating kubeconfig files for additional users](#)). If your cluster does not have the `ca.key` you must sign the embedded certificates in the `kubelet.conf` externally.
3. Copy this resulted `kubelet.conf` to `/etc/kubernetes/kubelet.conf` on the failed node.
4. Restart the kubelet (`systemctl restart kubelet`) on the failed node and wait for `/var/lib/kubelet/pki/kubelet-client-current.pem` to be recreated.
5. Manually edit the `kubelet.conf` to point to the rotated kubelet client certificates, by replacing `client-certificate-data` and `client-key-data` with:

```
client-certificate: /var/lib/kubelet/pki/kubelet-client-current.pem
client-key: /var/lib/kubelet/pki/kubelet-client-current.pem
```

6. Restart the kubelet.
7. Make sure the node becomes Ready.

## Default NIC When using flannel as the pod network in Vagrant

The following error might indicate that something was wrong in the pod network:

Error from server (NotFound): the server could not find the requested resource

- If you're using flannel as the pod network inside Vagrant, then you will have to specify the default interface name for flannel.

Vagrant typically assigns two interfaces to all VMs. The first, for which all hosts are assigned the IP address 10.0.2.15, is for external traffic that gets NATed.

This may lead to problems with flannel, which defaults to the first interface on a host. This leads to all hosts thinking they have the same public IP address. To prevent this, pass the `--iface eth1` flag to flannel so that the second interface is chosen.

## Non-public IP used for containers

In some situations `kubectl logs` and `kubectl run` commands may return with the following errors in an otherwise functional cluster:

```
Error from server: Get https://10.19.0.41:10250/containerLogs/default/mysql-ddc65b868-glc5m/mysql: dial tcp 10.19.0.41:10250: getsockopt: no route to host
```

- This may be due to Kubernetes using an IP that can not communicate with other IPs on the seemingly same subnet, possibly by policy of the machine provider.
- DigitalOcean assigns a public IP to `eth0` as well as a private one to be used internally as anchor for their floating IP feature, yet kubelet will pick the latter as the node's InternalIP instead of the public one.

Use `ip addr show` to check for this scenario instead of `ifconfig` because `ifconfig` will not display the offending alias IP address. Alternatively an API endpoint specific to DigitalOcean allows to query for the anchor IP from the droplet:

```
curl http://169.254.169.254/metadata/v1/interfaces/public/0/anchor_ip_v4/address
```

The workaround is to tell kubelet which IP to use using `--node-ip`. When using DigitalOcean, it can be the public one (assigned to `eth0`) or the private one (assigned to `eth1`) should you want to use the optional private network. The `kubeletExtraArgs` section of the `kubeadm NodeRegistrationOptions` structure can be used for this.

Then restart kubelet:

```
systemctl daemon-reload
systemctl restart kubelet
```

## coredns pods have CrashLoopBackOff or Error state

If you have nodes that are running SELinux with an older version of Docker, you might experience a scenario where the coredns pods are not starting. To solve that, you can try one of the following options:

- Upgrade to a [newer version of Docker](#).
- [Disable SELinux](#).
- Modify the coredns deployment to set `allowPrivilegeEscalation` to true:

```
kubectl -n kube-system get deployment coredns -o yaml | \
sed 's/allowPrivilegeEscalation: false/allowPrivilegeEscalation: true/g' | \
kubectl apply -f -
```

Another cause for CoreDNS to have CrashLoopBackOff is when a CoreDNS Pod deployed in Kubernetes detects a loop. [A number of workarounds](#) are available to avoid Kubernetes trying to restart the CoreDNS Pod every time CoreDNS detects the loop and exits.

### Warning:

Disabling SELinux or setting allowPrivilegeEscalation to true can compromise the security of your cluster.

## etcd pods restart continually

If you encounter the following error:

```
rpc error: code = 2 desc = oci runtime error: exec failed: container_linux.go:247: starting container process caused "process_linux.go:110: decoding init error from pipe caused \"read parent: connection reset by peer\""
```

This issue appears if you run CentOS 7 with Docker 1.13.1.84. This version of Docker can prevent the kubelet from executing into the etcd container.

To work around the issue, choose one of these options:

- Roll back to an earlier version of Docker, such as 1.13.1-75

```
yum downgrade docker-1.13.1-75.git8633870.el7.centos.x86_64 docker-client-1.13.1-75.git8633870.el7.centos.x86_64 docker-common-1.13.1-75.git8633870.el7.centos.x86_64
```

- Install one of the more recent recommended versions, such as 18.06:

```
sudo yum-config-manager --add-repo https://download.docker.com/linux/centos/docker-ce.repo
yum install docker-ce-18.06.1.ce-3.el7.x86_64
```

## Not possible to pass a comma separated list of values to arguments inside a --component-extra-args flag

kubeadm init flags such as --component-extra-args allow you to pass custom arguments to a control-plane component like the kube-apiserver. However, this mechanism is limited due to the underlying type used for parsing the values (mapStringString).

If you decide to pass an argument that supports multiple, comma-separated values such as --apiserver-extra-args "enable-admission-plugins=LimitRanger,NamespaceExists" this flag will fail with flag: malformed pair, expect string=string. This happens because the list of arguments for --apiserver-extra-args expects key=value pairs and in this case NamespaceExists is considered as a key that is missing a value.

Alternatively, you can try separating the key=value pairs like so: --apiserver-extra-args "enable-admission-plugins=LimitRanger,enable-admission-plugins=NamespaceExists" but this will result in the key enable-admission-plugins only having the value of NamespaceExists.

A known workaround is to use the kubeadm [configuration file](#).

## kube-proxy scheduled before node is initialized by cloud-controller-manager

In cloud provider scenarios, kube-proxy can end up being scheduled on new worker nodes before the cloud-controller-manager has initialized the node addresses. This causes kube-proxy to fail to pick up the node's IP address properly and has knock-on effects to the proxy function managing load balancers.

The following error can be seen in kube-proxy Pods:

```
server.go:610] Failed to retrieve node IP: host IP unknown; known addresses: []
proxier.go:340] invalid nodeIP, initializing kube-proxy with 127.0.0.1 as nodeIP
```

A known solution is to patch the kube-proxy DaemonSet to allow scheduling it on control-plane nodes regardless of their conditions, keeping it off of other nodes until their initial guarding conditions abate:

```
kubectl -n kube-system patch ds kube-proxy -p='{
 "spec": {
 "template": {
 "spec": {
 "tolerations": [
 {
 "key": "CriticalAddonsOnly",
 "operator": "Exists"
 },
 {
 "effect": "NoSchedule",
 "key": "node-role.kubernetes.io/control-plane"
 }
]
 }
 }
 }
}'
```

The tracking issue for this problem is [here](#).

## /usr is mounted read-only on nodes

On Linux distributions such as Fedora CoreOS or Flatcar Container Linux, the directory /usr is mounted as a read-only filesystem. For [flex-volume support](#), Kubernetes components like the kubelet and kube-controller-manager use the default path of /usr/libexec/kubernetes/kubelet-plugins/volume/exec/, yet the flex-volume directory *must be writeable* for the feature to work.

### Note:

FlexVolume was deprecated in the Kubernetes v1.23 release.

To workaround this issue, you can configure the flex-volume directory using the [kubeadm configuration file](#).

On the primary control-plane Node (created using `kubeadm init`), pass the following file using `--config`:

```
apiVersion: kubeadm.k8s.io/v1beta3
kind: InitConfiguration
nodeRegistration:
 kubeletExtraArgs:
 volume-plugin-dir: "/opt/libexec/kubernetes/kubelet-plugins/volume/exec/"

apiVersion: kubeadm.k8s.io/v1beta3
kind: ClusterConfiguration
controllerManager:
 extraArgs:
 flex-volume-plugin-dir: "/opt/libexec/kubernetes/kubelet-plugins/volume/exec/"
```

On joining Nodes:

```
apiVersion: kubeadm.k8s.io/v1beta3
kind: JoinConfiguration
nodeRegistration:
 kubeletExtraArgs:
 volume-plugin-dir: "/opt/libexec/kubernetes/kubelet-plugins/volume/exec/"
```

Alternatively, you can modify `/etc/fstab` to make the `/usr` mount writeable, but please be advised that this is modifying a design principle of the Linux distribution.

## kubeadm upgrade plan prints out context deadline exceeded error message

This error message is shown when upgrading a Kubernetes cluster with `kubeadm` in the case of running an external `etcd`. This is not a critical bug and happens because older versions of `kubeadm` perform a version check on the external `etcd` cluster. You can proceed with `kubeadm upgrade apply ...`

This issue is fixed as of version 1.19.

## kubeadm reset unmounts /var/lib/kubelet

If `/var/lib/kubelet` is being mounted, performing a `kubeadm reset` will effectively unmount it.

To workaround the issue, re-mount the `/var/lib/kubelet` directory after performing the `kubeadm reset` operation.

This is a regression introduced in `kubeadm` 1.15. The issue is fixed in 1.20.

## Cannot use the metrics-server securely in a kubeadm cluster

In a `kubeadm` cluster, the [metrics-server](#) can be used insecurely by passing the `--kubelet-insecure-tls` to it. This is not recommended for production clusters.

If you want to use TLS between the metrics-server and the kubelet there is a problem, since kubeadm deploys a self-signed serving certificate for the kubelet. This can cause the following errors on the side of the metrics-server:

```
x509: certificate signed by unknown authority
x509: certificate is valid for IP-foo not IP-bar
```

See [Enabling signed kubelet serving certificates](#) to understand how to configure the kubelets in a kubeadm cluster to have properly signed serving certificates.

Also see [How to run the metrics-server securely](#).

## Upgrade fails due to etcd hash not changing

Only applicable to upgrading a control plane node with a kubeadm binary v1.28.3 or later, where the node is currently managed by kubeadm versions v1.28.0, v1.28.1 or v1.28.2.

Here is the error message you may encounter:

```
[upgrade/etcd] Failed to upgrade etcd: couldn't upgrade control plane. kubeadm has tried to
recover everything into the earlier state. Errors faced: static Pod hash for component etcd on
Node kinder-upgrade-control-plane-1 did not change after 5m0s: timed out waiting for the
condition
[upgrade/etcd] Waiting for previous etcd to become available
I0907 10:10:09.109104 3704 etcd.go:588] [etcd] attempting to see if all cluster endpoints
([https://172.17.0.6:2379/ https://172.17.0.4:2379/ https://172.17.0.3:2379/]) are available 1/10
[upgrade/etcd] Etcd was rolled back and is now available
static Pod hash for component etcd on Node kinder-upgrade-control-plane-1 did not change
after 5m0s: timed out waiting for the condition
couldn't upgrade control plane. kubeadm has tried to recover everything into the earlier state.
Errors faced
k8s.io/kubernetes/cmd/kubeadm/app/phases/upgrade.rollbackOldManifests
cmd/kubeadm/app/phases/upgrade/staticpods.go:525
k8s.io/kubernetes/cmd/kubeadm/app/phases/upgrade.upgradeComponent
cmd/kubeadm/app/phases/upgrade/staticpods.go:254
k8s.io/kubernetes/cmd/kubeadm/app/phases/upgrade.performEtcdStaticPodUpgrade
cmd/kubeadm/app/phases/upgrade/staticpods.go:338
...
```

The reason for this failure is that the affected versions generate an etcd manifest file with unwanted defaults in the PodSpec. This will result in a diff from the manifest comparison, and kubeadm will expect a change in the Pod hash, but the kubelet will never update the hash.

There are two way to workaround this issue if you see it in your cluster:

- The etcd upgrade can be skipped between the affected versions and v1.28.3 (or later) by using:

```
kubeadm upgrade {apply|node} [version] --etcd-upgrade=false
```

This is not recommended in case a new etcd version was introduced by a later v1.28 patch version.

- Before upgrade, patch the manifest for the etcd static pod, to remove the problematic
- defaulted attributes:

```
diff --git a/etc/kubernetes/manifests/etcd_defaults.yaml b/etc/kubernetes/manifests/etcd_origin.yaml
index d807ccbe0aa..46b35f00e15 100644

More information can be found in the [tracking issue](#) for this bug.

## Creating a cluster with kubeadm

Using kubeadm, you can create a minimum viable Kubernetes cluster that conforms to best practices. In fact, you can use kubeadm to set up a cluster that will pass the [Kubernetes Conformance tests](#). kubeadm also supports other cluster lifecycle functions, such as [bootstrap tokens](#) and cluster upgrades.

The kubeadm tool is good if you need:

- A simple way for you to try out Kubernetes, possibly for the first time.
- A way for existing users to automate setting up a cluster and test their application.
- A building block in other ecosystem and/or installer tools with a larger scope.

You can install and use kubeadm on various machines: your laptop, a set of cloud servers, a Raspberry Pi, and more. Whether you're deploying into the cloud or on-premises, you can integrate kubeadm into provisioning systems such as Ansible or Terraform.

## Before you begin

To follow this guide, you need:

- One or more machines running a deb/rpm-compatible Linux OS; for example: Ubuntu or CentOS.
- 2 GiB or more of RAM per machine--any less leaves little room for your apps.
- At least 2 CPUs on the machine that you use as a control-plane node.
- Full network connectivity among all machines in the cluster. You can use either a public or a private network.

You also need to use a version of kubeadm that can deploy the version of Kubernetes that you want to use in your new cluster.

[Kubernetes' version and version skew support policy](#) applies to kubeadm as well as to Kubernetes overall. Check that policy to learn about what versions of Kubernetes and kubeadm are supported. This page is written for Kubernetes v1.30.

The kubeadm tool's overall feature state is General Availability (GA). Some sub-features are still under active development. The implementation of creating the cluster may change slightly as the tool evolves, but the overall implementation should be pretty stable.

### Note:

Any commands under kubeadm alpha are, by definition, supported on an alpha level.

## Objectives

- Install a single control-plane Kubernetes cluster
- Install a Pod network on the cluster so that your Pods can talk to each other

## Instructions

### Preparing the hosts

#### Component installation

Install a [container runtime](#) and kubeadm on all the hosts. For detailed instructions and other prerequisites, see [Installing kubeadm](#).

**Note:**

If you have already installed kubeadm, see the first two steps of the [Upgrading Linux nodes](#) document for instructions on how to upgrade kubeadm.

When you upgrade, the kubelet restarts every few seconds as it waits in a crashloop for kubeadm to tell it what to do. This crashloop is expected and normal. After you initialize your control-plane, the kubelet runs normally.

**Network setup**

kubeadm similarly to other Kubernetes components tries to find a usable IP on the network interfaces associated with a default gateway on a host. Such an IP is then used for the advertising and/or listening performed by a component.

To find out what this IP is on a Linux host you can use:

```
ip route show # Look for a line starting with "default via"
```

**Note:**

If two or more default gateways are present on the host, a Kubernetes component will try to use the first one it encounters that has a suitable global unicast IP address. While making this choice, the exact ordering of gateways might vary between different operating systems and kernel versions.

Kubernetes components do not accept custom network interface as an option, therefore a custom IP address must be passed as a flag to all components instances that need such a custom configuration.

**Note:**

If the host does not have a default gateway and if a custom IP address is not passed to a Kubernetes component, the component may exit with an error.

To configure the API server advertise address for control plane nodes created with both init and join, the flag `--apiserver-advertise-address` can be used. Preferably, this option can be set in the [kubeadm API](#) as `InitConfiguration.localAPIEndpoint` and `JoinConfiguration.controlPlane.localAPIEndpoint`.

For kubelets on all nodes, the `--node-ip` option can be passed in `.nodeRegistration.kubeletExtraArgs` inside a kubeadm configuration file (`InitConfiguration` or `JoinConfiguration`).

For dual-stack see [Dual-stack support with kubeadm](#).

The IP addresses that you assign to control plane components become part of their X.509 certificates' subject alternative name fields. Changing these IP addresses would require signing new certificates and restarting the affected components, so that the change in certificate files is reflected. See [Manual certificate renewal](#) for more details on this topic.

## Warning:

The Kubernetes project recommends against this approach (configuring all component instances with custom IP addresses). Instead, the Kubernetes maintainers recommend to setup the host network, so that the default gateway IP is the one that Kubernetes components auto-detect and use. On Linux nodes, you can use commands such as `ip route` to configure networking; your operating system might also provide higher level network management tools. If your node's default gateway is a public IP address, you should configure packet filtering or other security measures that protect the nodes and your cluster.

## Preparing the required container images

This step is optional and only applies in case you wish `kubeadm init` and `kubeadm join` to not download the default container images which are hosted at `registry.k8s.io`.

Kubeadm has commands that can help you pre-pull the required images when creating a cluster without an internet connection on its nodes. See [Running kubeadm without an internet connection](#) for more details.

Kubeadm allows you to use a custom image repository for the required images. See [Using custom images](#) for more details.

## Initializing your control-plane node

The control-plane node is the machine where the control plane components run, including [etcd](#) (the cluster database) and the [API Server](#) (which the [kubectx](#) command line tool communicates with).

1. (Recommended) If you have plans to upgrade this single control-plane kubeadm cluster to high availability you should specify the `--control-plane-endpoint` to set the shared endpoint for all control-plane nodes. Such an endpoint can be either a DNS name or an IP address of a load-balancer.
2. Choose a Pod network add-on, and verify whether it requires any arguments to be passed to `kubeadm init`. Depending on which third-party provider you choose, you might need to set the `--pod-network-cidr` to a provider-specific value. See [Installing a Pod network add-on](#).
3. (Optional) `kubeadm` tries to detect the container runtime by using a list of well known endpoints. To use different container runtime or if there are more than one installed on the provisioned node, specify the `--cri-socket` argument to `kubeadm`. See [Installing a runtime](#).

To initialize the control-plane node run:

```
kubeadm init <args>
```

## Considerations about apiserver-advertise-address and ControlPlaneEndpoint

While `--apiserver-advertise-address` can be used to set the advertise address for this particular control-plane node's API server, `--control-plane-endpoint` can be used to set the shared endpoint for all control-plane nodes.

--control-plane-endpoint allows both IP addresses and DNS names that can map to IP addresses. Please contact your network administrator to evaluate possible solutions with respect to such mapping.

Here is an example mapping:

192.168.0.102 cluster-endpoint

Where 192.168.0.102 is the IP address of this node and cluster-endpoint is a custom DNS name that maps to this IP. This will allow you to pass --control-plane-endpoint=cluster-endpoint to kubeadm init and pass the same DNS name to kubeadm join. Later you can modify cluster-endpoint to point to the address of your load-balancer in an high availability scenario.

Turning a single control plane cluster created without --control-plane-endpoint into a highly available cluster is not supported by kubeadm.

## More information

For more information about kubeadm init arguments, see the [kubeadm reference guide](#).

To configure kubeadm init with a configuration file see [Using kubeadm init with a configuration file](#).

To customize control plane components, including optional IPv6 assignment to liveness probe for control plane components and etcd server, provide extra arguments to each component as documented in [custom arguments](#).

To reconfigure a cluster that has already been created see [Reconfiguring a kubeadm cluster](#).

To run kubeadm init again, you must first [tear down the cluster](#).

If you join a node with a different architecture to your cluster, make sure that your deployed DaemonSets have container image support for this architecture.

kubeadm init first runs a series of prechecks to ensure that the machine is ready to run Kubernetes. These prechecks expose warnings and exit on errors. kubeadm init then downloads and installs the cluster control plane components. This may take several minutes. After it finishes you should see:

Your Kubernetes control-plane has initialized successfully!

To start using your cluster, you need to run the following as a regular user:

```
mkdir -p $HOME/.kube
sudo cp -i /etc/kubernetes/admin.conf $HOME/.kube/config
sudo chown $(id -u):$(id -g) $HOME/.kube/config
```

You should now deploy a Pod network to the cluster.

Run "kubectl apply -f [podnetwork].yaml" with one of the options listed at: [/docs/concepts/cluster-administration/addons/](#)

You can now join any number of machines by running the following on each node as root:

```
kubeadm join <control-plane-host>:<control-plane-port> --token <token> --discovery-token-ca-cert-hash sha256:<hash>
```

To make kubectl work for your non-root user, run these commands, which are also part of the kubeadm init output:

```
mkdir -p $HOME/.kube
sudo cp -i /etc/kubernetes/admin.conf $HOME/.kube/config
sudo chown $(id -u):$(id -g) $HOME/.kube/config
```

Alternatively, if you are the root user, you can run:

```
export KUBECONFIG=/etc/kubernetes/admin.conf
```

### Warning:

The kubeconfig file admin.conf that kubeadm init generates contains a certificate with Subject: O = kubeadm:cluster-admins, CN = kubernetes-admin. The group kubeadm:cluster-admins is bound to the built-in cluster-admin ClusterRole. Do not share the admin.conf file with anyone.

kubeadm init generates another kubeconfig file super-admin.conf that contains a certificate with Subject: O = system:masters, CN = kubernetes-super-admin. system:masters is a break-glass, super user group that bypasses the authorization layer (for example RBAC). Do not share the super-admin.conf file with anyone. It is recommended to move the file to a safe location.

See [Generating kubeconfig files for additional users](#) on how to use kubeadm kubeconfig user to generate kubeconfig files for additional users.

Make a record of the kubeadm join command that kubeadm init outputs. You need this command to [join nodes to your cluster](#).

The token is used for mutual authentication between the control-plane node and the joining nodes. The token included here is secret. Keep it safe, because anyone with this token can add authenticated nodes to your cluster. These tokens can be listed, created, and deleted with the kubeadm token command. See the [kubeadm reference guide](#).

## Installing a Pod network add-on

### Caution:

This section contains important information about networking setup and deployment order. Read all of this advice carefully before proceeding.

**You must deploy a [Container Network Interface](#) (CNI) based Pod network add-on so that your Pods can communicate with each other. Cluster DNS (CoreDNS) will not start up before a network is installed.**

- Take care that your Pod network must not overlap with any of the host networks: you are likely to see problems if there is any overlap. (If you find a collision between your network plugin's preferred Pod network and some of your host networks, you should think of a suitable CIDR block to use instead, then use that during kubeadm init with --pod-network-cidr and as a replacement in your network plugin's YAML).

- By default, kubeadm sets up your cluster to use and enforce use of [RBAC](#) (role based access control). Make sure that your Pod network plugin supports RBAC, and so do any manifests that you use to deploy it.
- If you want to use IPv6--either dual-stack, or single-stack IPv6 only networking--for your cluster, make sure that your Pod network plugin supports IPv6. IPv6 support was added to CNI in [v0.6.0](#).

**Note:**

Kubeadm should be CNI agnostic and the validation of CNI providers is out of the scope of our current e2e testing. If you find an issue related to a CNI plugin you should log a ticket in its respective issue tracker instead of the kubeadm or kubernetes issue trackers.

Several external projects provide Kubernetes Pod networks using CNI, some of which also support [Network Policy](#).

See a list of add-ons that implement the [Kubernetes networking model](#).

Please refer to the [Installing Addons](#) page for a non-exhaustive list of networking addons supported by Kubernetes. You can install a Pod network add-on with the following command on the control-plane node or a node that has the kubeconfig credentials:

```
kubectl apply -f <add-on.yaml>
```

You can install only one Pod network per cluster.

Once a Pod network has been installed, you can confirm that it is working by checking that the CoreDNS Pod is Running in the output of `kubectl get pods --all-namespaces`. And once the CoreDNS Pod is up and running, you can continue by joining your nodes.

If your network is not working or CoreDNS is not in the Running state, check out the [troubleshooting guide](#) for kubeadm.

## Managed node labels

By default, kubeadm enables the [NodeRestriction](#) admission controller that restricts what labels can be self-applied by kubelets on node registration. The admission controller documentation covers what labels are permitted to be used with the kubelet `--node-labels` option. The `node-role.kubernetes.io/control-plane` label is such a restricted label and kubeadm manually applies it using a privileged client after a node has been created. To do that manually you can do the same by using `kubectl label` and ensure it is using a privileged kubeconfig such as the `kubeadm managed /etc/kubernetes/admin.conf`.

## Control plane node isolation

By default, your cluster will not schedule Pods on the control plane nodes for security reasons. If you want to be able to schedule Pods on the control plane nodes, for example for a single machine Kubernetes cluster, run:

```
kubectl taint nodes --all node-role.kubernetes.io/control-plane-
```

The output will look something like:

```
node "test-01" untainted
...
```

This will remove the `node-role.kubernetes.io/control-plane:NoSchedule` taint from any nodes that have it, including the control plane nodes, meaning that the scheduler will then be able to schedule Pods everywhere.

Additionally, you can execute the following command to remove the [node.kubernetes.io/exclude-from-external-load-balancers](https://kubernetes.io/docs/concepts/configuration/label/#exclude-from-external-load-balancers) label from the control plane node, which excludes it from the list of backend servers:

```
kubectll label nodes --all node.kubernetes.io/exclude-from-external-load-balancers-
```

## Joining your nodes

The nodes are where your workloads (containers and Pods, etc) run. To add new nodes to your cluster do the following for each machine:

- SSH to the machine
- Become root (e.g. `sudo su -`)
- [Install a runtime](#) if needed
- Run the command that was output by `kubeadm init`. For example:

```
kubeadm join --token <token> <control-plane-host>:<control-plane-port> --discovery-
token-ca-cert-hash sha256:<hash>
```

If you do not have the token, you can get it by running the following command on the control-plane node:

```
kubeadm token list
```

The output is similar to this:

| TOKEN GROUPS            | TTL | EXPIRES              | USAGES                  | DESCRIPTION                        | EXTRA                                                                    |
|-------------------------|-----|----------------------|-------------------------|------------------------------------|--------------------------------------------------------------------------|
| 8ewj1p.9r9hcjoqgajrj4gi | 23h | 2018-06-12T02:51:28Z | authentication, signing | token generated by 'kubeadm init'. | The default bootstrap system: bootstrappers: kubeadm: default-node-token |

By default, tokens expire after 24 hours. If you are joining a node to the cluster after the current token has expired, you can create a new token by running the following command on the control-plane node:

```
kubeadm token create
```

The output is similar to this:

```
5didvk.d09sbcov8ph2amjw
```

If you don't have the value of `--discovery-token-ca-cert-hash`, you can get it by running the following command chain on the control-plane node:

```
openssl x509 -pubkey -in /etc/kubernetes/pki/ca.crt | openssl rsa -pubin -outform der 2>/dev/null | \
 openssl dgst -sha256 -hex | sed 's/^.* //'
```

The output is similar to:

```
8cb2de97839780a412b93877f8507ad6c94f73add17d5d7058e91741c9d5ec78
```

### **Note:**

To specify an IPv6 tuple for `<control-plane-host>:<control-plane-port>`, IPv6 address must be enclosed in square brackets, for example: `[2001:db8::101]:2073`.

The output should look something like:

```
[preflight] Running pre-flight checks
```

```
... (log output of join workflow) ...
```

```
Node join complete:
```

- \* Certificate signing request sent to control-plane and response received.
- \* Kubelet informed of new secure connection details.

```
Run 'kubectl get nodes' on control-plane to see this machine join.
```

A few seconds later, you should notice this node in the output from `kubectl get nodes` when run on the control-plane node.

### **Note:**

As the cluster nodes are usually initialized sequentially, the CoreDNS Pods are likely to all run on the first control-plane node. To provide higher availability, please rebalance the CoreDNS Pods with `kubectl -n kube-system rollout restart deployment coredns` after at least one new node is joined.

## **(Optional) Controlling your cluster from machines other than the control-plane node**

In order to get a `kubectl` on some other computer (e.g. laptop) to talk to your cluster, you need to copy the administrator kubeconfig file from your control-plane node to your workstation like this:

```
scp root@<control-plane-host>:/etc/kubernetes/admin.conf .
kubectl --kubeconfig ./admin.conf get nodes
```

## Note:

The example above assumes SSH access is enabled for root. If that is not the case, you can copy the `admin.conf` file to be accessible by some other user and `scp` using that other user instead.

The `admin.conf` file gives the user *superuser* privileges over the cluster. This file should be used sparingly. For normal users, it's recommended to generate a unique credential to which you grant privileges. You can do this with the `kubeadm kubeconfig user --client-name <CN>` command. That command will print out a KubeConfig file to STDOUT which you should save to a file and distribute to your user. After that, grant privileges by using `kubectl create (cluster)rolebinding`.

## (Optional) Proxying API Server to localhost

If you want to connect to the API Server from outside the cluster you can use `kubectl proxy`:

```
scp root@<control-plane-host>:/etc/kubernetes/admin.conf .
kubectl --kubeconfig ./admin.conf proxy
```

You can now access the API Server locally at `http://localhost:8001/api/v1`

## Clean up

If you used disposable servers for your cluster, for testing, you can switch those off and do no further clean up. You can use `kubectl config delete-cluster` to delete your local references to the cluster.

However, if you want to deprovision your cluster more cleanly, you should first [drain the node](#) and make sure that the node is empty, then deconfigure the node.

## Remove the node

Talking to the control-plane node with the appropriate credentials, run:

```
kubectl drain <node name> --delete-emptydir-data --force --ignore-daemonsets
```

Before removing the node, reset the state installed by `kubeadm`:

```
kubeadm reset
```

The reset process does not reset or clean up iptables rules or IPVS tables. If you wish to reset iptables, you must do so manually:

```
iptables -F && iptables -t nat -F && iptables -t mangle -F && iptables -X
```

If you want to reset the IPVS tables, you must run the following command:

```
ipvsadm -C
```

Now remove the node:

```
kubectl delete node <node name>
```

If you wish to start over, run `kubeadm init` or `kubeadm join` with the appropriate arguments.

## Clean up the control plane

You can use `kubeadm reset` on the control plane host to trigger a best-effort clean up.

See the [kubeadm reset](#) reference documentation for more information about this subcommand and its options.

## Version skew policy

While `kubeadm` allows version skew against some components that it manages, it is recommended that you match the `kubeadm` version with the versions of the control plane components, `kube-proxy` and `kubelet`.

### kubeadm's skew against the Kubernetes version

`kubeadm` can be used with Kubernetes components that are the same version as `kubeadm` or one version older. The Kubernetes version can be specified to `kubeadm` by using the `--kubernetes-version` flag of `kubeadm init` or the [ClusterConfiguration.kubernetesVersion](#) field when using `--config`. This option will control the versions of `kube-apiserver`, `kube-controller-manager`, `kube-scheduler` and `kube-proxy`.

Example:

- `kubeadm` is at 1.30
- `kubernetesVersion` must be at 1.30 or 1.29

### kubeadm's skew against the kubelet

Similarly to the Kubernetes version, `kubeadm` can be used with a `kubelet` version that is the same version as `kubeadm` or three versions older.

Example:

- `kubeadm` is at 1.30
- `kubelet` on the host must be at 1.30, 1.29, 1.28 or 1.27

### kubeadm's skew against kubeadm

There are certain limitations on how `kubeadm` commands can operate on existing nodes or whole clusters managed by `kubeadm`.

If new nodes are joined to the cluster, the `kubeadm` binary used for `kubeadm join` must match the last version of `kubeadm` used to either create the cluster with `kubeadm init` or to upgrade the same node with `kubeadm upgrade`. Similar rules apply to the rest of the `kubeadm` commands with the exception of `kubeadm upgrade`.

Example for `kubeadm join`:

- `kubeadm` version 1.30 was used to create a cluster with `kubeadm init`
- Joining nodes must use a `kubeadm` binary that is at version 1.30

Nodes that are being upgraded must use a version of kubeadm that is the same MINOR version or one MINOR version newer than the version of kubeadm used for managing the node.

Example for kubeadm upgrade:

- kubeadm version 1.29 was used to create or upgrade the node
- The version of kubeadm used for upgrading the node must be at 1.29 or 1.30

To learn more about the version skew between the different Kubernetes component see the [Version Skew Policy](#).

## Limitations

### Cluster resilience

The cluster created here has a single control-plane node, with a single etcd database running on it. This means that if the control-plane node fails, your cluster may lose data and may need to be recreated from scratch.

Workarounds:

- Regularly [back up etcd](#). The etcd data directory configured by kubeadm is at `/var/lib/etcd` on the control-plane node.
- Use multiple control-plane nodes. You can read [Options for Highly Available topology](#) to pick a cluster topology that provides [high-availability](#).

### Platform compatibility

kubeadm deb/rpm packages and binaries are built for amd64, arm (32-bit), arm64, ppc64le, and s390x following the [multi-platform proposal](#).

Multiplatform container images for the control plane and addons are also supported since v1.12.

Only some of the network providers offer solutions for all platforms. Please consult the list of network providers above or the documentation from each provider to figure out whether the provider supports your chosen platform.

## Troubleshooting

If you are running into difficulties with kubeadm, please consult our [troubleshooting docs](#).

## What's next

- Verify that your cluster is running properly with [Sonobuoy](#)
- See [Upgrading kubeadm clusters](#) for details about upgrading your cluster using kubeadm.
- Learn about advanced kubeadm usage in the [kubeadm reference documentation](#)
- Learn more about Kubernetes [concepts](#) and [kubect](#)l.
- See the [Cluster Networking](#) page for a bigger list of Pod network add-ons.
- See the [list of add-ons](#) to explore other add-ons, including tools for logging, monitoring, network policy, visualization & control of your Kubernetes cluster.

- Configure how your cluster handles logs for cluster events and from applications running in Pods. See [Logging Architecture](#) for an overview of what is involved.

## Feedback

- For bugs, visit the [kubeadm GitHub issue tracker](#)
- For support, visit the [#kubeadm](#) Slack channel
- General SIG Cluster Lifecycle development Slack channel: [#sig-cluster-lifecycle](#)
- SIG Cluster Lifecycle [SIG information](#)
- SIG Cluster Lifecycle mailing list: [kubernetes-sig-cluster-lifecycle](#)

# Customizing components with the kubeadm API

This page covers how to customize the components that kubeadm deploys. For control plane components you can use flags in the ClusterConfiguration structure or patches per-node. For the kubelet and kube-proxy you can use KubeletConfiguration and KubeProxyConfiguration, accordingly.

All of these options are possible via the kubeadm configuration API. For more details on each field in the configuration you can navigate to our [API reference pages](#).

### Note:

Customizing the CoreDNS deployment of kubeadm is currently not supported. You must manually patch the kube-system/coredns [ConfigMap](#) and recreate the CoreDNS [Pods](#) after that. Alternatively, you can skip the default CoreDNS deployment and deploy your own variant. For more details on that see [Using init phases with kubeadm](#).

### Note:

To reconfigure a cluster that has already been created see [Reconfiguring a kubeadm cluster](#).

## Customizing the control plane with flags in ClusterConfiguration

The kubeadm ClusterConfiguration object exposes a way for users to override the default flags passed to control plane components such as the APIServer, ControllerManager, Scheduler and Etd. The components are defined using the following structures:

- apiServer
- controllerManager
- scheduler
- etcd

These structures contain a common extraArgs field, that consists of key: value pairs. To override a flag for a control plane component:

1. Add the appropriate extraArgs to your configuration.

2. Add flags to the extraArgs field.
3. Run kubeadm init with --config <YOUR CONFIG YAML>.

**Note:**

You can generate a ClusterConfiguration object with default values by running `kubeadm config print init-defaults` and saving the output to a file of your choice.

**Note:**

The ClusterConfiguration object is currently global in kubeadm clusters. This means that any flags that you add, will apply to all instances of the same component on different nodes. To apply individual configuration per component on different nodes you can use [patches](#).

**Note:**

Duplicate flags (keys), or passing the same flag --foo multiple times, is currently not supported. To workaroud that you must use [patches](#).

## APIServer flags

For details, see the [reference documentation for kube-apiserver](#).

Example usage:

```
apiVersion: kubeadm.k8s.io/v1beta3
kind: ClusterConfiguration
kubernetesVersion: v1.16.0
apiServer:
 extraArgs:
 anonymous-auth: "false"
 enable-admission-plugins: AlwaysPullImages,DefaultStorageClass
 audit-log-path: /home/johndoe/audit.log
```

## ControllerManager flags

For details, see the [reference documentation for kube-controller-manager](#).

Example usage:

```
apiVersion: kubeadm.k8s.io/v1beta3
kind: ClusterConfiguration
kubernetesVersion: v1.16.0
controllerManager:
 extraArgs:
 cluster-signing-key-file: /home/johndoe/keys/ca.key
 deployment-controller-sync-period: "50"
```

## Scheduler flags

For details, see the [reference documentation for kube-scheduler](#).

Example usage:

```
apiVersion: kubeadm.k8s.io/v1beta3
kind: ClusterConfiguration
kubernetesVersion: v1.16.0
scheduler:
 extraArgs:
 config: /etc/kubernetes/scheduler-config.yaml
 extraVolumes:
 - name: schedulerconfig
 hostPath: /home/johndoe/schedconfig.yaml
 mountPath: /etc/kubernetes/scheduler-config.yaml
 readOnly: true
 pathType: "File"
```

## Etcd flags

For details, see the [etcd server documentation](#).

Example usage:

```
apiVersion: kubeadm.k8s.io/v1beta3
kind: ClusterConfiguration
etcd:
 local:
 extraArgs:
 election-timeout: 1000
```

## Customizing with patches

FEATURE STATE: Kubernetes v1.22 [beta]

Kubeadm allows you to pass a directory with patch files to `InitConfiguration` and `JoinConfiguration` on individual nodes. These patches can be used as the last customization step before component configuration is written to disk.

You can pass this file to `kubeadm init` with `--config <YOUR CONFIG YAML>`:

```
apiVersion: kubeadm.k8s.io/v1beta3
kind: InitConfiguration
patches:
 directory: /home/user/somedir
```

### Note:

For `kubeadm init` you can pass a file containing both a `ClusterConfiguration` and `InitConfiguration` separated by `---`.

You can pass this file to `kubeadm join` with `--config <YOUR CONFIG YAML>`:

```
apiVersion: kubeadm.k8s.io/v1beta3
kind: JoinConfiguration
```

patches:  
directory: /home/user/somedir

The directory must contain files named `target[suffix][+patchtype].extension`. For example, `kube-apiserver0+merge.yaml` or just `etcd.json`.

- `target` can be one of `kube-apiserver`, `kube-controller-manager`, `kube-scheduler`, `etcd` and `kubeletconfiguration`.
- `suffix` is an optional string that can be used to determine which patches are applied first alpha-numerically.
- `patchtype` can be one of `strategic`, `merge` or `json` and these must match the patching formats [supported by kubectrl](#). The default patchtype is `strategic`.
- `extension` must be either `json` or `yaml`.

#### Note:

If you are using `kubeadm upgrade` to upgrade your `kubeadm` nodes you must again provide the same patches, so that the customization is preserved after upgrade. To do that you can use the `--patches` flag, which must point to the same directory. `kubeadm upgrade` currently does not support a configuration API structure that can be used for the same purpose.

## Customizing the kubelet

To customize the kubelet you can add a [KubeletConfiguration](#) next to the `ClusterConfiguration` or `InitConfiguration` separated by `---` within the same configuration file. This file can then be passed to `kubeadm init` and `kubeadm` will apply the same base `KubeletConfiguration` to all nodes in the cluster.

For applying instance-specific configuration over the base `KubeletConfiguration` you can use the [kubeletconfiguration patch target](#).

Alternatively, you can use kubelet flags as overrides by passing them in the `nodeRegistration.kubeletExtraArgs` field supported by both `InitConfiguration` and `JoinConfiguration`. Some kubelet flags are deprecated, so check their status in the [kubelet reference documentation](#) before using them.

For additional details see [Configuring each kubelet in your cluster using kubeadm](#)

## Customizing kube-proxy

To customize kube-proxy you can pass a `KubeProxyConfiguration` next your `ClusterConfiguration` or `InitConfiguration` to `kubeadm init` separated by `---`.

For more details you can navigate to our [API reference pages](#).

#### Note:

`kubeadm` deploys kube-proxy as a [DaemonSet](#), which means that the `KubeProxyConfiguration` would apply to all instances of kube-proxy in the cluster.

# Options for Highly Available Topology

This page explains the two options for configuring the topology of your highly available (HA) Kubernetes clusters.

You can set up an HA cluster:

- With stacked control plane nodes, where etcd nodes are colocated with control plane nodes
- With external etcd nodes, where etcd runs on separate nodes from the control plane

You should carefully consider the advantages and disadvantages of each topology before setting up an HA cluster.

## Note:

kubeadm bootstraps the etcd cluster statically. Read the etcd [Clustering Guide](#) for more details.

## Stacked etcd topology

A stacked HA cluster is a [topology](#) where the distributed data storage cluster provided by etcd is stacked on top of the cluster formed by the nodes managed by kubeadm that run control plane components.

Each control plane node runs an instance of the kube-apiserver, kube-scheduler, and kube-controller-manager. The kube-apiserver is exposed to worker nodes using a load balancer.

Each control plane node creates a local etcd member and this etcd member communicates only with the kube-apiserver of this node. The same applies to the local kube-controller-manager and kube-scheduler instances.

This topology couples the control planes and etcd members on the same nodes. It is simpler to set up than a cluster with external etcd nodes, and simpler to manage for replication.

However, a stacked cluster runs the risk of failed coupling. If one node goes down, both an etcd member and a control plane instance are lost, and redundancy is compromised. You can mitigate this risk by adding more control plane nodes.

You should therefore run a minimum of three stacked control plane nodes for an HA cluster.

This is the default topology in kubeadm. A local etcd member is created automatically on control plane nodes when using `kubeadm init` and `kubeadm join --control-plane`.

Stacked etcd topology

## External etcd topology

An HA cluster with external etcd is a [topology](#) where the distributed data storage cluster provided by etcd is external to the cluster formed by the nodes that run control plane components.

Like the stacked etcd topology, each control plane node in an external etcd topology runs an instance of the kube-apiserver, kube-scheduler, and kube-controller-manager. And the kube-apiserver is exposed to worker nodes using a load balancer. However, etcd members run on separate hosts, and each etcd host communicates with the kube-apiserver of each control plane node.

This topology decouples the control plane and etcd member. It therefore provides an HA setup where losing a control plane instance or an etcd member has less impact and does not affect the cluster redundancy as much as the stacked HA topology.

However, this topology requires twice the number of hosts as the stacked HA topology. A minimum of three hosts for control plane nodes and three hosts for etcd nodes are required for an HA cluster with this topology.

External etcd topology

## What's next

- [Set up a highly available cluster with kubeadm](#)

# Creating Highly Available Clusters with kubeadm

This page explains two different approaches to setting up a highly available Kubernetes cluster using kubeadm:

- With stacked control plane nodes. This approach requires less infrastructure. The etcd members and control plane nodes are co-located.
- With an external etcd cluster. This approach requires more infrastructure. The control plane nodes and etcd members are separated.

Before proceeding, you should carefully consider which approach best meets the needs of your applications and environment. [Options for Highly Available topology](#) outlines the advantages and disadvantages of each.

If you encounter issues with setting up the HA cluster, please report these in the kubeadm [issue tracker](#).

See also the [upgrade documentation](#).

### Caution:

This page does not address running your cluster on a cloud provider. In a cloud environment, neither approach documented here works with Service objects of type LoadBalancer, or with dynamic PersistentVolumes.

# Before you begin

The prerequisites depend on which topology you have selected for your cluster's control plane:

- [Stacked etcd](#)
- [External etcd](#)

You need:

- Three or more machines that meet [kubeadm's minimum requirements](#) for the control-plane nodes. Having an odd number of control plane nodes can help with leader selection in the case of machine or zone failure.
  - including a [container runtime](#), already set up and working
- Three or more machines that meet [kubeadm's minimum requirements](#) for the workers
  - including a container runtime, already set up and working
- Full network connectivity between all machines in the cluster (public or private network)
- Superuser privileges on all machines using sudo
  - You can use a different tool; this guide uses sudo in the examples.
- SSH access from one device to all nodes in the system
- kubeadm and kubelet already installed on all machines.

See [Stacked etcd topology](#) for context.

You need:

- Three or more machines that meet [kubeadm's minimum requirements](#) for the control-plane nodes. Having an odd number of control plane nodes can help with leader selection in the case of machine or zone failure.
  - including a [container runtime](#), already set up and working
- Three or more machines that meet [kubeadm's minimum requirements](#) for the workers
  - including a container runtime, already set up and working
- Full network connectivity between all machines in the cluster (public or private network)
- Superuser privileges on all machines using sudo
  - You can use a different tool; this guide uses sudo in the examples.
- SSH access from one device to all nodes in the system
- kubeadm and kubelet already installed on all machines.

And you also need:

- Three or more additional machines, that will become etcd cluster members. Having an odd number of members in the etcd cluster is a requirement for achieving optimal voting quorum.
  - These machines again need to have kubeadm and kubelet installed.
  - These machines also require a container runtime, that is already set up and working.

See [External etcd topology](#) for context.

## Container images

Each host should have access read and fetch images from the Kubernetes container image registry, registry.k8s.io. If you want to deploy a highly-available cluster where the hosts do not

have access to pull images, this is possible. You must ensure by some other means that the correct container images are already available on the relevant hosts.

## Command line interface

To manage Kubernetes once your cluster is set up, you should [install kubectl](#) on your PC. It is also useful to install the kubectl tool on each control plane node, as this can be helpful for troubleshooting.

## First steps for both methods

### Create load balancer for kube-apiserver

#### Note:

There are many configurations for load balancers. The following example is only one option. Your cluster requirements may need a different configuration.

1. Create a kube-apiserver load balancer with a name that resolves to DNS.
  - In a cloud environment you should place your control plane nodes behind a TCP forwarding load balancer. This load balancer distributes traffic to all healthy control plane nodes in its target list. The health check for an apiserver is a TCP check on the port the kube-apiserver listens on (default value :6443).
  - It is not recommended to use an IP address directly in a cloud environment.
  - The load balancer must be able to communicate with all control plane nodes on the apiserver port. It must also allow incoming traffic on its listening port.
  - Make sure the address of the load balancer always matches the address of kubeadm's ControlPlaneEndpoint.
  - Read the [Options for Software Load Balancing](#) guide for more details.
2. Add the first control plane node to the load balancer, and test the connection:

```
nc -v <LOAD_BALANCER_IP> <PORT>
```

A connection refused error is expected because the API server is not yet running. A timeout, however, means the load balancer cannot communicate with the control plane node. If a timeout occurs, reconfigure the load balancer to communicate with the control plane node.

3. Add the remaining control plane nodes to the load balancer target group.

## Stacked control plane and etcd nodes

### Steps for the first control plane node

1. Initialize the control plane:

```
sudo kubeadm init --control-plane-endpoint "LOAD_BALANCER_DNS:LOAD_BALANCER_PORT" --upload-certs
```

- You can use the `--kubernetes-version` flag to set the Kubernetes version to use. It is recommended that the versions of kubeadm, kubelet, kubectl and Kubernetes match.
- The `--control-plane-endpoint` flag should be set to the address or DNS and port of the load balancer.
- The `--upload-certs` flag is used to upload the certificates that should be shared across all the control-plane instances to the cluster. If instead, you prefer to copy certs across control-plane nodes manually or using automation tools, please remove this flag and refer to [Manual certificate distribution](#) section below.

**Note:**

The kubeadm init flags `--config` and `--certificate-key` cannot be mixed, therefore if you want to use the [kubeadm configuration](#) you must add the `certificateKey` field in the appropriate config locations (under `InitConfiguration` and `JoinConfiguration: controlPlane`).

**Note:**

Some CNI network plugins require additional configuration, for example specifying the pod IP CIDR, while others do not. See the [CNI network documentation](#). To add a pod CIDR pass the flag `--pod-network-cidr`, or if you are using a kubeadm configuration file set the `podSubnet` field under the `networking` object of `ClusterConfiguration`.

The output looks similar to:

...

You can now join any number of control-plane node by running the following command on each as a root:

```
kubeadm join 192.168.0.200:6443 --token 9vr73a.a8uxyaju799qwdjv --discovery-token-ca-cert-hash sha256:7c2e69131a36ae2a042a339b33381c6d0d43887e2de83720eff5359e26aec866 --control-plane --certificate-key f8902e114ef118304e561c3ecd4d0b543adc226b7a07f675f56564185ffe0c07
```

Please note that the `certificate-key` gives access to cluster sensitive data, keep it secret! As a safeguard, uploaded-certs will be deleted in two hours; If necessary, you can use `kubeadm init phase upload-certs` to reload certs afterward.

Then you can join any number of worker nodes by running the following on each as root:

```
kubeadm join 192.168.0.200:6443 --token 9vr73a.a8uxyaju799qwdjv --discovery-token-ca-cert-hash sha256:7c2e69131a36ae2a042a339b33381c6d0d43887e2de83720eff5359e26aec866
```

- Copy this output to a text file. You will need it later to join control plane and worker nodes to the cluster.

When `--upload-certs` is used with `kubeadm init`, the certificates of the primary control plane are encrypted and uploaded in the `kubeadm-certs` Secret.

- To re-upload the certificates and generate a new decryption key, use the following command on a control plane node that is already joined to the cluster:

```
sudo kubeadm init phase upload-certs --upload-certs
```

- You can also specify a custom `--certificate-key` during `init` that can later be used by `join`. To generate such a key you can use the following command:

```
kubeadm certs certificate-key
```

The certificate key is a hex encoded string that is an AES key of size 32 bytes.

**Note:**

The `kubeadm-certs` Secret and the decryption key expire after two hours.

**Caution:**

As stated in the command output, the certificate key gives access to cluster sensitive data, keep it secret!

2. Apply the CNI plugin of your choice: [Follow these instructions](#) to install the CNI provider. Make sure the configuration corresponds to the Pod CIDR specified in the `kubeadm` configuration file (if applicable).

**Note:**

You must pick a network plugin that suits your use case and deploy it before you move on to next step. If you don't do this, you will not be able to launch your cluster properly.

3. Type the following and watch the pods of the control plane components get started:

```
kubectrl get pod -n kube-system -w
```

## Steps for the rest of the control plane nodes

For each additional control plane node you should:

1. Execute the join command that was previously given to you by the `kubeadm init` output on the first node. It should look something like this:

```
sudo kubeadm join 192.168.0.200:6443 --token 9vr73a.a8uxyaju799qwdjv --discovery-
token-ca-cert-hash
sha256:7c2e69131a36ae2a042a339b33381c6d0d43887e2de83720eff5359e26aec866 --control-
plane --certificate-key
f8902e114ef118304e561c3ecd4d0b543adc226b7a07f675f56564185ffe0c07
```

- The `--control-plane` flag tells `kubeadm join` to create a new control plane.
- The `--certificate-key ...` will cause the control plane certificates to be downloaded from the `kubeadm-certs` Secret in the cluster and be decrypted using the given key.

You can join multiple control-plane nodes in parallel.

## External etcd nodes

Setting up a cluster with external etcd nodes is similar to the procedure used for stacked etcd with the exception that you should setup etcd first, and you should pass the etcd information in the kubeadm config file.

### Set up the etcd cluster

1. Follow these [instructions](#) to set up the etcd cluster.
2. Set up SSH as described [here](#).
3. Copy the following files from any etcd node in the cluster to the first control plane node:

```
export CONTROL_PLANE="ubuntu@10.0.0.7"
scp /etc/kubernetes/pki/etcd/ca.crt "${CONTROL_PLANE}":
scp /etc/kubernetes/pki/apiserver-etcd-client.crt "${CONTROL_PLANE}":
scp /etc/kubernetes/pki/apiserver-etcd-client.key "${CONTROL_PLANE}":
```

- Replace the value of CONTROL\_PLANE with the user@host of the first control-plane node.

### Set up the first control plane node

1. Create a file called kubeadm-config.yaml with the following contents:

```

apiVersion: kubeadm.k8s.io/v1beta3
kind: ClusterConfiguration
kubernetesVersion: stable
controlPlaneEndpoint: "LOAD_BALANCER_DNS:LOAD_BALANCER_PORT" # change
this (see below)
etcd:
 external:
 endpoints:
 - https://ETCD_0_IP:2379 # change ETCD_0_IP appropriately
 - https://ETCD_1_IP:2379 # change ETCD_1_IP appropriately
 - https://ETCD_2_IP:2379 # change ETCD_2_IP appropriately
 caFile: /etc/kubernetes/pki/etcd/ca.crt
 certFile: /etc/kubernetes/pki/apiserver-etcd-client.crt
 keyFile: /etc/kubernetes/pki/apiserver-etcd-client.key
```

**Note:**

The difference between stacked etcd and external etcd here is that the external etcd setup requires a configuration file with the etcd endpoints under the external object for etcd. In the case of the stacked etcd topology, this is managed automatically.

- Replace the following variables in the config template with the appropriate values for your cluster:
  - `LOAD_BALANCER_DNS`
  - `LOAD_BALANCER_PORT`
  - `ETCD_0_IP`
  - `ETCD_1_IP`
  - `ETCD_2_IP`

The following steps are similar to the stacked etcd setup:

1. Run `sudo kubeadm init --config kubeadm-config.yaml --upload-certs` on this node.
2. Write the output join commands that are returned to a text file for later use.
3. Apply the CNI plugin of your choice.

**Note:**

You must pick a network plugin that suits your use case and deploy it before you move on to next step. If you don't do this, you will not be able to launch your cluster properly.

## Steps for the rest of the control plane nodes

The steps are the same as for the stacked etcd setup:

- Make sure the first control plane node is fully initialized.
- Join each control plane node with the join command you saved to a text file. It's recommended to join the control plane nodes one at a time.
- Don't forget that the decryption key from `--certificate-key` expires after two hours, by default.

## Common tasks after bootstrapping control plane

### Install workers

Worker nodes can be joined to the cluster with the command you stored previously as the output from the `kubeadm init` command:

```
sudo kubeadm join 192.168.0.200:6443 --token 9vr73a.a8uxyaju799qwdjv --discovery-token-ca-cert-hash sha256:7c2e69131a36ae2a042a339b33381c6d0d43887e2de83720eff5359e26aec866
```

# Manual certificate distribution

If you choose to not use `kubeadm init` with the `--upload-certs` flag this means that you are going to have to manually copy the certificates from the primary control plane node to the joining control plane nodes.

There are many ways to do this. The following example uses `ssh` and `scp`:

SSH is required if you want to control all nodes from a single machine.

1. Enable `ssh-agent` on your main device that has access to all other nodes in the system:

```
eval $(ssh-agent)
```

2. Add your SSH identity to the session:

```
ssh-add ~/.ssh/path_to_private_key
```

3. SSH between nodes to check that the connection is working correctly.

- When you SSH to any node, add the `-A` flag. This flag allows the node that you have logged into via SSH to access the SSH agent on your PC. Consider alternative methods if you do not fully trust the security of your user session on the node.

```
ssh -A 10.0.0.7
```

- When using `sudo` on any node, make sure to preserve the environment so SSH forwarding works:

```
sudo -E -s
```

4. After configuring SSH on all the nodes you should run the following script on the first control plane node after running `kubeadm init`. This script will copy the certificates from the first control plane node to the other control plane nodes:

In the following example, replace `CONTROL_PLANE_IPS` with the IP addresses of the other control plane nodes.

```
USER=ubuntu # customizable
CONTROL_PLANE_IPS="10.0.0.7 10.0.0.8"
for host in ${CONTROL_PLANE_IPS}; do
 scp /etc/kubernetes/pki/ca.crt "${USER}"@$host:
 scp /etc/kubernetes/pki/ca.key "${USER}"@$host:
 scp /etc/kubernetes/pki/sa.key "${USER}"@$host:
 scp /etc/kubernetes/pki/sa.pub "${USER}"@$host:
 scp /etc/kubernetes/pki/front-proxy-ca.crt "${USER}"@$host:
 scp /etc/kubernetes/pki/front-proxy-ca.key "${USER}"@$host:
 scp /etc/kubernetes/pki/etcd/ca.crt "${USER}"@$host:etcd-ca.crt
 # Skip the next line if you are using external etcd
 scp /etc/kubernetes/pki/etcd/ca.key "${USER}"@$host:etcd-ca.key
done
```

### Caution:

Copy only the certificates in the above list. kubeadm will take care of generating the rest of the certificates with the required SANs for the joining control-plane instances. If you copy all the certificates by mistake, the creation of additional nodes could fail due to a lack of required SANs.

5. Then on each joining control plane node you have to run the following script before running kubeadm join. This script will move the previously copied certificates from the home directory to /etc/kubernetes/pki:

```
USER=ubuntu # customizable
mkdir -p /etc/kubernetes/pki/etcd
mv /home/${USER}/ca.crt /etc/kubernetes/pki/
mv /home/${USER}/ca.key /etc/kubernetes/pki/
mv /home/${USER}/sa.pub /etc/kubernetes/pki/
mv /home/${USER}/sa.key /etc/kubernetes/pki/
mv /home/${USER}/front-proxy-ca.crt /etc/kubernetes/pki/
mv /home/${USER}/front-proxy-ca.key /etc/kubernetes/pki/
mv /home/${USER}/etcd-ca.crt /etc/kubernetes/pki/etcd/ca.crt
Skip the next line if you are using external etcd
mv /home/${USER}/etcd-ca.key /etc/kubernetes/pki/etcd/ca.key
```

## Set up a High Availability etcd Cluster with kubeadm

### Note:

While kubeadm is being used as the management tool for external etcd nodes in this guide, please note that kubeadm does not plan to support certificate rotation or upgrades for such nodes. The long-term plan is to empower the tool [etcdadm](#) to manage these aspects.

By default, kubeadm runs a local etcd instance on each control plane node. It is also possible to treat the etcd cluster as external and provision etcd instances on separate hosts. The differences between the two approaches are covered in the [Options for Highly Available topology](#) page.

This task walks through the process of creating a high availability external etcd cluster of three members that can be used by kubeadm during cluster creation.

### Before you begin

- Three hosts that can talk to each other over TCP ports 2379 and 2380. This document assumes these default ports. However, they are configurable through the kubeadm config file.
- Each host must have systemd and a bash compatible shell installed.
- Each host must [have a container runtime, kubelet, and kubeadm installed](#).
- Each host should have access to the Kubernetes container image registry (registry.k8s.io) or list/pull the required etcd image using kubeadm config images list/pull. This guide will set up etcd instances as [static pods](#) managed by a kubelet.

- Some infrastructure to copy files between hosts. For example `ssh` and `scp` can satisfy this requirement.

## Setting up the cluster

The general approach is to generate all certs on one node and only distribute the *necessary* files to the other nodes.

### Note:

kubeadm contains all the necessary cryptographic machinery to generate the certificates described below; no other cryptographic tooling is required for this example.

### Note:

The examples below use IPv4 addresses but you can also configure kubeadm, the kubelet and etcd to use IPv6 addresses. Dual-stack is supported by some Kubernetes options, but not by etcd. For more details on Kubernetes dual-stack support see [Dual-stack support with kubeadm](#).

1. Configure the kubelet to be a service manager for etcd.

### Note:

You must do this on every host where etcd should be running.

Since etcd was created first, you must override the service priority by creating a new unit file that has higher precedence than the kubeadm-provided kubelet unit file.

```
cat << EOF > /etc/systemd/system/kubelet.service.d/kubelet.conf
Replace "systemd" with the cgroup driver of your container runtime. The default value
in the kubelet is "cgroupfs".
Replace the value of "containerRuntimeEndpoint" for a different container runtime if
needed.
#
apiVersion: kubelet.config.k8s.io/v1beta1
kind: KubeletConfiguration
authentication:
 anonymous:
 enabled: false
 webhook:
 enabled: false
authorization:
 mode: AlwaysAllow
cgroupDriver: systemd
address: 127.0.0.1
containerRuntimeEndpoint: unix:///var/run/containerd/containerd.sock
staticPodPath: /etc/kubernetes/manifests
EOF
```

```
cat << EOF > /etc/systemd/system/kubelet.service.d/20-etcd-service-manager.conf
[Service]
ExecStart=
```

```
ExecStart=/usr/bin/kubelet --config=/etc/systemd/system/kubelet.service.d/kubelet.conf
Restart=always
EOF
```

```
systemctl daemon-reload
systemctl restart kubelet
```

Check the kubelet status to ensure it is running.

```
systemctl status kubelet
```

## 2. Create configuration files for kubeadm.

Generate one kubeadm configuration file for each host that will have an etcd member running on it using the following script.

```
Update HOST0, HOST1 and HOST2 with the IPs of your hosts
export HOST0=10.0.0.6
export HOST1=10.0.0.7
export HOST2=10.0.0.8

Update NAME0, NAME1 and NAME2 with the hostnames of your hosts
export NAME0="infra0"
export NAME1="infra1"
export NAME2="infra2"

Create temp directories to store files that will end up on other hosts
mkdir -p /tmp/${HOST0}/ /tmp/${HOST1}/ /tmp/${HOST2}/

HOSTS=(${HOST0} ${HOST1} ${HOST2})
NAMES=(${NAME0} ${NAME1} ${NAME2})

for i in "${!HOSTS[@]}"; do
 HOST=${HOSTS[$i]}
 NAME=${NAMES[$i]}
 cat << EOF > /tmp/${HOST}/kubeadmcfg.yaml

 apiVersion: "kubeadm.k8s.io/v1beta3"
 kind: InitConfiguration
 nodeRegistration:
 name: ${NAME}
 localAPIEndpoint:
 advertiseAddress: ${HOST}

 apiVersion: "kubeadm.k8s.io/v1beta3"
 kind: ClusterConfiguration
 etcd:
 local:
 serverCertSANs:
 - "${HOST}"
 peerCertSANs:
 - "${HOST}"
 extraArgs:
```

```

 initial-cluster: ${NAMES[0]}=https://${HOSTS[0]}:2380,${NAMES[1]}=https://$
 {HOSTS[1]}:2380,${NAMES[2]}=https://${HOSTS[2]}:2380
 initial-cluster-state: new
 name: ${NAME}
 listen-peer-urls: https://${HOST}:2380
 listen-client-urls: https://${HOST}:2379
 advertise-client-urls: https://${HOST}:2379
 initial-advertise-peer-urls: https://${HOST}:2380
EOF
done

```

### 3. Generate the certificate authority.

If you already have a CA then the only action that is copying the CA's crt and key file to /etc/kubernetes/pki/etcd/ca.crt and /etc/kubernetes/pki/etcd/ca.key. After those files have been copied, proceed to the next step, "Create certificates for each member".

If you do not already have a CA then run this command on \$HOST0 (where you generated the configuration files for kubeadm).

```
kubeadm init phase certs etcd-ca
```

This creates two files:

- /etc/kubernetes/pki/etcd/ca.crt
- /etc/kubernetes/pki/etcd/ca.key

### 4. Create certificates for each member.

```

kubeadm init phase certs etcd-server --config=/tmp/${HOST2}/kubeadmcfg.yaml
kubeadm init phase certs etcd-peer --config=/tmp/${HOST2}/kubeadmcfg.yaml
kubeadm init phase certs etcd-healthcheck-client --config=/tmp/${HOST2}/
kubeadmcfg.yaml
kubeadm init phase certs apiserver-etcd-client --config=/tmp/${HOST2}/kubeadmcfg.yaml
cp -R /etc/kubernetes/pki /tmp/${HOST2}/
cleanup non-reusable certificates
find /etc/kubernetes/pki -not -name ca.crt -not -name ca.key -type f -delete

kubeadm init phase certs etcd-server --config=/tmp/${HOST1}/kubeadmcfg.yaml
kubeadm init phase certs etcd-peer --config=/tmp/${HOST1}/kubeadmcfg.yaml
kubeadm init phase certs etcd-healthcheck-client --config=/tmp/${HOST1}/
kubeadmcfg.yaml
kubeadm init phase certs apiserver-etcd-client --config=/tmp/${HOST1}/kubeadmcfg.yaml
cp -R /etc/kubernetes/pki /tmp/${HOST1}/
find /etc/kubernetes/pki -not -name ca.crt -not -name ca.key -type f -delete

kubeadm init phase certs etcd-server --config=/tmp/${HOST0}/kubeadmcfg.yaml
kubeadm init phase certs etcd-peer --config=/tmp/${HOST0}/kubeadmcfg.yaml
kubeadm init phase certs etcd-healthcheck-client --config=/tmp/${HOST0}/
kubeadmcfg.yaml
kubeadm init phase certs apiserver-etcd-client --config=/tmp/${HOST0}/kubeadmcfg.yaml
No need to move the certs because they are for HOST0

clean up certs that should not be copied off this host

```

```
find /tmp/${HOST2} -name ca.key -type f -delete
find /tmp/${HOST1} -name ca.key -type f -delete
```

#### 5. Copy certificates and kubeadm configs.

The certificates have been generated and now they must be moved to their respective hosts.

```
USER=ubuntu
HOST=${HOST1}
scp -r /tmp/${HOST}/* ${USER}@${HOST}:
ssh ${USER}@${HOST}
USER@HOST $ sudo -Es
root@HOST $ chown -R root:root pki
root@HOST $ mv pki /etc/kubernetes/
```

#### 6. Ensure all expected files exist.

The complete list of required files on \$HOST0 is:

```
/tmp/${HOST0}
└─ kubeadmcfg.yaml

/etc/kubernetes/pki
├─ apiserver-etcd-client.crt
├─ apiserver-etcd-client.key
├─ etcd
│ ├─ ca.crt
│ ├─ ca.key
│ ├─ healthcheck-client.crt
│ ├─ healthcheck-client.key
│ ├─ peer.crt
│ ├─ peer.key
│ ├─ server.crt
│ └─ server.key
```

On \$HOST1:

```
$HOME
└─ kubeadmcfg.yaml

/etc/kubernetes/pki
├─ apiserver-etcd-client.crt
├─ apiserver-etcd-client.key
├─ etcd
│ ├─ ca.crt
│ ├─ healthcheck-client.crt
│ ├─ healthcheck-client.key
│ ├─ peer.crt
│ ├─ peer.key
│ ├─ server.crt
│ └─ server.key
```

On \$HOST2:

```

$HOME
└── kubeadmcfg.yaml

/etc/kubernetes/pki
├── apiserver-etcd-client.crt
├── apiserver-etcd-client.key
└── etcd
 ├── ca.crt
 ├── healthcheck-client.crt
 ├── healthcheck-client.key
 ├── peer.crt
 ├── peer.key
 ├── server.crt
 └── server.key

```

## 7. Create the static pod manifests.

Now that the certificates and configs are in place it's time to create the manifests. On each host run the kubeadm command to generate a static manifest for etcd.

```

root@HOST0 $ kubeadm init phase etcd local --config=/tmp/${HOST0}/kubeadmcfg.yaml
root@HOST1 $ kubeadm init phase etcd local --config=$HOME/kubeadmcfg.yaml
root@HOST2 $ kubeadm init phase etcd local --config=$HOME/kubeadmcfg.yaml

```

## 8. Optional: Check the cluster health.

If etcdctl isn't available, you can run this tool inside a container image. You would do that directly with your container runtime using a tool such as crictl run and not through Kubernetes

```

ETCDCTL_API=3 etcdctl \
--cert /etc/kubernetes/pki/etcd/peer.crt \
--key /etc/kubernetes/pki/etcd/peer.key \
--cacert /etc/kubernetes/pki/etcd/ca.crt \
--endpoints https://${HOST0}:2379 endpoint health
...
https://[HOST0 IP]:2379 is healthy: successfully committed proposal: took = 16.283339ms
https://[HOST1 IP]:2379 is healthy: successfully committed proposal: took = 19.44402ms
https://[HOST2 IP]:2379 is healthy: successfully committed proposal: took = 35.926451ms

```

- Set \${HOST0} to the IP address of the host you are testing.

## What's next

Once you have an etcd cluster with 3 working members, you can continue setting up a highly available control plane using the [external etcd method with kubeadm](#).

# Configuring each kubelet in your cluster using kubeadm

**Note:** Dockershim has been removed from the Kubernetes project as of release 1.24. Read the [Dockershim Removal FAQ](#) for further details.

FEATURE STATE: Kubernetes v1.11 [stable]

The lifecycle of the kubeadm CLI tool is decoupled from the [kubelet](#), which is a daemon that runs on each node within the Kubernetes cluster. The kubeadm CLI tool is executed by the user when Kubernetes is initialized or upgraded, whereas the kubelet is always running in the background.

Since the kubelet is a daemon, it needs to be maintained by some kind of an init system or service manager. When the kubelet is installed using DEBs or RPMs, systemd is configured to manage the kubelet. You can use a different service manager instead, but you need to configure it manually.

Some kubelet configuration details need to be the same across all kubelets involved in the cluster, while other configuration aspects need to be set on a per-kubelet basis to accommodate the different characteristics of a given machine (such as OS, storage, and networking). You can manage the configuration of your kubelets manually, but kubeadm now provides a KubeletConfiguration API type for [managing your kubelet configurations centrally](#).

## Kubelet configuration patterns

The following sections describe patterns to kubelet configuration that are simplified by using kubeadm, rather than managing the kubelet configuration for each Node manually.

### Propagating cluster-level configuration to each kubelet

You can provide the kubelet with default values to be used by kubeadm init and kubeadm join commands. Interesting examples include using a different container runtime or setting the default subnet used by services.

If you want your services to use the subnet 10.96.0.0/12 as the default for services, you can pass the --service-cidr parameter to kubeadm:

```
kubeadm init --service-cidr 10.96.0.0/12
```

Virtual IPs for services are now allocated from this subnet. You also need to set the DNS address used by the kubelet, using the --cluster-dns flag. This setting needs to be the same for every kubelet on every manager and Node in the cluster. The kubelet provides a versioned, structured API object that can configure most parameters in the kubelet and push out this configuration to each running kubelet in the cluster. This object is called [KubeletConfiguration](#). The KubeletConfiguration allows the user to specify flags such as the cluster DNS IP addresses expressed as a list of values to a camelCased key, illustrated by the following example:

```
apiVersion: kubelet.config.k8s.io/v1beta1
kind: KubeletConfiguration
clusterDNS:
- 10.96.0.10
```

For more details on the KubeletConfiguration have a look at [this section](#).

## Providing instance-specific configuration details

Some hosts require specific kubelet configurations due to differences in hardware, operating system, networking, or other host-specific parameters. The following list provides a few examples.

- The path to the DNS resolution file, as specified by the `--resolv-conf` kubelet configuration flag, may differ among operating systems, or depending on whether you are using `systemd-resolved`. If this path is wrong, DNS resolution will fail on the Node whose kubelet is configured incorrectly.
- The Node API object `.metadata.name` is set to the machine's hostname by default, unless you are using a cloud provider. You can use the `--hostname-override` flag to override the default behavior if you need to specify a Node name different from the machine's hostname.
- Currently, the kubelet cannot automatically detect the cgroup driver used by the container runtime, but the value of `--cgroup-driver` must match the cgroup driver used by the container runtime to ensure the health of the kubelet.
- To specify the container runtime you must set its endpoint with the `--container-runtime-endpoint=<path>` flag.

The recommended way of applying such instance-specific configuration is by using [KubeletConfiguration patches](#).

## Configure kubelets using kubeadm

It is possible to configure the kubelet that kubeadm will start if a custom [KubeletConfiguration](#) API object is passed with a configuration file like so `kubeadm ... --config some-config-file.yaml`.

By calling `kubeadm config print init-defaults --component-configs KubeletConfiguration` you can see all the default values for this structure.

It is also possible to apply instance-specific patches over the base KubeletConfiguration. Have a look at [Customizing the kubelet](#) for more details.

## Workflow when using kubeadm init

When you call `kubeadm init`, the kubelet configuration is marshalled to disk at `/var/lib/kubelet/config.yaml`, and also uploaded to a `kubelet-config` ConfigMap in the `kube-system` namespace of the cluster. A kubelet configuration file is also written to `/etc/kubernetes/kubelet.conf` with the baseline cluster-wide configuration for all kubelets in the cluster. This configuration file points to the client certificates that allow the kubelet to communicate with the API server. This addresses the need to [propagate cluster-level configuration to each kubelet](#).

To address the second pattern of [providing instance-specific configuration details](#), kubeadm writes an environment file to `/var/lib/kubelet/kubeadm-flags.env`, which contains a list of flags to pass to the kubelet when it starts. The flags are presented in the file like this:

```
KUBELET_KUBEADM_ARGS="--flag1=value1 --flag2=value2 ..."
```

In addition to the flags used when starting the kubelet, the file also contains dynamic parameters such as the cgroup driver and whether to use a different container runtime socket (`--cri-socket`).

After marshalling these two files to disk, kubeadm attempts to run the following two commands, if you are using systemd:

```
systemctl daemon-reload && systemctl restart kubelet
```

If the reload and restart are successful, the normal kubeadm init workflow continues.

## Workflow when using kubeadm join

When you run `kubeadm join`, kubeadm uses the Bootstrap Token credential to perform a TLS bootstrap, which fetches the credential needed to download the kubelet-config ConfigMap and writes it to `/var/lib/kubelet/config.yaml`. The dynamic environment file is generated in exactly the same way as `kubeadm init`.

Next, kubeadm runs the following two commands to load the new configuration into the kubelet:

```
systemctl daemon-reload && systemctl restart kubelet
```

After the kubelet loads the new configuration, kubeadm writes the `/etc/kubernetes/bootstrap-kubelet.conf` KubeConfig file, which contains a CA certificate and Bootstrap Token. These are used by the kubelet to perform the TLS Bootstrap and obtain a unique credential, which is stored in `/etc/kubernetes/kubelet.conf`.

When the `/etc/kubernetes/kubelet.conf` file is written, the kubelet has finished performing the TLS Bootstrap. Kubeadm deletes the `/etc/kubernetes/bootstrap-kubelet.conf` file after completing the TLS Bootstrap.

## The kubelet drop-in file for systemd

kubeadm ships with configuration for how systemd should run the kubelet. Note that the kubeadm CLI command never touches this drop-in file.

This configuration file installed by the kubeadm [package](#) is written to `/usr/lib/systemd/system/kubelet.service.d/10-kubeadm.conf` and is used by systemd. It augments the basic [kubelet.service](#).

If you want to override that further, you can make a directory `/etc/systemd/system/kubelet.service.d/` (not `/usr/lib/systemd/system/kubelet.service.d/`) and put your own customizations into a file there. For example, you might add a new local file `/etc/systemd/system/kubelet.service.d/local-overrides.conf` to override the unit settings configured by kubeadm.

Here is what you are likely to find in `/usr/lib/systemd/system/kubelet.service.d/10-kubeadm.conf`:

## Note:

The contents below are just an example. If you don't want to use a package manager follow the guide outlined in the ([Without a package manager](#)) section.

```
[Service]
Environment="KUBELET_KUBECONFIG_ARGS=--bootstrap-kubeconfig=/etc/kubernetes/
bootstrap-kubelet.conf --kubeconfig=/etc/kubernetes/kubelet.conf"
Environment="KUBELET_CONFIG_ARGS=--config=/var/lib/kubelet/config.yaml"
This is a file that "kubeadm init" and "kubeadm join" generate at runtime, populating
the KUBELET_KUBEADM_ARGS variable dynamically
EnvironmentFile=-/var/lib/kubelet/kubeadm-flags.env
This is a file that the user can use for overrides of the kubelet args as a last resort. Preferably,
the user should use the .NodeRegistration.KubeletExtraArgs object in the configuration files
instead.
KUBELET_EXTRA_ARGS should be sourced from this file.
EnvironmentFile=-/etc/default/kubelet
ExecStart=
ExecStart=/usr/bin/kubelet $KUBELET_KUBECONFIG_ARGS $KUBELET_CONFIG_ARGS
$KUBELET_KUBEADM_ARGS $KUBELET_EXTRA_ARGS
```

This file specifies the default locations for all of the files managed by kubeadm for the kubelet.

- The KubeConfig file to use for the TLS Bootstrap is `/etc/kubernetes/bootstrap-kubelet.conf`, but it is only used if `/etc/kubernetes/kubelet.conf` does not exist.
- The KubeConfig file with the unique kubelet identity is `/etc/kubernetes/kubelet.conf`.
- The file containing the kubelet's ComponentConfig is `/var/lib/kubelet/config.yaml`.
- The dynamic environment file that contains `KUBELET_KUBEADM_ARGS` is sourced from `/var/lib/kubelet/kubeadm-flags.env`.
- The file that can contain user-specified flag overrides with `KUBELET_EXTRA_ARGS` is sourced from `/etc/default/kubelet` (for DEBs), or `/etc/sysconfig/kubelet` (for RPMs). `KUBELET_EXTRA_ARGS` is last in the flag chain and has the highest priority in the event of conflicting settings.

## Kubernetes binaries and package contents

The DEB and RPM packages shipped with the Kubernetes releases are:

| Package name   | Description                                                                                                       |
|----------------|-------------------------------------------------------------------------------------------------------------------|
| kubeadm        | Installs the <code>/usr/bin/kubeadm</code> CLI tool and the <a href="#">kubelet drop-in file</a> for the kubelet. |
| kubelet        | Installs the <code>/usr/bin/kubelet</code> binary.                                                                |
| kubectl        | Installs the <code>/usr/bin/kubectl</code> binary.                                                                |
| cri-tools      | Installs the <code>/usr/bin/crictl</code> binary from the <a href="#">cri-tools git repository</a> .              |
| kubernetes-cni | Installs the <code>/opt/cni/bin</code> binaries from the <a href="#">plugins git repository</a> .                 |

## Dual-stack support with kubeadm

FEATURE STATE: Kubernetes v1.23 [stable]

Your Kubernetes cluster includes [dual-stack](#) networking, which means that cluster networking lets you use either address family. In a cluster, the control plane can assign both an IPv4 address and an IPv6 address to a single [Pod](#) or a [Service](#).

## Before you begin

You need to have installed the [kubeadm](#) tool, following the steps from [Installing kubeadm](#).

For each server that you want to use as a [node](#), make sure it allows IPv6 forwarding. On Linux, you can set this by running `run systemctl -w net.ipv6.conf.all.forwarding=1` as the root user on each server.

You need to have an IPv4 and an IPv6 address range to use. Cluster operators typically use private address ranges for IPv4. For IPv6, a cluster operator typically chooses a global unicast address block from within `2000::/3`, using a range that is assigned to the operator. You don't have to route the cluster's IP address ranges to the public internet.

The size of the IP address allocations should be suitable for the number of Pods and Services that you are planning to run.

### Note:

If you are upgrading an existing cluster with the `kubeadm upgrade` command, `kubeadm` does not support making modifications to the pod IP address range ("cluster CIDR") nor to the cluster's Service address range ("Service CIDR").

## Create a dual-stack cluster

To create a dual-stack cluster with `kubeadm init` you can pass command line arguments similar to the following example:

```
These address ranges are examples
kubeadm init --pod-network-cidr=10.244.0.0/16,2001:db8:42:0::/56 --service-cidr=10.96.0.0/16,2001:db8:42:1::/112
```

To make things clearer, here is an example `kubeadm` [configuration file](#) `kubeadm-config.yaml` for the primary dual-stack control plane node.

```

apiVersion: kubeadm.k8s.io/v1beta3
kind: ClusterConfiguration
networking:
 podSubnet: 10.244.0.0/16,2001:db8:42:0::/56
 serviceSubnet: 10.96.0.0/16,2001:db8:42:1::/112

apiVersion: kubeadm.k8s.io/v1beta3
kind: InitConfiguration
localAPIEndpoint:
 advertiseAddress: "10.100.0.1"
 bindPort: 6443
nodeRegistration:
```

```
kubeletExtraArgs:
 node-ip: 10.100.0.2,fd00:1:2:3::2
```

advertiseAddress in InitConfiguration specifies the IP address that the API Server will advertise it is listening on. The value of advertiseAddress equals the `--apiserver-advertise-address` flag of `kubeadm init`.

Run `kubeadm` to initiate the dual-stack control plane node:

```
kubeadm init --config=kubeadm-config.yaml
```

The kube-controller-manager flags `--node-cidr-mask-size-ipv4|--node-cidr-mask-size-ipv6` are set with default values. See [configure IPv4/IPv6 dual stack](#).

### Note:

The `--apiserver-advertise-address` flag does not support dual-stack.

## Join a node to dual-stack cluster

Before joining a node, make sure that the node has IPv6 routable network interface and allows IPv6 forwarding.

Here is an example `kubeadm` [configuration file](#) `kubeadm-config.yaml` for joining a worker node to the cluster.

```
apiVersion: kubeadm.k8s.io/v1beta3
kind: JoinConfiguration
discovery:
 bootstrapToken:
 apiServerEndpoint: 10.100.0.1:6443
 token: "clvldh.vjjwg16ucnhp94qr"
 caCertHashes:
 - "sha256:a4863cde706cfc580a439f842cc65d5ef112b7b2be31628513a9881cf0d9fe0e"
 # change auth info above to match the actual token and CA certificate hash for your cluster
nodeRegistration:
 kubeletExtraArgs:
 node-ip: 10.100.0.3,fd00:1:2:3::3
```

Also, here is an example `kubeadm` [configuration file](#) `kubeadm-config.yaml` for joining another control plane node to the cluster.

```
apiVersion: kubeadm.k8s.io/v1beta3
kind: JoinConfiguration
controlPlane:
 localAPIEndpoint:
 advertiseAddress: "10.100.0.2"
 bindPort: 6443
discovery:
 bootstrapToken:
 apiServerEndpoint: 10.100.0.1:6443
 token: "clvldh.vjjwg16ucnhp94qr"
 caCertHashes:
```

```
- "sha256:a4863cde706cfc580a439f842cc65d5ef112b7b2be31628513a9881cf0d9fe0e"
change auth info above to match the actual token and CA certificate hash for your cluster
nodeRegistration:
 kubeletExtraArgs:
 node-ip: 10.100.0.4,fd00:1:2:3::4
```

advertiseAddress in JoinConfiguration.controlPlane specifies the IP address that the API Server will advertise it is listening on. The value of advertiseAddress equals the --apiserver-advertise-address flag of kubeadm join.

```
kubeadm join --config=kubeadm-config.yaml
```

## Create a single-stack cluster

### Note:

Dual-stack support doesn't mean that you need to use dual-stack addressing. You can deploy a single-stack cluster that has the dual-stack networking feature enabled.

To make things more clear, here is an example kubeadm [configuration file](#) kubeadm-config.yaml for the single-stack control plane node.

```
apiVersion: kubeadm.k8s.io/v1beta3
kind: ClusterConfiguration
networking:
 podSubnet: 10.244.0.0/16
 serviceSubnet: 10.96.0.0/16
```

## What's next

- [Validate IPv4/IPv6 dual-stack](#) networking
- Read about [Dual-stack](#) cluster networking
- Learn more about the kubeadm [configuration format](#)

[Enforcing Pod Security Standards](#)

# Considerations for large clusters

A cluster is a set of [nodes](#) (physical or virtual machines) running Kubernetes agents, managed by the [control plane](#). Kubernetes v1.30 supports clusters with up to 5,000 nodes. More specifically, Kubernetes is designed to accommodate configurations that meet *all* of the following criteria:

- No more than 110 pods per node
- No more than 5,000 nodes
- No more than 150,000 total pods
- No more than 300,000 total containers

You can scale your cluster by adding or removing nodes. The way you do this depends on how your cluster is deployed.

## Cloud provider resource quotas

To avoid running into cloud provider quota issues, when creating a cluster with many nodes, consider:

- Requesting a quota increase for cloud resources such as:
  - Computer instances
  - CPUs
  - Storage volumes
  - In-use IP addresses
  - Packet filtering rule sets
  - Number of load balancers
  - Network subnets
  - Log streams
- Gating the cluster scaling actions to bring up new nodes in batches, with a pause between batches, because some cloud providers rate limit the creation of new instances.

## Control plane components

For a large cluster, you need a control plane with sufficient compute and other resources.

Typically you would run one or two control plane instances per failure zone, scaling those instances vertically first and then scaling horizontally after reaching the point of falling returns to (vertical) scale.

You should run at least one instance per failure zone to provide fault-tolerance. Kubernetes nodes do not automatically steer traffic towards control-plane endpoints that are in the same failure zone; however, your cloud provider might have its own mechanisms to do this.

For example, using a managed load balancer, you configure the load balancer to send traffic that originates from the kubelet and Pods in failure zone *A*, and direct that traffic only to the control plane hosts that are also in zone *A*. If a single control-plane host or endpoint failure zone *A* goes offline, that means that all the control-plane traffic for nodes in zone *A* is now being sent

between zones. Running multiple control plane hosts in each zone makes that outcome less likely.

## etcd storage

To improve performance of large clusters, you can store Event objects in a separate dedicated etcd instance.

When creating a cluster, you can (using custom tooling):

- start and configure additional etcd instance
- configure the [API server](#) to use it for storing events

See [Operating etcd clusters for Kubernetes](#) and [Set up a High Availability etcd cluster with kubeadm](#) for details on configuring and managing etcd for a large cluster.

## Addon resources

Kubernetes [resource limits](#) help to minimize the impact of memory leaks and other ways that pods and containers can impact on other components. These resource limits apply to [addon](#) resources just as they apply to application workloads.

For example, you can set CPU and memory limits for a logging component:

```
...
containers:
- name: fluentd-cloud-logging
 image: fluent/fluentd-kubernetes-daemonset:v1
 resources:
 limits:
 cpu: 100m
 memory: 200Mi
```

Addons' default limits are typically based on data collected from experience running each addon on small or medium Kubernetes clusters. When running on large clusters, addons often consume more of some resources than their default limits. If a large cluster is deployed without adjusting these values, the addon(s) may continuously get killed because they keep hitting the memory limit. Alternatively, the addon may run but with poor performance due to CPU time slice restrictions.

To avoid running into cluster addon resource issues, when creating a cluster with many nodes, consider the following:

- Some addons scale vertically - there is one replica of the addon for the cluster or serving a whole failure zone. For these addons, increase requests and limits as you scale out your cluster.
- Many addons scale horizontally - you add capacity by running more pods - but with a very large cluster you may also need to raise CPU or memory limits slightly. The VerticalPodAutoscaler can run in *recommender* mode to provide suggested figures for requests and limits.
- Some addons run as one copy per node, controlled by a [DaemonSet](#): for example, a node-level log aggregator. Similar to the case with horizontally-scaled addons, you may also need to raise CPU or memory limits slightly.

## What's next

- VerticalPodAutoscaler is a custom resource that you can deploy into your cluster to help you manage resource requests and limits for pods. Learn more about [Vertical Pod Autoscaler](#) and how you can use it to scale cluster components, including cluster-critical addons.
- Read about [cluster autoscaling](#)
- The [addon resizer](#) helps you in resizing the addons automatically as your cluster's scale changes.

## Running in multiple zones

This page describes running Kubernetes across multiple zones.

### Background

Kubernetes is designed so that a single Kubernetes cluster can run across multiple failure zones, typically where these zones fit within a logical grouping called a *region*. Major cloud providers define a region as a set of failure zones (also called *availability zones*) that provide a consistent set of features: within a region, each zone offers the same APIs and services.

Typical cloud architectures aim to minimize the chance that a failure in one zone also impairs services in another zone.

### Control plane behavior

All [control plane components](#) support running as a pool of interchangeable resources, replicated per component.

When you deploy a cluster control plane, place replicas of control plane components across multiple failure zones. If availability is an important concern, select at least three failure zones and replicate each individual control plane component (API server, scheduler, etcd, cluster controller manager) across at least three failure zones. If you are running a cloud controller manager then you should also replicate this across all the failure zones you selected.

#### Note:

Kubernetes does not provide cross-zone resilience for the API server endpoints. You can use various techniques to improve availability for the cluster API server, including DNS round-robin, SRV records, or a third-party load balancing solution with health checking.

### Node behavior

Kubernetes automatically spreads the Pods for workload resources (such as [Deployment](#) or [StatefulSet](#)) across different nodes in a cluster. This spreading helps reduce the impact of failures.

When nodes start up, the kubelet on each node automatically adds [labels](#) to the Node object that represents that specific kubelet in the Kubernetes API. These labels can include [zone information](#).

If your cluster spans multiple zones or regions, you can use node labels in conjunction with [Pod topology spread constraints](#) to control how Pods are spread across your cluster among fault domains: regions, zones, and even specific nodes. These hints enable the [scheduler](#) to place Pods for better expected availability, reducing the risk that a correlated failure affects your whole workload.

For example, you can set a constraint to make sure that the 3 replicas of a StatefulSet are all running in different zones to each other, whenever that is feasible. You can define this declaratively without explicitly defining which availability zones are in use for each workload.

## Distributing nodes across zones

Kubernetes' core does not create nodes for you; you need to do that yourself, or use a tool such as the [Cluster API](#) to manage nodes on your behalf.

Using tools such as the Cluster API you can define sets of machines to run as worker nodes for your cluster across multiple failure domains, and rules to automatically heal the cluster in case of whole-zone service disruption.

## Manual zone assignment for Pods

You can apply [node selector constraints](#) to Pods that you create, as well as to Pod templates in workload resources such as Deployment, StatefulSet, or Job.

## Storage access for zones

When persistent volumes are created, Kubernetes automatically adds zone labels to any PersistentVolumes that are linked to a specific zone. The [scheduler](#) then ensures, through its NoVolumeZoneConflict predicate, that pods which claim a given PersistentVolume are only placed into the same zone as that volume.

Please note that the method of adding zone labels can depend on your cloud provider and the storage provisioner you're using. Always refer to the specific documentation for your environment to ensure correct configuration.

You can specify a [StorageClass](#) for PersistentVolumeClaims that specifies the failure domains (zones) that the storage in that class may use. To learn about configuring a StorageClass that is aware of failure domains or zones, see [Allowed topologies](#).

## Networking

By itself, Kubernetes does not include zone-aware networking. You can use a [network plugin](#) to configure cluster networking, and that network solution might have zone-specific elements. For example, if your cloud provider supports Services with type=LoadBalancer, the load balancer might only send traffic to Pods running in the same zone as the load balancer element processing a given connection. Check your cloud provider's documentation for details.

For custom or on-premises deployments, similar considerations apply. [Service](#) and [Ingress](#) behavior, including handling of different failure zones, does vary depending on exactly how your cluster is set up.

## Fault recovery

When you set up your cluster, you might also need to consider whether and how your setup can restore service if all the failure zones in a region go off-line at the same time. For example, do you rely on there being at least one node able to run Pods in a zone?

Make sure that any cluster-critical repair work does not rely on there being at least one healthy node in your cluster. For example: if all nodes are unhealthy, you might need to run a repair Job with a special [toleration](#) so that the repair can complete enough to bring at least one node into service.

Kubernetes doesn't come with an answer for this challenge; however, it's something to consider.

## What's next

To learn how the scheduler places Pods in a cluster, honoring the configured constraints, visit [Scheduling and Eviction](#).

# Validate node setup

## Node Conformance Test

*Node conformance test* is a containerized test framework that provides a system verification and functionality test for a node. The test validates whether the node meets the minimum requirements for Kubernetes; a node that passes the test is qualified to join a Kubernetes cluster.

## Node Prerequisite

To run node conformance test, a node must satisfy the same prerequisites as a standard Kubernetes node. At a minimum, the node should have the following daemons installed:

- CRI-compatible container runtimes such as Docker, Containerd and CRI-O
- Kubelet

## Running Node Conformance Test

To run the node conformance test, perform the following steps:

1. Work out the value of the `--kubeconfig` option for the kubelet; for example: `--kubeconfig=/var/lib/kubelet/config.yaml`. Because the test framework starts a local

control plane to test the kubelet, use `http://localhost:8080` as the URL of the API server. There are some other kubelet command line parameters you may want to use:

- `--cloud-provider`: If you are using `--cloud-provider=gce`, you should remove the flag to run the test.

1. Run the node conformance test with command:

```
$CONFIG_DIR is the pod manifest path of your Kubelet.
$LOG_DIR is the test output path.
sudo docker run -it --rm --privileged --net=host \
-v /:/rootfs -v $CONFIG_DIR:$CONFIG_DIR -v $LOG_DIR:/var/result \
registry.k8s.io/node-test:0.2
```

## Running Node Conformance Test for Other Architectures

Kubernetes also provides node conformance test docker images for other architectures:

| Arch  | Image           |
|-------|-----------------|
| amd64 | node-test-amd64 |
| arm   | node-test-arm   |
| arm64 | node-test-arm64 |

## Running Selected Test

To run specific tests, overwrite the environment variable `FOCUS` with the regular expression of tests you want to run.

```
sudo docker run -it --rm --privileged --net=host \
-v /:/rootfs:ro -v $CONFIG_DIR:$CONFIG_DIR -v $LOG_DIR:/var/result \
-e FOCUS=MirrorPod \ # Only run MirrorPod test
registry.k8s.io/node-test:0.2
```

To skip specific tests, overwrite the environment variable `SKIP` with the regular expression of tests you want to skip.

```
sudo docker run -it --rm --privileged --net=host \
-v /:/rootfs:ro -v $CONFIG_DIR:$CONFIG_DIR -v $LOG_DIR:/var/result \
-e SKIP=MirrorPod \ # Run all conformance tests but skip MirrorPod test
registry.k8s.io/node-test:0.2
```

Node conformance test is a containerized version of [node e2e test](#). By default, it runs all conformance tests.

Theoretically, you can run any node e2e test if you configure the container and mount required volumes properly. But **it is strongly recommended to only run conformance test**, because it requires much more complex configuration to run non-conformance test.

## Caveats

- The test leaves some docker images on the node, including the node conformance test image and images of containers used in the functionality test.
- The test leaves dead containers on the node. These containers are created during the functionality test.

# Enforcing Pod Security Standards

This page provides an overview of best practices when it comes to enforcing [Pod Security Standards](#).

## Using the built-in Pod Security Admission Controller

FEATURE STATE: Kubernetes v1.25 [stable]

The [Pod Security Admission Controller](#) intends to replace the deprecated PodSecurityPolicies.

### Configure all cluster namespaces

Namespaces that lack any configuration at all should be considered significant gaps in your cluster security model. We recommend taking the time to analyze the types of workloads occurring in each namespace, and by referencing the Pod Security Standards, decide on an appropriate level for each of them. Unlabeled namespaces should only indicate that they've yet to be evaluated.

In the scenario that all workloads in all namespaces have the same security requirements, we provide an [example](#) that illustrates how the PodSecurity labels can be applied in bulk.

### Embrace the principle of least privilege

In an ideal world, every pod in every namespace would meet the requirements of the restricted policy. However, this is not possible nor practical, as some workloads will require elevated privileges for legitimate reasons.

- Namespaces allowing privileged workloads should establish and enforce appropriate access controls.
- For workloads running in those permissive namespaces, maintain documentation about their unique security requirements. If at all possible, consider how those requirements could be further constrained.

### Adopt a multi-mode strategy

The audit and warn modes of the Pod Security Standards admission controller make it easy to collect important security insights about your pods without breaking existing workloads.

It is good practice to enable these modes for all namespaces, setting them to the *desired* level and version you would eventually like to enforce. The warnings and audit annotations generated in this phase can guide you toward that state. If you expect workload authors to

make changes to fit within the desired level, enable the warn mode. If you expect to use audit logs to monitor/drive changes to fit within the desired level, enable the audit mode.

When you have the enforce mode set to your desired value, these modes can still be useful in a few different ways:

- By setting warn to the same level as enforce, clients will receive warnings when attempting to create Pods (or resources that have Pod templates) that do not pass validation. This will help them update those resources to become compliant.
- In Namespaces that pin enforce to a specific non-latest version, setting the audit and warn modes to the same level as enforce, but to the latest version, gives visibility into settings that were allowed by previous versions but are not allowed per current best practices.

## Third-party alternatives

**Note:** This section links to third party projects that provide functionality required by Kubernetes. The Kubernetes project authors aren't responsible for these projects, which are listed alphabetically. To add a project to this list, read the [content guide](#) before submitting a change. [More information.](#)

Other alternatives for enforcing security profiles are being developed in the Kubernetes ecosystem:

- [Kubewarden](#).
- [Kyverno](#).
- [OPA Gatekeeper](#).

The decision to go with a *built-in* solution (e.g. PodSecurity admission controller) versus a third-party tool is entirely dependent on your own situation. When evaluating any solution, trust of your supply chain is crucial. Ultimately, using *any* of the aforementioned approaches will be better than doing nothing.

## PKI certificates and requirements

Kubernetes requires PKI certificates for authentication over TLS. If you install Kubernetes with [kubeadm](#), the certificates that your cluster requires are automatically generated. You can also generate your own certificates -- for example, to keep your private keys more secure by not storing them on the API server. This page explains the certificates that your cluster requires.

## How certificates are used by your cluster

Kubernetes requires PKI for the following operations:

- Client certificates for the kubelet to authenticate to the API server
- Kubelet [server certificates](#) for the API server to talk to the kubelets
- Server certificate for the API server endpoint
- Client certificates for administrators of the cluster to authenticate to the API server
- Client certificates for the API server to talk to the kubelets
- Client certificate for the API server to talk to etcd
- Client certificate/kubeconfig for the controller manager to talk to the API server

- Client certificate/kubeconfig for the scheduler to talk to the API server.
- Client and server certificates for the [front-proxy](#)

**Note:**

front-proxy certificates are required only if you run kube-proxy to support [an extension API server](#).

etcd also implements mutual TLS to authenticate clients and peers.

## Where certificates are stored

If you install Kubernetes with kubeadm, most certificates are stored in `/etc/kubernetes/pki`. All paths in this documentation are relative to that directory, with the exception of user account certificates which kubeadm places in `/etc/kubernetes`.

## Configure certificates manually

If you don't want kubeadm to generate the required certificates, you can create them using a single root CA or by providing all certificates. See [Certificates](#) for details on creating your own certificate authority. See [Certificate Management with kubeadm](#) for more on managing certificates.

### Single root CA

You can create a single root CA, controlled by an administrator. This root CA can then create multiple intermediate CAs, and delegate all further creation to Kubernetes itself.

Required CAs:

| path                   | Default CN                | description                             |
|------------------------|---------------------------|-----------------------------------------|
| ca.crt,key             | kubernetes-ca             | Kubernetes general CA                   |
| etcd/ca.crt,key        | etcd-ca                   | For all etcd-related functions          |
| front-proxy-ca.crt,key | kubernetes-front-proxy-ca | For the <a href="#">front-end proxy</a> |

On top of the above CAs, it is also necessary to get a public/private key pair for service account management, `sa.key` and `sa.pub`. The following example illustrates the CA key and certificate files shown in the previous table:

```
/etc/kubernetes/pki/ca.crt
/etc/kubernetes/pki/ca.key
/etc/kubernetes/pki/etcd/ca.crt
/etc/kubernetes/pki/etcd/ca.key
/etc/kubernetes/pki/front-proxy-ca.crt
/etc/kubernetes/pki/front-proxy-ca.key
```

### All certificates

If you don't wish to copy the CA private keys to your cluster, you can generate all certificates yourself.

Required certificates:

| Default CN                    | Parent CA                 | O (in Subject) | kind              | hosts (SAN)                                    |
|-------------------------------|---------------------------|----------------|-------------------|------------------------------------------------|
| kube-etcd                     | etcd-ca                   |                | server,<br>client | <hostname>, <Host_IP>, localhost,<br>127.0.0.1 |
| kube-etcd-peer                | etcd-ca                   |                | server,<br>client | <hostname>, <Host_IP>, localhost,<br>127.0.0.1 |
| kube-etcd-healthcheck-client  | etcd-ca                   |                | client            |                                                |
| kube-apiserver-etcd-client    | etcd-ca                   |                | client            |                                                |
| kube-apiserver                | kubernetes-ca             |                | server            | <hostname>, <Host_IP>, <advertise_IP>,<br>[1]  |
| kube-apiserver-kubelet-client | kubernetes-ca             | system:masters | client            |                                                |
| front-proxy-client            | kubernetes-front-proxy-ca |                | client            |                                                |

**Note:**

Instead of using the super-user group `system:masters` for `kube-apiserver-kubelet-client` a less privileged group can be used. `kubeadm` uses the `kubeadm:cluster-admins` group for that purpose.

[1]: any other IP or DNS name you contact your cluster on (as used by [kubeadm](#) the load balancer stable IP and/or DNS name, `kubernetes`, `kubernetes.default`, `kubernetes.default.svc`, `kubernetes.default.svc.cluster`, `kubernetes.default.svc.cluster.local`)

where `kind` maps to one or more of the x509 key usage, which is also documented in the `.spec.usages` of a [CertificateSigningRequest](#) type:

| kind   | Key usage                                        |
|--------|--------------------------------------------------|
| server | digital signature, key encipherment, server auth |
| client | digital signature, key encipherment, client auth |

**Note:**

Hosts/SAN listed above are the recommended ones for getting a working cluster; if required by a specific setup, it is possible to add additional SANs on all the server certificates.

**Note:**

For `kubeadm` users only:

- The scenario where you are copying to your cluster CA certificates without private keys is referred as external CA in the `kubeadm` documentation.

- If you are comparing the above list with a kubeadm generated PKI, please be aware that kube-etcd, kube-etcd-peer and kube-etcd-healthcheck-client certificates are not generated in case of external etcd.

## Certificate paths

Certificates should be placed in a recommended path (as used by [kubeadm](#)). Paths should be specified using the given argument regardless of location.

| Default CN                    | recommended key path         | recommended cert path        | command                 | key argument               | cert argument                                                 |
|-------------------------------|------------------------------|------------------------------|-------------------------|----------------------------|---------------------------------------------------------------|
| etcd-ca                       | etcd/ca.key                  | etcd/ca.crt                  | kube-apiserver          |                            | --etcd-cafile                                                 |
| kube-apiserver-etcd-client    | apiserver-etcd-client.key    | apiserver-etcd-client.crt    | kube-apiserver          | --etcd-keyfile             | --etcd-certfile                                               |
| kubernetes-ca                 | ca.key                       | ca.crt                       | kube-apiserver          |                            | --client-ca-file                                              |
| kubernetes-ca                 | ca.key                       | ca.crt                       | kube-controller-manager | --cluster-signing-key-file | --client-ca-file, --root-ca-file, --cluster-signing-cert-file |
| kube-apiserver                | apiserver.key                | apiserver.crt                | kube-apiserver          | --tls-private-key-file     | --tls-cert-file                                               |
| kube-apiserver-kubelet-client | apiserver-kubelet-client.key | apiserver-kubelet-client.crt | kube-apiserver          | --kubelet-client-key       | --kubelet-client-certificate                                  |
| front-proxy-ca                | front-proxy-ca.key           | front-proxy-ca.crt           | kube-apiserver          |                            | --requestheader-client-ca-file                                |
| front-proxy-ca                | front-proxy-ca.key           | front-proxy-ca.crt           | kube-controller-manager |                            | --requestheader-client-ca-file                                |
| front-proxy-client            | front-proxy-client.key       | front-proxy-client.crt       | kube-apiserver          | --proxy-client-key-file    | --proxy-client-cert-file                                      |
| etcd-ca                       | etcd/ca.key                  | etcd/ca.crt                  | etcd                    |                            | --trusted-ca-file, --peer-trusted-ca-file                     |
| kube-etcd                     | etcd/server.key              | etcd/server.crt              | etcd                    | --key-file                 | --cert-file                                                   |
| kube-etcd-peer                | etcd/peer.key                | etcd/peer.crt                | etcd                    | --peer-key-file            | --peer-cert-file                                              |
| etcd-ca                       |                              | etcd/ca.crt                  | etcdctl                 |                            | --cacert                                                      |
| kube-etcd-healthcheck-client  | etcd/healthcheck-client.key  | etcd/healthcheck-client.crt  | etcdctl                 | --key                      | --cert                                                        |

Same considerations apply for the service account key pair:

| private key path | public key path | command                 | argument                           |
|------------------|-----------------|-------------------------|------------------------------------|
| sa.key           |                 | kube-controller-manager | --service-account-private-key-file |

| private key path | public key path | command        | argument                   |
|------------------|-----------------|----------------|----------------------------|
|                  | sa.pub          | kube-apiserver | --service-account-key-file |

The following example illustrates the file paths [from the previous tables](#) you need to provide if you are generating all of your own keys and certificates:

```

/etc/kubernetes/pki/etcd/ca.key
/etc/kubernetes/pki/etcd/ca.crt
/etc/kubernetes/pki/apiserver-etcd-client.key
/etc/kubernetes/pki/apiserver-etcd-client.crt
/etc/kubernetes/pki/ca.key
/etc/kubernetes/pki/ca.crt
/etc/kubernetes/pki/apiserver.key
/etc/kubernetes/pki/apiserver.crt
/etc/kubernetes/pki/apiserver-kubelet-client.key
/etc/kubernetes/pki/apiserver-kubelet-client.crt
/etc/kubernetes/pki/front-proxy-ca.key
/etc/kubernetes/pki/front-proxy-ca.crt
/etc/kubernetes/pki/front-proxy-client.key
/etc/kubernetes/pki/front-proxy-client.crt
/etc/kubernetes/pki/etcd/server.key
/etc/kubernetes/pki/etcd/server.crt
/etc/kubernetes/pki/etcd/peer.key
/etc/kubernetes/pki/etcd/peer.crt
/etc/kubernetes/pki/etcd/healthcheck-client.key
/etc/kubernetes/pki/etcd/healthcheck-client.crt
/etc/kubernetes/pki/sa.key
/etc/kubernetes/pki/sa.pub

```

## Configure certificates for user accounts

You must manually configure these administrator account and service accounts:

| filename                | credential name            | Default CN                        | O (in Subject) |
|-------------------------|----------------------------|-----------------------------------|----------------|
| admin.conf              | default-admin              | kubernetes-admin                  | <admin-group>  |
| super-admin.conf        | default-super-admin        | kubernetes-super-admin            | system:masters |
| kubelet.conf            | default-auth               | system:node:<nodeName> (see note) | system:nodes   |
| controller-manager.conf | default-controller-manager | system:kube-controller-manager    |                |
| scheduler.conf          | default-scheduler          | system:kube-scheduler             |                |

### Note:

The value of <nodeName> for kubelet.conf **must** match precisely the value of the node name provided by the kubelet as it registers with the apiserver. For further details, read the [Node Authorization](#).

## Note:

In the above example `<admin-group>` is implementation specific. Some tools sign the certificate in the default `admin.conf` to be part of the `system:masters` group. `system:masters` is a break-glass, super user group can bypass the authorization layer of Kubernetes, such as RBAC. Also some tools do not generate a separate `super-admin.conf` with a certificate bound to this super user group.

kubeadm generates two separate administrator certificates in kubeconfig files. One is in `admin.conf` and has Subject: O = kubeadm:cluster-admins, CN = kubernetes-admin. `kubeadm:cluster-admins` is a custom group bound to the cluster-admin ClusterRole. This file is generated on all kubeadm managed control plane machines.

Another is in `super-admin.conf` that has Subject: O = system:masters, CN = kubernetes-super-admin. This file is generated only on the node where kubeadm init was called.

1. For each config, generate an x509 cert/key pair with the given CN and O.
2. Run `kubect`l as follows for each config:

```
KUBECONFIG=<filename> kubectl config set-cluster default-cluster --server=https://<host ip>:6443 --certificate-authority <path-to-kubernetes-ca> --embed-certs
KUBECONFIG=<filename> kubectl config set-credentials <credential-name> --client-key <path-to-key>.pem --client-certificate <path-to-cert>.pem --embed-certs
KUBECONFIG=<filename> kubectl config set-context default-system --cluster default-cluster --user <credential-name>
KUBECONFIG=<filename> kubectl config use-context default-system
```

These files are used as follows:

| filename                | command                 | comment                                                             |
|-------------------------|-------------------------|---------------------------------------------------------------------|
| admin.conf              | kubect                  | Configures administrator user for the cluster                       |
| super-admin.conf        | kubect                  | Configures super administrator user for the cluster                 |
| kubelet.conf            | kubelet                 | One required for each node in the cluster.                          |
| controller-manager.conf | kube-controller-manager | Must be added to manifest in manifests/kube-controller-manager.yaml |
| scheduler.conf          | kube-scheduler          | Must be added to manifest in manifests/kube-scheduler.yaml          |

The following files illustrate full paths to the files listed in the previous table:

```
/etc/kubernetes/admin.conf
/etc/kubernetes/super-admin.conf
/etc/kubernetes/kubelet.conf
/etc/kubernetes/controller-manager.conf
/etc/kubernetes/scheduler.conf
```

This section of the Kubernetes documentation contains pages that show how to do individual tasks. A task page shows how to do a single thing, typically by giving a short sequence of steps.

If you would like to write a task page, see [Creating a Documentation Pull Request](#).

---

### [Install Tools](#)

Set up Kubernetes tools on your computer.

### [Administer a Cluster](#)

Learn common tasks for administering a cluster.

### [Configure Pods and Containers](#)

Perform common configuration tasks for Pods and containers.

### [Monitoring, Logging, and Debugging](#)

Set up monitoring and logging to troubleshoot a cluster, or debug a containerized application.

### [Manage Kubernetes Objects](#)

Declarative and imperative paradigms for interacting with the Kubernetes API.

### [Managing Secrets](#)

Managing confidential settings data using Secrets.

### [Inject Data Into Applications](#)

Specify configuration and other data for the Pods that run your workload.

### [Run Applications](#)

Run and manage both stateless and stateful applications.

### [Run Jobs](#)

Run Jobs using parallel processing.

### [Access Applications in a Cluster](#)

Configure load balancing, port forwarding, or setup firewall or DNS configurations to access applications in a cluster.

### [Extend Kubernetes](#)

Understand advanced ways to adapt your Kubernetes cluster to the needs of your work environment.

### [TLS](#)

Understand how to protect traffic within your cluster using Transport Layer Security (TLS).

### [Manage Cluster Daemons](#)

Perform common tasks for managing a DaemonSet, such as performing a rolling update.

### [Networking](#)

Learn how to configure networking for your cluster.

### [Extend kubectl with plugins](#)

Extend kubectl by creating and installing kubectl plugins.

### [Manage HugePages](#)

Configure and manage huge pages as a schedulable resource in a cluster.

### [Schedule GPUs](#)

Configure and schedule GPUs for use as a resource by nodes in a cluster.

## Install Tools

Set up Kubernetes tools on your computer.

### kubectl

The Kubernetes command-line tool, [kubectl](#), allows you to run commands against Kubernetes clusters. You can use kubectl to deploy applications, inspect and manage cluster resources, and view logs. For more information including a complete list of kubectl operations, see the [kubectl reference documentation](#).

kubectl is installable on a variety of Linux platforms, macOS and Windows. Find your preferred operating system below.

- [Install kubectl on Linux](#)
- [Install kubectl on macOS](#)
- [Install kubectl on Windows](#)

## kind

[kind](#) lets you run Kubernetes on your local computer. This tool requires that you have either [Docker](#) or [Podman](#) installed.

The kind [Quick Start](#) page shows you what you need to do to get up and running with kind.

[View kind Quick Start Guide](#)

## minikube

Like kind, [minikube](#) is a tool that lets you run Kubernetes locally. minikube runs an all-in-one or a multi-node local Kubernetes cluster on your personal computer (including Windows, macOS and Linux PCs) so that you can try out Kubernetes, or for daily development work.

You can follow the official [Get Started!](#) guide if your focus is on getting the tool installed.

[View minikube Get Started! Guide](#)

Once you have minikube working, you can use it to [run a sample application](#).

## kubeadm

You can use the [kubeadm](#) tool to create and manage Kubernetes clusters. It performs the actions necessary to get a minimum viable, secure cluster up and running in a user friendly way.

[Installing kubeadm](#) shows you how to install kubeadm. Once installed, you can use it to [create a cluster](#).

[View kubeadm Install Guide](#)

# Install and Set Up kubectl on Linux

## Before you begin

You must use a kubectl version that is within one minor version difference of your cluster. For example, a v1.30 client can communicate with v1.29, v1.30, and v1.31 control planes. Using the latest compatible version of kubectl helps avoid unforeseen issues.

## Install kubectl on Linux

The following methods exist for installing kubectl on Linux:

- [Install kubectl binary with curl on Linux](#)
- [Install using native package management](#)
- [Install using other package management](#)

## Install kubectl binary with curl on Linux

1. Download the latest release with the command:

- [x86-64](#)
- [ARM64](#)

```
curl -LO "https://dl.k8s.io/release/$(curl -L -s https://dl.k8s.io/release/stable.txt)/bin/linux/amd64/kubectl"
```

```
curl -LO "https://dl.k8s.io/release/$(curl -L -s https://dl.k8s.io/release/stable.txt)/bin/linux/arm64/kubectl"
```

### Note:

To download a specific version, replace the `$(curl -L -s https://dl.k8s.io/release/stable.txt)` portion of the command with the specific version.

For example, to download version 1.30.0 on Linux x86-64, type:

```
curl -LO https://dl.k8s.io/release/v1.30.0/bin/linux/amd64/kubectl
```

And for Linux ARM64, type:

```
curl -LO https://dl.k8s.io/release/v1.30.0/bin/linux/arm64/kubectl
```

2. Validate the binary (optional)

Download the kubectl checksum file:

- [x86-64](#)
- [ARM64](#)

```
curl -LO "https://dl.k8s.io/release/$(curl -L -s https://dl.k8s.io/release/stable.txt)/bin/linux/amd64/kubectl.sha256"
```

```
curl -LO "https://dl.k8s.io/release/$(curl -L -s https://dl.k8s.io/release/stable.txt)/bin/linux/arm64/kubectl.sha256"
```

Validate the kubectl binary against the checksum file:

```
echo "$(cat kubectl.sha256) kubectl" | sha256sum --check
```

If valid, the output is:

```
kubectl: OK
```

If the check fails, sha256 exits with nonzero status and prints output similar to:

```
kubectrl: FAILED
sha256sum: WARNING: 1 computed checksum did NOT match
```

**Note:**

Download the same version of the binary and checksum.

3. Install kubectrl

```
sudo install -o root -g root -m 0755 kubectrl /usr/local/bin/kubectrl
```

**Note:**

If you do not have root access on the target system, you can still install kubectrl to the `~/local/bin` directory:

```
chmod +x kubectrl
mkdir -p ~/.local/bin
mv ./kubectrl ~/.local/bin/kubectrl
and then append (or prepend) ~/.local/bin to $PATH
```

4. Test to ensure the version you installed is up-to-date:

```
kubectrl version --client
```

Or use this for detailed view of version:

```
kubectrl version --client --output=yaml
```

## Install using native package management

- [Debian-based distributions](#)
- [Red Hat-based distributions](#)
- [SUSE-based distributions](#)

1. Update the apt package index and install packages needed to use the Kubernetes apt repository:

```
sudo apt-get update
apt-transport-https may be a dummy package; if so, you can skip that package
sudo apt-get install -y apt-transport-https ca-certificates curl gnupg
```

2. Download the public signing key for the Kubernetes package repositories. The same signing key is used for all repositories so you can disregard the version in the URL:

```
If the folder `/etc/apt/keyrings` does not exist, it should be created before the curl
command, read the note below.
sudo mkdir -p -m 755 /etc/apt/keyrings
curl -fsSL https://pkgs.k8s.io/core:/stable:/v1.30/deb/Release.key | sudo gpg --dearmor -o /
etc/apt/keyrings/kubernetes-apt-keyring.gpg
```

```
sudo chmod 644 /etc/apt/keyrings/kubernetes-apt-keyring.gpg # allow unprivileged APT programs to read this keyring
```

**Note:**

In releases older than Debian 12 and Ubuntu 22.04, folder `/etc/apt/keyrings` does not exist by default, and it should be created before the `curl` command.

1. Add the appropriate Kubernetes apt repository. If you want to use Kubernetes version different than v1.30, replace v1.30 with the desired minor version in the command below:

```
This overwrites any existing configuration in /etc/apt/sources.list.d/kubernetes.list
echo 'deb [signed-by=/etc/apt/keyrings/kubernetes-apt-keyring.gpg] https://pkgs.k8s.io/core:/stable:/v1.30/deb/ ' | sudo tee /etc/apt/sources.list.d/kubernetes.list
sudo chmod 644 /etc/apt/sources.list.d/kubernetes.list # helps tools such as command-not-found to work correctly
```

**Note:**

To upgrade `kubectl` to another minor release, you'll need to bump the version in `/etc/apt/sources.list.d/kubernetes.list` before running `apt-get update` and `apt-get upgrade`. This procedure is described in more detail in [Changing The Kubernetes Package Repository](#).

1. Update apt package index, then install `kubectl`:

```
sudo apt-get update
sudo apt-get install -y kubectl
```

1. Add the Kubernetes yum repository. If you want to use Kubernetes version different than v1.30, replace v1.30 with the desired minor version in the command below.

```
This overwrites any existing configuration in /etc/yum.repos.d/kubernetes.repo
cat <<EOF | sudo tee /etc/yum.repos.d/kubernetes.repo
[kubernetes]
name=Kubernetes
baseurl=https://pkgs.k8s.io/core:/stable:/v1.30/rpm/
enabled=1
gpgcheck=1
gpgkey=https://pkgs.k8s.io/core:/stable:/v1.30/rpm/repodata/repomd.xml.key
EOF
```

**Note:**

To upgrade `kubectl` to another minor release, you'll need to bump the version in `/etc/yum.repos.d/kubernetes.repo` before running `yum update`. This procedure is described in more detail in [Changing The Kubernetes Package Repository](#).

1. Install `kubectl` using `yum`:

```
sudo yum install -y kubectl
```

1. Add the Kubernetes zypper repository. If you want to use Kubernetes version different than v1.30, replace v1.30 with the desired minor version in the command below.

```
This overwrites any existing configuration in /etc/zypp/repos.d/kubernetes.repo
cat <<EOF | sudo tee /etc/zypp/repos.d/kubernetes.repo
[kubernetes]
name=Kubernetes
baseurl=https://pkgs.k8s.io/core:/stable:/v1.30/rpm/
enabled=1
gpgcheck=1
gpgkey=https://pkgs.k8s.io/core:/stable:/v1.30/rpm/repodata/repomd.xml.key
EOF
```

### Note:

To upgrade kubectl to another minor release, you'll need to bump the version in `/etc/zypp/repos.d/kubernetes.repo` before running zypper update. This procedure is described in more detail in [Changing The Kubernetes Package Repository](#).

1. Install kubectl using zypper:

```
sudo zypper install -y kubectl
```

## Install using other package management

- [Snap](#)
- [Homebrew](#)

If you are on Ubuntu or another Linux distribution that supports the [snap](#) package manager, kubectl is available as a [snap](#) application.

```
snap install kubectl --classic
kubectl version --client
```

If you are on Linux and using [Homebrew](#) package manager, kubectl is available for [installation](#).

```
brew install kubectl
kubectl version --client
```

## Verify kubectl configuration

In order for kubectl to find and access a Kubernetes cluster, it needs a [kubeconfig file](#), which is created automatically when you create a cluster using [kube-up.sh](#) or successfully deploy a Minikube cluster. By default, kubectl configuration is located at `~/.kube/config`.

Check that kubectl is properly configured by getting the cluster state:

```
kubectl cluster-info
```

If you see a URL response, kubectl is correctly configured to access your cluster.

If you see a message similar to the following, kubectl is not configured correctly or is not able to connect to a Kubernetes cluster.

The connection to the server <server-name:port> was refused - did you specify the right host or port?

For example, if you are intending to run a Kubernetes cluster on your laptop (locally), you will need a tool like [Minikube](#) to be installed first and then re-run the commands stated above.

If `kubectl cluster-info` returns the url response but you can't access your cluster, to check whether it is configured properly, use:

```
kubectl cluster-info dump
```

## Troubleshooting the 'No Auth Provider Found' error message

In Kubernetes 1.26, `kubectl` removed the built-in authentication for the following cloud providers' managed Kubernetes offerings. These providers have released `kubectl` plugins to provide the cloud-specific authentication. For instructions, refer to the following provider documentation:

- Azure AKS: [kubelogin plugin](#)
- Google Kubernetes Engine: [gke-gcloud-auth-plugin](#)

(There could also be other reasons to see the same error message, unrelated to that change.)

## Optional kubectl configurations and plugins

### Enable shell autocompletion

`kubectl` provides autocompletion support for Bash, Zsh, Fish, and PowerShell, which can save you a lot of typing.

Below are the procedures to set up autocompletion for Bash, Fish, and Zsh.

- [Bash](#)
- [Fish](#)
- [Zsh](#)

### Introduction

The `kubectl` completion script for Bash can be generated with the command `kubectl completion bash`. Sourcing the completion script in your shell enables `kubectl` autocompletion.

However, the completion script depends on [bash-completion](#), which means that you have to install this software first (you can test if you have `bash-completion` already installed by running `type _init_completion`).

### Install bash-completion

`bash-completion` is provided by many package managers (see [here](#)). You can install it with `apt-get install bash-completion` or `yum install bash-completion`, etc.

The above commands create `/usr/share/bash-completion/bash_completion`, which is the main script of `bash-completion`. Depending on your package manager, you have to manually source this file in your `~/.bashrc` file.

To find out, reload your shell and run `type _init_completion`. If the command succeeds, you're already set, otherwise add the following to your `~/.bashrc` file:

```
source /usr/share/bash-completion/bash_completion
```

Reload your shell and verify that bash-completion is correctly installed by typing `type _init_completion`.

## Enable kubectl autocompletion

### Bash

You now need to ensure that the kubectl completion script gets sourced in all your shell sessions. There are two ways in which you can do this:

- [User](#)
- [System](#)

```
echo 'source <(kubectl completion bash)' >> ~/.bashrc
```

```
kubectl completion bash | sudo tee /etc/bash_completion.d/kubectl > /dev/null
sudo chmod a+r /etc/bash_completion.d/kubectl
```

If you have an alias for kubectl, you can extend shell completion to work with that alias:

```
echo 'alias k=kubectl' >> ~/.bashrc
echo 'complete -o default -F __start_kubectl k' >> ~/.bashrc
```

### Note:

bash-completion sources all completion scripts in `/etc/bash_completion.d`.

Both approaches are equivalent. After reloading your shell, kubectl autocompletion should be working. To enable bash autocompletion in current session of shell, source the `~/.bashrc` file:

```
source ~/.bashrc
```

### Note:

Autocomplete for Fish requires kubectl 1.23 or later.

The kubectl completion script for Fish can be generated with the command `kubectl completion fish`. Sourcing the completion script in your shell enables kubectl autocompletion.

To do so in all your shell sessions, add the following line to your `~/.config/fish/config.fish` file:

```
kubectl completion fish | source
```

After reloading your shell, kubectl autocompletion should be working.

The kubectl completion script for Zsh can be generated with the command `kubectl completion zsh`. Sourcing the completion script in your shell enables kubectl autocompletion.

To do so in all your shell sessions, add the following to your `~/.zshrc` file:

```
source <(kubectl completion zsh)
```

If you have an alias for kubectl, kubectl autocompletion will automatically work with it.

After reloading your shell, kubectl autocompletion should be working.

If you get an error like `2: command not found: compdef`, then add the following to the beginning of your `~/.zshrc` file:

```
autoload -Uz compinit
compinit
```

## Install kubectl convert plugin

A plugin for Kubernetes command-line tool kubectl, which allows you to convert manifests between different API versions. This can be particularly helpful to migrate manifests to a non-deprecated api version with newer Kubernetes release. For more info, visit [migrate to non deprecated apis](#)

1. Download the latest release with the command:

- [x86-64](#)
- [ARM64](#)

```
curl -LO "https://dl.k8s.io/release/$(curl -L -s https://dl.k8s.io/release/stable.txt)/bin/linux/amd64/kubectl-convert"
```

```
curl -LO "https://dl.k8s.io/release/$(curl -L -s https://dl.k8s.io/release/stable.txt)/bin/linux/arm64/kubectl-convert"
```

2. Validate the binary (optional)

Download the kubectl-convert checksum file:

- [x86-64](#)
- [ARM64](#)

```
curl -LO "https://dl.k8s.io/release/$(curl -L -s https://dl.k8s.io/release/stable.txt)/bin/linux/amd64/kubectl-convert.sha256"
```

```
curl -LO "https://dl.k8s.io/release/$(curl -L -s https://dl.k8s.io/release/stable.txt)/bin/
```

```
linux/arm64/kubectl-convert.sha256"
```

Validate the kubectl-convert binary against the checksum file:

```
echo "$(cat kubectl-convert.sha256) kubectl-convert" | sha256sum --check
```

If valid, the output is:

```
kubectl-convert: OK
```

If the check fails, sha256 exits with nonzero status and prints output similar to:

```
kubectl-convert: FAILED
sha256sum: WARNING: 1 computed checksum did NOT match
```

**Note:**

Download the same version of the binary and checksum.

3. Install kubectl-convert

```
sudo install -o root -g root -m 0755 kubectl-convert /usr/local/bin/kubectl-convert
```

4. Verify plugin is successfully installed

```
kubectl convert --help
```

If you do not see an error, it means the plugin is successfully installed.

5. After installing the plugin, clean up the installation files:

```
rm kubectl-convert kubectl-convert.sha256
```

## What's next

- [Install Minikube](#)
- See the [getting started guides](#) for more about creating clusters.
- [Learn how to launch and expose your application.](#)
- If you need access to a cluster you didn't create, see the [Sharing Cluster Access document](#).
- Read the [kubectl reference docs](#)

# Install and Set Up kubectl on macOS

## Before you begin

You must use a kubectl version that is within one minor version difference of your cluster. For example, a v1.30 client can communicate with v1.29, v1.30, and v1.31 control planes. Using the latest compatible version of kubectl helps avoid unforeseen issues.

# Install kubectl on macOS

The following methods exist for installing kubectl on macOS:

- [Install kubectl on macOS](#)
  - [Install kubectl binary with curl on macOS](#)
  - [Install with Homebrew on macOS](#)
  - [Install with Macports on macOS](#)
- [Verify kubectl configuration](#)
- [Optional kubectl configurations and plugins](#)
  - [Enable shell autocompletion](#)
  - [Install kubectl convert plugin](#)

## Install kubectl binary with curl on macOS

1. Download the latest release:

- [Intel](#)
- [Apple Silicon](#)

```
curl -LO "https://dl.k8s.io/release/$(curl -L -s https://dl.k8s.io/release/stable.txt)/bin/darwin/amd64/kubectl"
```

```
curl -LO "https://dl.k8s.io/release/$(curl -L -s https://dl.k8s.io/release/stable.txt)/bin/darwin/arm64/kubectl"
```

### Note:

To download a specific version, replace the `$(curl -L -s https://dl.k8s.io/release/stable.txt)` portion of the command with the specific version.

For example, to download version 1.30.0 on Intel macOS, type:

```
curl -LO "https://dl.k8s.io/release/v1.30.0/bin/darwin/amd64/kubectl"
```

And for macOS on Apple Silicon, type:

```
curl -LO "https://dl.k8s.io/release/v1.30.0/bin/darwin/arm64/kubectl"
```

2. Validate the binary (optional)

Download the kubectl checksum file:

- [Intel](#)
- [Apple Silicon](#)

```
curl -LO "https://dl.k8s.io/release/$(curl -L -s https://dl.k8s.io/release/stable.txt)/bin/
```

```
darwin/amd64/kubect1.sha256"
```

```
curl -LO "https://dl.k8s.io/release/$(curl -L -s https://dl.k8s.io/release/stable.txt)/bin/darwin/arm64/kubect1.sha256"
```

Validate the kubect1 binary against the checksum file:

```
echo "$(cat kubect1.sha256) kubect1" | shasum -a 256 --check
```

If valid, the output is:

```
kubect1: OK
```

If the check fails, shasum exits with nonzero status and prints output similar to:

```
kubect1: FAILED
shasum: WARNING: 1 computed checksum did NOT match
```

**Note:**

Download the same version of the binary and checksum.

3. Make the kubect1 binary executable.

```
chmod +x ./kubect1
```

4. Move the kubect1 binary to a file location on your system PATH.

```
sudo mv ./kubect1 /usr/local/bin/kubect1
sudo chown root: /usr/local/bin/kubect1
```

**Note:**

Make sure /usr/local/bin is in your PATH environment variable.

5. Test to ensure the version you installed is up-to-date:

```
kubect1 version --client
```

Or use this for detailed view of version:

```
kubect1 version --client --output=yaml
```

6. After installing and validating kubect1, delete the checksum file:

```
rm kubect1.sha256
```

## Install with Homebrew on macOS

If you are on macOS and using [Homebrew](#) package manager, you can install kubectl with Homebrew.

1. Run the installation command:

```
brew install kubectl
```

or

```
brew install kubernetes-cli
```

2. Test to ensure the version you installed is up-to-date:

```
kubectl version --client
```

## Install with Macports on macOS

If you are on macOS and using [Macports](#) package manager, you can install kubectl with Macports.

1. Run the installation command:

```
sudo port selfupdate
sudo port install kubectl
```

2. Test to ensure the version you installed is up-to-date:

```
kubectl version --client
```

## Verify kubectl configuration

In order for kubectl to find and access a Kubernetes cluster, it needs a [kubeconfig file](#), which is created automatically when you create a cluster using [kube-up.sh](#) or successfully deploy a Minikube cluster. By default, kubectl configuration is located at ~/.kube/config.

Check that kubectl is properly configured by getting the cluster state:

```
kubectl cluster-info
```

If you see a URL response, kubectl is correctly configured to access your cluster.

If you see a message similar to the following, kubectl is not configured correctly or is not able to connect to a Kubernetes cluster.

```
The connection to the server <server-name:port> was refused - did you specify the right host or port?
```

For example, if you are intending to run a Kubernetes cluster on your laptop (locally), you will need a tool like [Minikube](#) to be installed first and then re-run the commands stated above.

If kubectl cluster-info returns the url response but you can't access your cluster, to check whether it is configured properly, use:

```
kubectl cluster-info dump
```

## Troubleshooting the 'No Auth Provider Found' error message

In Kubernetes 1.26, kubectl removed the built-in authentication for the following cloud providers' managed Kubernetes offerings. These providers have released kubectl plugins to provide the cloud-specific authentication. For instructions, refer to the following provider documentation:

- Azure AKS: [kubelogin plugin](#)
- Google Kubernetes Engine: [gke-gcloud-auth-plugin](#)

(There could also be other reasons to see the same error message, unrelated to that change.)

## Optional kubectl configurations and plugins

### Enable shell autocompletion

kubectl provides autocompletion support for Bash, Zsh, Fish, and PowerShell which can save you a lot of typing.

Below are the procedures to set up autocompletion for Bash, Fish, and Zsh.

- [Bash](#)
- [Fish](#)
- [Zsh](#)

### Introduction

The kubectl completion script for Bash can be generated with `kubectl completion bash`. Sourcing this script in your shell enables kubectl completion.

However, the kubectl completion script depends on [bash-completion](#) which you thus have to previously install.

#### Warning:

There are two versions of bash-completion, v1 and v2. V1 is for Bash 3.2 (which is the default on macOS), and v2 is for Bash 4.1+. The kubectl completion script **doesn't work** correctly with bash-completion v1 and Bash 3.2. It requires **bash-completion v2** and **Bash 4.1+**. Thus, to be able to correctly use kubectl completion on macOS, you have to install and use Bash 4.1+ ([instructions](#)). The following instructions assume that you use Bash 4.1+ (that is, any Bash version of 4.1 or newer).

### Upgrade Bash

The instructions here assume you use Bash 4.1+. You can check your Bash's version by running:

```
echo $BASH_VERSION
```

If it is too old, you can install/upgrade it using Homebrew:

```
brew install bash
```

Reload your shell and verify that the desired version is being used:

```
echo $BASH_VERSION $SHELL
```

Homebrew usually installs it at `/usr/local/bin/bash`.

## Install bash-completion

### Note:

As mentioned, these instructions assume you use Bash 4.1+, which means you will install bash-completion v2 (in contrast to Bash 3.2 and bash-completion v1, in which case kubectl completion won't work).

You can test if you have bash-completion v2 already installed with `type _init_completion`. If not, you can install it with Homebrew:

```
brew install bash-completion@2
```

As stated in the output of this command, add the following to your `~/.bash_profile` file:

```
brew_etc="$(brew --prefix)/etc" && [[-r "${brew_etc}/profile.d/bash_completion.sh"]] && . "${brew_etc}/profile.d/bash_completion.sh"
```

Reload your shell and verify that bash-completion v2 is correctly installed with `type _init_completion`.

## Enable kubectl autocompletion

You now have to ensure that the kubectl completion script gets sourced in all your shell sessions. There are multiple ways to achieve this:

- Source the completion script in your `~/.bash_profile` file:

```
echo 'source <(kubectl completion bash)' >> ~/.bash_profile
```

- Add the completion script to the `/usr/local/etc/bash_completion.d` directory:

```
kubectl completion bash >/usr/local/etc/bash_completion.d/kubectl
```

- If you have an alias for kubectl, you can extend shell completion to work with that alias:

```
echo 'alias k=kubectl' >> ~/.bash_profile
echo 'complete -o default -F __start_kubectl k' >> ~/.bash_profile
```

- If you installed kubectl with Homebrew (as explained [here](#)), then the kubectl completion script should already be in `/usr/local/etc/bash_completion.d/kubectl`. In that case, you don't need to do anything.

**Note:**

The Homebrew installation of bash-completion v2 sources all the files in the BASH\_COMPLETION\_COMPAT\_DIR directory, that's why the latter two methods work.

In any case, after reloading your shell, kubectl completion should be working.

**Note:**

Autocomplete for Fish requires kubectl 1.23 or later.

The kubectl completion script for Fish can be generated with the command `kubectl completion fish`. Sourcing the completion script in your shell enables kubectl autocompletion.

To do so in all your shell sessions, add the following line to your `~/.config/fish/config.fish` file:

```
kubectl completion fish | source
```

After reloading your shell, kubectl autocompletion should be working.

The kubectl completion script for Zsh can be generated with the command `kubectl completion zsh`. Sourcing the completion script in your shell enables kubectl autocompletion.

To do so in all your shell sessions, add the following to your `~/.zshrc` file:

```
source <(kubectl completion zsh)
```

If you have an alias for kubectl, kubectl autocompletion will automatically work with it.

After reloading your shell, kubectl autocompletion should be working.

If you get an error like `2: command not found: compdef`, then add the following to the beginning of your `~/.zshrc` file:

```
autoload -Uz compinit
compinit
```

## Install kubectl convert plugin

A plugin for Kubernetes command-line tool kubectl, which allows you to convert manifests between different API versions. This can be particularly helpful to migrate manifests to a non-deprecated api version with newer Kubernetes release. For more info, visit [migrate to non deprecated apis](#)

1. Download the latest release with the command:

- [Intel](#)
- [Apple Silicon](#)

```
curl -LO "https://dl.k8s.io/release/${curl -L -s https://dl.k8s.io/release/stable.txt}/bin/darwin/amd64/kubectl-convert"
```

```
curl -LO "https://dl.k8s.io/release/$(curl -L -s https://dl.k8s.io/release/stable.txt)/bin/darwin/arm64/kubectl-convert"
```

## 2. Validate the binary (optional)

Download the kubectl-convert checksum file:

- [Intel](#)
- [Apple Silicon](#)

```
curl -LO "https://dl.k8s.io/release/$(curl -L -s https://dl.k8s.io/release/stable.txt)/bin/darwin/amd64/kubectl-convert.sha256"
```

```
curl -LO "https://dl.k8s.io/release/$(curl -L -s https://dl.k8s.io/release/stable.txt)/bin/darwin/arm64/kubectl-convert.sha256"
```

Validate the kubectl-convert binary against the checksum file:

```
echo "$(cat kubectl-convert.sha256) kubectl-convert" | shasum -a 256 --check
```

If valid, the output is:

```
kubectl-convert: OK
```

If the check fails, shasum exits with nonzero status and prints output similar to:

```
kubectl-convert: FAILED
shasum: WARNING: 1 computed checksum did NOT match
```

### **Note:**

Download the same version of the binary and checksum.

## 3. Make kubectl-convert binary executable

```
chmod +x ./kubectl-convert
```

## 4. Move the kubectl-convert binary to a file location on your system PATH.

```
sudo mv ./kubectl-convert /usr/local/bin/kubectl-convert
sudo chown root: /usr/local/bin/kubectl-convert
```

### **Note:**

Make sure `/usr/local/bin` is in your PATH environment variable.

## 5. Verify plugin is successfully installed

```
kubectrl convert --help
```

If you do not see an error, it means the plugin is successfully installed.

6. After installing the plugin, clean up the installation files:

```
rm kubectrl-convert kubectrl-convert.sha256
```

## Uninstall kubectrl on macOS

Depending on how you installed kubectrl, use one of the following methods.

### Uninstall kubectrl using the command-line

1. Locate the kubectrl binary on your system:

```
which kubectrl
```

2. Remove the kubectrl binary:

```
sudo rm <path>
```

Replace <path> with the path to the kubectrl binary from the previous step. For example, `sudo rm /usr/local/bin/kubectrl`.

### Uninstall kubectrl using homebrew

If you installed kubectrl using Homebrew, run the following command:

```
brew remove kubectrl
```

## What's next

- [Install Minikube](#)
- See the [getting started guides](#) for more about creating clusters.
- [Learn how to launch and expose your application.](#)
- If you need access to a cluster you didn't create, see the [Sharing Cluster Access document](#).
- Read the [kubectrl reference docs](#)

# Install and Set Up kubectrl on Windows

## Before you begin

You must use a kubectrl version that is within one minor version difference of your cluster. For example, a v1.30 client can communicate with v1.29, v1.30, and v1.31 control planes. Using the latest compatible version of kubectrl helps avoid unforeseen issues.

# Install kubectl on Windows

The following methods exist for installing kubectl on Windows:

- [Install kubectl binary with curl on Windows](#)
- [Install on Windows using Chocolatey, Scoop, or winget](#)

## Install kubectl binary with curl on Windows

1. Download the latest 1.30 patch release: [kubectl 1.30.0](#).

Or if you have curl installed, use this command:

```
curl.exe -LO "https://dl.k8s.io/release/v1.30.0/bin/windows/amd64/kubectl.exe"
```

### Note:

To find out the latest stable version (for example, for scripting), take a look at <https://dl.k8s.io/release/stable.txt>.

2. Validate the binary (optional)

Download the kubectl checksum file:

```
curl.exe -LO "https://dl.k8s.io/v1.30.0/bin/windows/amd64/kubectl.exe.sha256"
```

Validate the kubectl binary against the checksum file:

- Using Command Prompt to manually compare CertUtil's output to the checksum file downloaded:

```
CertUtil -hashfile kubectl.exe SHA256
type kubectl.exe.sha256
```

- Using PowerShell to automate the verification using the -eq operator to get a True or False result:

```
$(Get-FileHash -Algorithm SHA256 .\kubectl.exe).Hash -eq $(Get-Content .
\kubectl.exe.sha256)
```

3. Append or prepend the kubectl binary folder to your PATH environment variable.
4. Test to ensure the version of kubectl is the same as downloaded:

```
kubectl version --client
```

Or use this for detailed view of version:

```
kubectl version --client --output=yaml
```

**Note:**

[Docker Desktop for Windows](#) adds its own version of kubectl to PATH. If you have installed Docker Desktop before, you may need to place your PATH entry before the one added by the Docker Desktop installer or remove the Docker Desktop's kubectl.

**Install on Windows using Chocolatey, Scoop, or winget**

1. To install kubectl on Windows you can use either [Chocolatey](#) package manager, [Scoop](#) command-line installer, or [winget](#) package manager.

- [choco](#)
- [scoop](#)
- [winget](#)

```
choco install kubernetes-cli
```

```
scoop install kubectl
```

```
winget install -e --id Kubernetes.kubectl
```

2. Test to ensure the version you installed is up-to-date:

```
kubectl version --client
```

3. Navigate to your home directory:

```
If you're using cmd.exe, run: cd %USERPROFILE%
cd ~
```

4. Create the .kube directory:

```
mkdir .kube
```

5. Change to the .kube directory you just created:

```
cd .kube
```

6. Configure kubectl to use a remote Kubernetes cluster:

```
New-Item config -type file
```

**Note:**

Edit the config file with a text editor of your choice, such as Notepad.

**Verify kubectl configuration**

In order for kubectl to find and access a Kubernetes cluster, it needs a [kubeconfig file](#), which is created automatically when you create a cluster using [kube-up.sh](#) or successfully deploy a Minikube cluster. By default, kubectl configuration is located at ~/.kube/config.

Check that kubectl is properly configured by getting the cluster state:

```
kubectl cluster-info
```

If you see a URL response, kubectl is correctly configured to access your cluster.

If you see a message similar to the following, kubectl is not configured correctly or is not able to connect to a Kubernetes cluster.

The connection to the server <server-name:port> was refused - did you specify the right host or port?

For example, if you are intending to run a Kubernetes cluster on your laptop (locally), you will need a tool like [Minikube](#) to be installed first and then re-run the commands stated above.

If kubectl cluster-info returns the url response but you can't access your cluster, to check whether it is configured properly, use:

```
kubectl cluster-info dump
```

## Troubleshooting the 'No Auth Provider Found' error message

In Kubernetes 1.26, kubectl removed the built-in authentication for the following cloud providers' managed Kubernetes offerings. These providers have released kubectl plugins to provide the cloud-specific authentication. For instructions, refer to the following provider documentation:

- Azure AKS: [kubelogin plugin](#)
- Google Kubernetes Engine: [gke-gcloud-auth-plugin](#)

(There could also be other reasons to see the same error message, unrelated to that change.)

## Optional kubectl configurations and plugins

### Enable shell autocompletion

kubectl provides autocompletion support for Bash, Zsh, Fish, and PowerShell, which can save you a lot of typing.

Below are the procedures to set up autocompletion for PowerShell.

The kubectl completion script for PowerShell can be generated with the command `kubectl completion powershell`.

To do so in all your shell sessions, add the following line to your \$PROFILE file:

```
kubectl completion powershell | Out-String | Invoke-Expression
```

This command will regenerate the auto-completion script on every PowerShell start up. You can also add the generated script directly to your \$PROFILE file.

To add the generated script to your \$PROFILE file, run the following line in your powershell prompt:

```
kubectl completion powershell >> $PROFILE
```

After reloading your shell, kubectl autocompletion should be working.

## Install kubectl convert plugin

A plugin for Kubernetes command-line tool kubectl, which allows you to convert manifests between different API versions. This can be particularly helpful to migrate manifests to a non-deprecated api version with newer Kubernetes release. For more info, visit [migrate to non deprecated apis](#)

1. Download the latest release with the command:

```
curl.exe -LO "https://dl.k8s.io/release/v1.30.0/bin/windows/amd64/kubectl-convert.exe"
```

2. Validate the binary (optional).

Download the kubectl-convert checksum file:

```
curl.exe -LO "https://dl.k8s.io/v1.30.0/bin/windows/amd64/kubectl-convert.exe.sha256"
```

Validate the kubectl-convert binary against the checksum file:

- Using Command Prompt to manually compare CertUtil's output to the checksum file downloaded:

```
CertUtil -hashfile kubectl-convert.exe SHA256
type kubectl-convert.exe.sha256
```

- Using PowerShell to automate the verification using the -eq operator to get a True or False result:

```
$(($($CertUtil -hashfile .\kubectl-convert.exe SHA256)[1] -replace " ", "") -eq $(type .\k
ubectl-convert.exe.sha256)
```

3. Append or prepend the kubectl-convert binary folder to your PATH environment variable.
4. Verify the plugin is successfully installed.

```
kubectl convert --help
```

If you do not see an error, it means the plugin is successfully installed.

5. After installing the plugin, clean up the installation files:

```
del kubectl-convert.exe
del kubectl-convert.exe.sha256
```

## What's next

# Certificate Management with kubeadm

FEATURE STATE: Kubernetes v1.15 [stable]

Client certificates generated by [kubeadm](#) expire after 1 year. This page explains how to manage certificate renewals with kubeadm. It also covers other tasks related to kubeadm certificate management.

## Before you begin

You should be familiar with [PKI certificates and requirements in Kubernetes](#).

## Using custom certificates

By default, kubeadm generates all the certificates needed for a cluster to run. You can override this behavior by providing your own certificates.

To do so, you must place them in whatever directory is specified by the `--cert-dir` flag or the `certificatesDir` field of kubeadm's `ClusterConfiguration`. By default this is `/etc/kubernetes/pki`.

If a given certificate and private key pair exists before running `kubeadm init`, kubeadm does not overwrite them. This means you can, for example, copy an existing CA into `/etc/kubernetes/pki/ca.crt` and `/etc/kubernetes/pki/ca.key`, and kubeadm will use this CA for signing the rest of the certificates.

## External CA mode

It is also possible to provide only the `ca.crt` file and not the `ca.key` file (this is only available for the root CA file, not other cert pairs). If all other certificates and kubeconfig files are in place, kubeadm recognizes this condition and activates the "External CA" mode. kubeadm will proceed without the CA key on disk.

Instead, run the controller-manager standalone with `--controllers=csrsigner` and point to the CA certificate and key.

There are various ways to prepare the component credentials when using external CA mode.

## Manual preparation of component credentials

[PKI certificates and requirements](#) includes information on how to prepare all the required by kubeadm component credentials manually.

## Preparation of credentials by signing CSRs generated by kubeadm

kubeadm can [generate CSR files](#) that you can sign manually with tools like openssl and your external CA. These CSR files will include all the specification for credentials that components deployed by kubeadm require.

## Automated preparation of component credentials by using kubeadm phases

Alternatively, it is possible to use kubeadm phase commands to automate this process.

- Go to a host that you want to prepare as a kubeadm control plane node with external CA.
- Copy the external CA files ca.crt and ca.key that you have into /etc/kubernetes/pki on the node.
- Prepare a temporary [kubeadm configuration file](#) called config.yaml that can be used with kubeadm init. Make sure that this file includes any relevant cluster wide or host-specific information that could be included in certificates, such as, ClusterConfiguration.controlPlaneEndpoint, ClusterConfiguration.certSANs and InitConfiguration.APIEndpoint.
- On the same host execute the commands `kubeadm init phase kubeconfig all --config config.yaml` and `kubeadm init phase certs all --config config.yaml`. This will generate all required kubeconfig files and certificates under /etc/kubernetes/ and its pki sub directory.
- Inspect the generated files. Delete /etc/kubernetes/pki/ca.key, delete or move to a safe location the file /etc/kubernetes/super-admin.conf.
- On nodes where kubeadm join will be called also delete /etc/kubernetes/kubelet.conf. This file is only required on the first node where kubeadm init will be called.
- Note that some files such pki/sa.\*, pki/front-proxy-ca.\* and pki/etc/ca.\* are shared between control plane nodes, You can generate them once and [distribute them manually](#) to nodes where kubeadm join will be called, or you can use the [--upload-certs](#) functionality of kubeadm init and `--certificate-key` of kubeadm join to automate this distribution.

Once the credentials are prepared on all nodes, call kubeadm init and kubeadm join for these nodes to join the cluster. kubeadm will use the existing kubeconfig and certificate files under /etc/kubernetes/ and its pki sub directory.

## Check certificate expiration

You can use the check-expiration subcommand to check when certificates expire:

```
kubeadm certs check-expiration
```

The output is similar to this:

| CERTIFICATE              | EXPIRES                | RESIDUAL TIME | CERTIFICATE AUTHORITY |
|--------------------------|------------------------|---------------|-----------------------|
| EXTERNALLY MANAGED       |                        |               |                       |
| admin.conf               | Dec 30, 2020 23:36 UTC | 364d          | no                    |
| apiserver                | Dec 30, 2020 23:36 UTC | 364d          | ca no                 |
| apiserver-etcd-client    | Dec 30, 2020 23:36 UTC | 364d          | etcd-ca no            |

| ca                    | Dec 28, 2029 23:36 UTC | 9y      | no             |            |
| etcd-ca               | Dec 28, 2029 23:36 UTC | 9y      | no             |            |
| front-proxy-ca        | Dec 28, 2029 23:36 UTC | 9y      | no             |            |

The command shows expiration/residual time for the client certificates in the `/etc/kubernetes/pki` folder and for the client certificate embedded in the kubeconfig files used by kubeadm (`admin.conf`, `controller-manager.conf` and `scheduler.conf`).

Additionally, kubeadm informs the user if the certificate is externally managed; in this case, the user should take care of managing certificate renewal manually/using other tools.

### Warning:

kubeadm cannot manage certificates signed by an external CA.

### Note:

kubelet.conf is not included in the list above because kubeadm configures kubelet for [automatic certificate renewal](#) with rotatable certificates under `/var/lib/kubelet/pki`. To repair an expired kubelet client certificate see [Kubelet client certificate rotation fails](#).

### Warning:

On nodes created with kubeadm init, prior to kubeadm version 1.17, there is a [bug](#) where you manually have to modify the contents of kubelet.conf. After kubeadm init finishes, you should update kubelet.conf to point to the rotated kubelet client certificates, by replacing `client-certificate-data` and `client-key-data` with:

```
client-certificate: /var/lib/kubelet/pki/kubelet-client-current.pem
client-key: /var/lib/kubelet/pki/kubelet-client-current.pem
```

## Automatic certificate renewal

kubeadm renews all the certificates during control plane [upgrade](#).

This feature is designed for addressing the simplest use cases; if you don't have specific requirements on certificate renewal and perform Kubernetes version upgrades regularly (less than 1 year in between each upgrade), kubeadm will take care of keeping your cluster up to date and reasonably secure.

### Note:

It is a best practice to upgrade your cluster frequently in order to stay secure.

If you have more complex requirements for certificate renewal, you can opt out from the default behavior by passing `--certificate-renewal=false` to `kubeadm upgrade apply` or to `kubeadm upgrade node`.

### Warning:

Prior to `kubeadm` version 1.17 there is a [bug](#) where the default value for `--certificate-renewal` is false for the `kubeadm upgrade node` command. In that case, you should explicitly set `--certificate-renewal=true`.

## Manual certificate renewal

You can renew your certificates manually at any time with the `kubeadm certs renew` command, with the appropriate command line options.

This command performs the renewal using CA (or front-proxy-CA) certificate and key stored in `/etc/kubernetes/pki`.

After running the command you should restart the control plane Pods. This is required since dynamic certificate reload is currently not supported for all components and certificates. [Static Pods](#) are managed by the local kubelet and not by the API Server, thus `kubectl` cannot be used to delete and restart them. To restart a static Pod you can temporarily remove its manifest file from `/etc/kubernetes/manifests/` and wait for 20 seconds (see the `fileCheckFrequency` value in [KubeletConfiguration struct](#)). The kubelet will terminate the Pod if it's no longer in the manifest directory. You can then move the file back and after another `fileCheckFrequency` period, the kubelet will recreate the Pod and the certificate renewal for the component can complete.

### Warning:

If you are running an HA cluster, this command needs to be executed on all the control-plane nodes.

### Note:

`certs renew` uses the existing certificates as the authoritative source for attributes (Common Name, Organization, SAN, etc.) instead of the `kubeadm-config` ConfigMap. It is strongly recommended to keep them both in sync.

`kubeadm certs renew` can renew any specific certificate or, with the subcommand `all`, it can renew all of them, as shown below:

```
kubeadm certs renew all
```

### Note:

Clusters built with `kubeadm` often copy the `admin.conf` certificate into `$HOME/.kube/config`, as instructed in [Creating a cluster with kubeadm](#). On such a system, to update the contents of `$HOME/.kube/config` after renewing the `admin.conf`, you must run the following commands:

```
sudo cp -i /etc/kubernetes/admin.conf $HOME/.kube/config
sudo chown $(id -u):$(id -g) $HOME/.kube/config
```

# Renew certificates with the Kubernetes certificates API

This section provides more details about how to execute manual certificate renewal using the Kubernetes certificates API.

## Caution:

These are advanced topics for users who need to integrate their organization's certificate infrastructure into a kubeadm-built cluster. If the default kubeadm configuration satisfies your needs, you should let kubeadm manage certificates instead.

## Set up a signer

The Kubernetes Certificate Authority does not work out of the box. You can configure an external signer such as [cert-manager](#), or you can use the built-in signer.

The built-in signer is part of [kube-controller-manager](#).

To activate the built-in signer, you must pass the `--cluster-signing-cert-file` and `--cluster-signing-key-file` flags.

If you're creating a new cluster, you can use a kubeadm [configuration file](#):

```
apiVersion: kubeadm.k8s.io/v1beta3
kind: ClusterConfiguration
controllerManager:
 extraArgs:
 cluster-signing-cert-file: /etc/kubernetes/pki/ca.crt
 cluster-signing-key-file: /etc/kubernetes/pki/ca.key
```

## Create certificate signing requests (CSR)

See [Create CertificateSigningRequest](#) for creating CSRs with the Kubernetes API.

# Renew certificates with external CA

This section provide more details about how to execute manual certificate renewal using an external CA.

To better integrate with external CAs, kubeadm can also produce certificate signing requests (CSRs). A CSR represents a request to a CA for a signed certificate for a client. In kubeadm terms, any certificate that would normally be signed by an on-disk CA can be produced as a CSR instead. A CA, however, cannot be produced as a CSR.

## Renewal by using certificate signing requests (CSR)

Renewal of ceritficates is possible by generating new CSRs and signing them with the external CA. For more details about working with CSRs generated by kubeadm see the section [Signing certificate signing requests \(CSR\) generated by kubeadm](#).

# Certificate authority (CA) rotation

Kubeadm does not support rotation or replacement of CA certificates out of the box.

For more information about manual rotation or replacement of CA, see [manual rotation of CA certificates](#).

## Enabling signed kubelet serving certificates

By default the kubelet serving certificate deployed by kubeadm is self-signed. This means a connection from external services like the [metrics-server](#) to a kubelet cannot be secured with TLS.

To configure the kubelets in a new kubeadm cluster to obtain properly signed serving certificates you must pass the following minimal configuration to kubeadm init:

```
apiVersion: kubeadm.k8s.io/v1beta3
kind: ClusterConfiguration

apiVersion: kubelet.config.k8s.io/v1beta1
kind: KubeletConfiguration
serverTLSBootstrap: true
```

If you have already created the cluster you must adapt it by doing the following:

- Find and edit the kubelet-config-1.30 ConfigMap in the kube-system namespace. In that ConfigMap, the kubelet key has a [KubeletConfiguration](#) document as its value. Edit the KubeletConfiguration document to set serverTLSBootstrap: true.
- On each node, add the serverTLSBootstrap: true field in /var/lib/kubelet/config.yaml and restart the kubelet with systemctl restart kubelet

The field serverTLSBootstrap: true will enable the bootstrap of kubelet serving certificates by requesting them from the certificates.k8s.io API. One known limitation is that the CSRs (Certificate Signing Requests) for these certificates cannot be automatically approved by the default signer in the kube-controller-manager - [kubernetes.io/kubelet-serving](#). This will require action from the user or a third party controller.

These CSRs can be viewed using:

```
kubectl get csr
```

| NAME      | AGE   | SIGNERNAME                    | REQUESTOR                   | CONDITION |
|-----------|-------|-------------------------------|-----------------------------|-----------|
| csr-9wvgt | 112s  | kubernetes.io/kubelet-serving | system:node:worker-1        | Pending   |
| csr-lz97v | 1m58s | kubernetes.io/kubelet-serving | system:node:control-plane-1 | Pending   |

To approve them you can do the following:

```
kubectl certificate approve <CSR-name>
```

By default, these serving certificate will expire after one year. Kubeadm sets the KubeletConfiguration field rotateCertificates to true, which means that close to expiration a new set of CSRs for the serving certificates will be created and must be approved to complete the rotation. To understand more see [Certificate Rotation](#).

If you are looking for a solution for automatic approval of these CSRs it is recommended that you contact your cloud provider and ask if they have a CSR signer that verifies the node identity with an out of band mechanism.

**Note:** This section links to third party projects that provide functionality required by Kubernetes. The Kubernetes project authors aren't responsible for these projects, which are listed alphabetically. To add a project to this list, read the [content guide](#) before submitting a change. [More information](#).

Third party custom controllers can be used:

- [kubelet-csr-approver](#)

Such a controller is not a secure mechanism unless it not only verifies the CommonName in the CSR but also verifies the requested IPs and domain names. This would prevent a malicious actor that has access to a kubelet client certificate to create CSRs requesting serving certificates for any IP or domain name.

## Generating kubeconfig files for additional users

During cluster creation, kubeadm signs the certificate in the admin.conf to have Subject: O = system:masters, CN = kubernetes-admin. [system:masters](#) is a break-glass, super user group that bypasses the authorization layer (for example, [RBAC](#)). Sharing the admin.conf with additional users is **not recommended**!

Instead, you can use the [kubeadm kubeconfig user](#) command to generate kubeconfig files for additional users. The command accepts a mixture of command line flags and [kubeadm configuration](#) options. The generated kubeconfig will be written to stdout and can be piped to a file using `kubeadm kubeconfig user ... > somefile.conf`.

Example configuration file that can be used with `--config`:

```
example.yaml
apiVersion: kubeadm.k8s.io/v1beta3
kind: ClusterConfiguration
Will be used as the target "cluster" in the kubeconfig
clusterName: "kubernetes"
Will be used as the "server" (IP or DNS name) of this cluster in the kubeconfig
controlPlaneEndpoint: "some-dns-address:6443"
The cluster CA key and certificate will be loaded from this local directory
certificatesDir: "/etc/kubernetes/pki"
```

Make sure that these settings match the desired target cluster settings. To see the settings of an existing cluster use:

```
kubectl get cm kubeadm-config -n kube-system -o=jsonpath="{.data.ClusterConfiguration}"
```

The following example will generate a kubeconfig file with credentials valid for 24 hours for a new user johndoe that is part of the appdevs group:

```
kubeadm kubeconfig user --config example.yaml --org appdevs --client-name johndoe --
validity-period 24h
```

The following example will generate a kubeconfig file with administrator credentials valid for 1 week:

```
kubeadm kubeconfig user --config example.yaml --client-name admin --validity-period 168h
```

## Signing certificate signing requests (CSR) generated by kubeadm

You can create certificate signing requests with `kubeadm certs generate-csr`. Calling this command will generate `.csr` / `.key` file pairs for regular certificates. For certificates embedded in kubeconfig files, the command will generate a `.csr` / `.conf` pair where the key is already embedded in the `.conf` file.

A CSR file contains all relevant information for a CA to sign a certificate. kubeadm uses a [well defined specification](#) for all its certificates and CSRs.

The default certificate directory is `/etc/kubernetes/pki`, while the default directory for kubeconfig files is `/etc/kubernetes`. These defaults can be overridden with the flags `--cert-dir` and `--kubeconfig-dir`, respectively.

To pass custom options to `kubeadm certs generate-csr` use the `--config` flag, which accepts a [kubeadm configuration](#) file, similarly to commands such as `kubeadm init`. Any specification such as extra SANs and custom IP addresses must be stored in the same configuration file and used for all relevant kubeadm commands by passing it as `--config`.

### Note:

This guide will cover the usage of the `openssl` command for signing the CSRs, but you can use your preferred tools.

### Note:

This guide will use the default Kubernetes directory `/etc/kubernetes`, which requires a super user. If you are following this guide with permissive directories (by passing `--cert-dir` and `--kubeconfig-dir`) you can omit the `sudo` command). But note that the resulted files must be copied to the `/etc/kubernetes` tree, so that `kubeadm init` or `kubeadm join` will find them.

## Preparing CA and service account files

On the primary control plane node, where `kubeadm init` will be executed, call the following commands:

```
sudo kubeadm init phase certs ca
sudo kubeadm init phase certs etcd-ca
sudo kubeadm init phase certs front-proxy-ca
sudo kubeadm init phase certs sa
```

This will populate the folders `/etc/kubernetes/pki` and `/etc/kubernetes/pki/etcd` with all self-signed CA files (certificates and keys) and service account (public and private keys) that kubeadm needs for a control plane node.

**Note:**

If you are using an external CA, you must generate the same files out of band and manually copy them to the primary control plane node in `/etc/kubernetes`. Once all CSRs are signed, you can delete the root CA key (`ca.key`) as noted in the [External CA mode](#) section.

For secondary control plane nodes (`kubeadm join --control-plane`) there is no need to call the above commands. Depending on how you setup the [High Availability](#) cluster, you either have to manually copy the same files from the primary control plane node, or use the automated `--upload-certs` functionality of `kubeadm init`.

## Generate CSRs

The `kubeadm certs generate-csr` command generates CSRs for all known certificates managed by `kubeadm`. Once the command is done you must manually delete `.csr`, `.conf` or `.key` files that you don't need.

## Considerations for kubelet.conf

This section applies to both control plane and worker nodes.

If you have deleted the `ca.key` file from control plane nodes ([External CA mode](#)), the active kube-controller-manager in this cluster will not be able to sign kubelet client certificates. If no external method for signing these certificates exists in your setup (such as an [external signer](#), you could manually sign the `kubelet.conf.csr` as explained in this guide.

Note that this also means that the automatic [kubelet client certificate rotation](#) will be disabled. If so, close to certificate expiration, you must generate a new `kubelet.conf.csr`, sign the certificate, embed it in `kubelet.conf` and restart the kubelet.

If this does not apply to your setup, you can skip processing the `kubelet.conf.csr` on secondary control plane and on workers nodes (all nodes that call `kubeadm join ...`). That is because the active kube-controller-manager will be responsible for signing new kubelet client certificates.

**Note:**

Processing the `kubelet.conf.csr` on the primary control plane node (`kubeadm init`) is required, because that is considered the node that bootstraps the cluster and a pre-populated `kubelet.conf` is needed.

## Control plane nodes

Execute the following command on primary (`kubeadm init`) and secondary (`kubeadm join --control-plane`) control plane nodes to generate all CSR files:

```
sudo kubeadm certs generate-csr
```

If external etcd is to be used, follow the [External etcd with kubeadm](#) guide to understand what CSR files are needed on the `kubeadm` and `etcd` nodes. Other `.csr` and `.key` files under `/etc/kubernetes/pki/etcd` can be removed.

Based on the explanation in [Considerations for kubelet.conf](#) keep or delete the kubelet.conf and kubelet.conf.csr files.

## Worker nodes

Based on the explanation in [Considerations for kubelet.conf](#), optionally call:

```
sudo kubeadm certs generate-csr
```

and keep only the kubelet.conf and kubelet.conf.csr files. Alternatively skip the steps for worker nodes entirely.

## Signing CSRs for all certificates

### Note:

If you are using external CA and already have CA serial number files (.srl) for openssl you can copy such files to a kubeadm node where CSRs will be processed. .srl files to copy are /etc/kubernetes/pki/ca.srl, /etc/kubernetes/pki/front-proxy-ca.srl and /etc/kubernetes/pki/etcd/ca.srl. The files can be then moved to a new node where CSR files will be processed.

If a .srl file is missing for a CA on a node, the script below will generate a new SRL file with a random starting serial number.

To read more about .srl files see the [openssl](#) documentation for the --CAserial flag.

Repeat this step for all nodes that have CSR files.

Write the following script in the /etc/kubernetes directory, navigate to the directory and execute the script. The script will generate certificates for all CSR files that are present in the /etc/kubernetes tree.

```
#!/bin/bash

Set certificate expiration time in days
DAYS=365

Process all CSR files except those for front-proxy and etcd
find ./ -name "*.csr" | grep -v "pki/etcd" | grep -v "front-proxy" | while read -r FILE;
do
 echo "* Processing ${FILE} ..."
 FILE=${FILE%.*} # Trim the extension
 if [-f "./pki/ca.srl"]; then
 SERIAL_FLAG="-CAserial ./pki/ca.srl"
 else
 SERIAL_FLAG="-CAcreateserial"
 fi
 openssl x509 -req -days "${DAYS}" -CA ./pki/ca.crt -CAkey ./pki/ca.key ${SERIAL_FLAG} \
 -in "${FILE}.csr" -out "${FILE}.crt"
 sleep 2
done

Process all etcd CSRs
```

```

find ./pki/etcd -name "*.csr" | while read -r FILE;
do
 echo "* Processing ${FILE} ..."
 FILE=${FILE%.*} # Trim the extension
 if [-f "./pki/etcd/ca.srl"]; then
 SERIAL_FLAG=-CAserial ./pki/etcd/ca.srl
 else
 SERIAL_FLAG=-CAcreateserial
 fi
 openssl x509 -req -days "${DAYS}" -CA ./pki/etcd/ca.crt -CAkey ./pki/etcd/ca.key ${SERIAL_F
LAG} \
 -in "${FILE}.csr" -out "${FILE}.crt"
done

Process front-proxy CSRs
echo "* Processing ./pki/front-proxy-client.csr ..."
openssl x509 -req -days "${DAYS}" -CA ./pki/front-proxy-ca.crt -CAkey ./pki/front-proxy-ca.key
-CAcreateserial \
 -in ./pki/front-proxy-client.csr -out ./pki/front-proxy-client.crt

```

## Embedding certificates in kubeconfig files

Repeat this step for all nodes that have CSR files.

Write the following script in the /etc/kubernetes directory, navigate to the directory and execute the script. The script will take the .crt files that were signed for kubeconfig files from CSRs in the previous step and will embed them in the kubeconfig files.

```

#!/bin/bash

CLUSTER=kubernetes
find ./ -name "*.conf" | while read -r FILE;
do
 echo "* Processing ${FILE} ..."
 KUBECONFIG="${FILE}" kubectl config set-cluster "${CLUSTER}" --certificate-authority ./pki/
ca.crt --embed-certs
 USER=$(KUBECONFIG="${FILE}" kubectl config view -o jsonpath='{.users[0].name}')
 KUBECONFIG="${FILE}" kubectl config set-credentials "${USER}" --client-certificate "${FILE}.c
rt" --embed-certs
done

```

## Performing cleanup

Perform this step on all nodes that have CSR files.

Write the following script in the /etc/kubernetes directory, navigate to the directory and execute the script.

```

#!/bin/bash

Cleanup CSR files
rm -f ./*.csr ./pki/*.csr ./pki/etcd/*.csr # Clean all CSR files

```

```
Cleanup CRT files that were already embedded in kubeconfig files
rm -f ./*.crt
```

Optionally, move .srl files to the next node to be processed.

Optionally, if using external CA remove the /etc/kubernetes/pki/ca.key file, as explained in the [External CA node](#) section.

## kubeadm node initialization

Once CSR files have been signed and required certificates are in place on the hosts you want to use as nodes, you can use the commands `kubeadm init` and `kubeadm join` to create a Kubernetes cluster from these nodes. During init and join, kubeadm uses existing certificates, encryption keys and kubeconfig files that it finds in the /etc/kubernetes tree on the host's local filesystem.

# Configuring a cgroup driver

This page explains how to configure the kubelet's cgroup driver to match the container runtime cgroup driver for kubeadm clusters.

## Before you begin

You should be familiar with the Kubernetes [container runtime requirements](#).

## Configuring the container runtime cgroup driver

The [Container runtimes](#) page explains that the systemd driver is recommended for kubeadm based setups instead of the kubelet's [default](#) cgroupfs driver, because kubeadm manages the kubelet as a [systemd service](#).

The page also provides details on how to set up a number of different container runtimes with the systemd driver by default.

## Configuring the kubelet cgroup driver

kubeadm allows you to pass a KubeletConfiguration structure during kubeadm init. This KubeletConfiguration can include the cgroupDriver field which controls the cgroup driver of the kubelet.

### Note:

In v1.22 and later, if the user does not set the cgroupDriver field under KubeletConfiguration, kubeadm defaults it to systemd.

In Kubernetes v1.28, you can enable automatic detection of the cgroup driver as an alpha feature. See [systemd cgroup driver](#) for more details.

A minimal example of configuring the field explicitly:

```
kubeadm-config.yaml
kind: ClusterConfiguration
apiVersion: kubeadm.k8s.io/v1beta3
kubernetesVersion: v1.21.0

kind: KubeletConfiguration
apiVersion: kubelet.config.k8s.io/v1beta1
cgroupDriver: systemd
```

Such a configuration file can then be passed to the kubeadm command:

```
kubeadm init --config kubeadm-config.yaml
```

**Note:**

Kubeadm uses the same KubeletConfiguration for all nodes in the cluster. The KubeletConfiguration is stored in a [ConfigMap](#) object under the kube-system namespace.

Executing the sub commands init, join and upgrade would result in kubeadm writing the KubeletConfiguration as a file under /var/lib/kubelet/config.yaml and passing it to the local node kubelet.

## Using the cgroupfs driver

To use cgroupfs and to prevent kubeadm upgrade from modifying the KubeletConfiguration cgroup driver on existing setups, you must be explicit about its value. This applies to a case where you do not wish future versions of kubeadm to apply the systemd driver by default.

See the below section on "[Modify the kubelet ConfigMap](#)" for details on how to be explicit about the value.

If you wish to configure a container runtime to use the cgroupfs driver, you must refer to the documentation of the container runtime of your choice.

## Migrating to the systemd driver

To change the cgroup driver of an existing kubeadm cluster from cgroupfs to systemd in-place, a similar procedure to a kubelet upgrade is required. This must include both steps outlined below.

**Note:**

Alternatively, it is possible to replace the old nodes in the cluster with new ones that use the systemd driver. This requires executing only the first step below before joining the new nodes and ensuring the workloads can safely move to the new nodes before deleting the old nodes.

### Modify the kubelet ConfigMap

- Call `kubectrl edit cm kubelet-config -n kube-system`.
- Either modify the existing cgroupDriver value or add a new field that looks like this:

```
cgroupDriver: systemd
```

This field must be present under the kubelet: section of the ConfigMap.

## Update the cgroup driver on all nodes

For each node in the cluster:

- [Drain the node](#) using `kubectldrain <node-name> --ignore-daemonsets`
- Stop the kubelet using `systemctl stop kubelet`
- Stop the container runtime
- Modify the container runtime cgroup driver to `systemd`
- Set `cgroupDriver: systemd` in `/var/lib/kubelet/config.yaml`
- Start the container runtime
- Start the kubelet using `systemctl start kubelet`
- [Uncordon the node](#) using `kubectluncordon <node-name>`

Execute these steps on nodes one at a time to ensure workloads have sufficient time to schedule on different nodes.

Once the process is complete ensure that all nodes and workloads are healthy.

# Reconfiguring a kubeadm cluster

kubeadm does not support automated ways of reconfiguring components that were deployed on managed nodes. One way of automating this would be by using a custom [operator](#).

To modify the components configuration you must manually edit associated cluster objects and files on disk.

This guide shows the correct sequence of steps that need to be performed to achieve kubeadm cluster reconfiguration.

## Before you begin

- You need a cluster that was deployed using kubeadm
- Have administrator credentials (`/etc/kubernetes/admin.conf`) and network connectivity to a running kube-apiserver in the cluster from a host that has kubectl installed
- Have a text editor installed on all hosts

## Reconfiguring the cluster

kubeadm writes a set of cluster wide component configuration options in ConfigMaps and other objects. These objects must be manually edited. The command `kubectledit` can be used for that.

The `kubectledit` command will open a text editor where you can edit and save the object directly.

You can use the environment variables `KUBECONFIG` and `KUBE_EDITOR` to specify the location of the kubectl consumed kubeconfig file and preferred text editor.

For example:

```
KUBECONFIG=/etc/kubernetes/admin.conf KUBE_EDITOR=nano kubectl edit <parameters>
```

**Note:**

Upon saving any changes to these cluster objects, components running on nodes may not be automatically updated. The steps below instruct you on how to perform that manually.

**Warning:**

Component configuration in ConfigMaps is stored as unstructured data (YAML string). This means that validation will not be performed upon updating the contents of a ConfigMap. You have to be careful to follow the documented API format for a particular component configuration and avoid introducing typos and YAML indentation mistakes.

## Applying cluster configuration changes

### Updating the ClusterConfiguration

During cluster creation and upgrade, kubeadm writes its [ClusterConfiguration](#) in a ConfigMap called kubeadm-config in the kube-system namespace.

To change a particular option in the ClusterConfiguration you can edit the ConfigMap with this command:

```
kubectl edit cm -n kube-system kubeadm-config
```

The configuration is located under the data.ClusterConfiguration key.

**Note:**

The ClusterConfiguration includes a variety of options that affect the configuration of individual components such as kube-apiserver, kube-scheduler, kube-controller-manager, CoreDNS, etcd and kube-proxy. Changes to the configuration must be reflected on node components manually.

### Reflecting ClusterConfiguration changes on control plane nodes

kubeadm manages the control plane components as static Pod manifests located in the directory /etc/kubernetes/manifests. Any changes to the ClusterConfiguration under the apiServer, controllerManager, scheduler or etcd keys must be reflected in the associated files in the manifests directory on a control plane node.

Such changes may include:

- extraArgs - requires updating the list of flags passed to a component container
- extraMounts - requires updated the volume mounts for a component container
- \*SANs - requires writing new certificates with updated Subject Alternative Names.

Before proceeding with these changes, make sure you have backed up the directory /etc/kubernetes/.

To write new certificates you can use:

```
kubeadm init phase certs <component-name> --config <config-file>
```

To write new manifest files in `/etc/kubernetes/manifests` you can use:

```
For Kubernetes control plane components
kubeadm init phase control-plane <component-name> --config <config-file>
For local etcd
kubeadm init phase etcd local --config <config-file>
```

The `<config-file>` contents must match the updated `ClusterConfiguration`. The `<component-name>` value must be a name of a Kubernetes control plane component (apiserver, controller-manager or scheduler).

**Note:**

Updating a file in `/etc/kubernetes/manifests` will tell the kubelet to restart the static Pod for the corresponding component. Try doing these changes one node at a time to leave the cluster without downtime.

## Applying kubelet configuration changes

### Updating the KubeletConfiguration

During cluster creation and upgrade, kubeadm writes its [KubeletConfiguration](#) in a ConfigMap called `kubelet-config` in the `kube-system` namespace.

You can edit the ConfigMap with this command:

```
kubectrl edit cm -n kube-system kubelet-config
```

The configuration is located under the `data.kubelet` key.

### Reflecting the kubelet changes

To reflect the change on kubeadm nodes you must do the following:

- Log in to a kubeadm node
- Run `kubeadm upgrade node phase kubelet-config` to download the latest kubelet-config ConfigMap contents into the local file `/var/lib/kubelet/config.yaml`
- Edit the file `/var/lib/kubelet/kubeadm-flags.env` to apply additional configuration with flags
- Restart the kubelet service with `systemctl restart kubelet`

**Note:**

Do these changes one node at a time to allow workloads to be rescheduled properly.

**Note:**

During kubeadm upgrade, kubeadm downloads the KubeletConfiguration from the kubelet-config ConfigMap and overwrite the contents of /var/lib/kubelet/config.yaml. This means that node local configuration must be applied either by flags in /var/lib/kubelet/kubeadm-flags.env or by manually updating the contents of /var/lib/kubelet/config.yaml after kubeadm upgrade, and then restarting the kubelet.

## Applying kube-proxy configuration changes

### Updating the KubeProxyConfiguration

During cluster creation and upgrade, kubeadm writes its [KubeProxyConfiguration](#) in a ConfigMap in the kube-system namespace called kube-proxy.

This ConfigMap is used by the kube-proxy DaemonSet in the kube-system namespace.

To change a particular option in the KubeProxyConfiguration, you can edit the ConfigMap with this command:

```
kubectrl edit cm -n kube-system kube-proxy
```

The configuration is located under the data.config.conf key.

### Reflecting the kube-proxy changes

Once the kube-proxy ConfigMap is updated, you can restart all kube-proxy Pods:

Obtain the Pod names:

```
kubectrl get po -n kube-system | grep kube-proxy
```

Delete a Pod with:

```
kubectrl delete po -n kube-system <pod-name>
```

New Pods that use the updated ConfigMap will be created.

**Note:**

Because kubeadm deploys kube-proxy as a DaemonSet, node specific configuration is unsupported.

## Applying CoreDNS configuration changes

### Updating the CoreDNS Deployment and Service

kubeadm deploys CoreDNS as a Deployment called coredns and with a Service kube-dns, both in the kube-system namespace.

To update any of the CoreDNS settings, you can edit the Deployment and Service objects:

```
kubectl edit deployment -n kube-system coredns
kubectl edit service -n kube-system kube-dns
```

## Reflecting the CoreDNS changes

Once the CoreDNS changes are applied you can delete the CoreDNS Pods:

Obtain the Pod names:

```
kubectl get po -n kube-system | grep coredns
```

Delete a Pod with:

```
kubectl delete po -n kube-system <pod-name>
```

New Pods with the updated CoreDNS configuration will be created.

### Note:

kubeadm does not allow CoreDNS configuration during cluster creation and upgrade. This means that if you execute kubeadm upgrade apply, your changes to the CoreDNS objects will be lost and must be reapplied.

## Persisting the reconfiguration

During the execution of kubeadm upgrade on a managed node, kubeadm might overwrite configuration that was applied after the cluster was created (reconfiguration).

### Persisting Node object reconfiguration

kubeadm writes Labels, Taints, CRI socket and other information on the Node object for a particular Kubernetes node. To change any of the contents of this Node object you can use:

```
kubectl edit no <node-name>
```

During kubeadm upgrade the contents of such a Node might get overwritten. If you would like to persist your modifications to the Node object after upgrade, you can prepare a [kubectl patch](#) and apply it to the Node object:

```
kubectl patch no <node-name> --patch-file <patch-file>
```

### Persisting control plane component reconfiguration

The main source of control plane configuration is the ClusterConfiguration object stored in the cluster. To extend the static Pod manifests configuration, [patches](#) can be used.

These patch files must remain as files on the control plane nodes to ensure that they can be used by the kubeadm upgrade ... --patches <directory>.

If reconfiguration is done to the ClusterConfiguration and static Pod manifests on disk, the set of node specific patches must be updated accordingly.

## Persisting kubelet reconfiguration

Any changes to the KubeletConfiguration stored in `/var/lib/kubelet/config.yaml` will be overwritten on kubeadm upgrade by downloading the contents of the cluster wide kubelet-config ConfigMap. To persist kubelet node specific configuration either the file `/var/lib/kubelet/config.yaml` has to be updated manually post-upgrade or the file `/var/lib/kubelet/kubeadm-flags.env` can include flags. The kubelet flags override the associated KubeletConfiguration options, but note that some of the flags are deprecated.

A kubelet restart will be required after changing `/var/lib/kubelet/config.yaml` or `/var/lib/kubelet/kubeadm-flags.env`.

- [Certificate management with kubeadm](#)
- [Find more about kubeadm set-up](#)

# Upgrading kubeadm clusters

This page explains how to upgrade a Kubernetes cluster created with kubeadm from version 1.29.x to version 1.30.x, and from version 1.30.x to 1.30.y (where  $y > x$ ). Skipping MINOR versions when upgrading is unsupported. For more details, please visit [Version Skew Policy](#).

To see information about upgrading clusters created using older versions of kubeadm, please refer to following pages instead:

- [Upgrading a kubeadm cluster from 1.28 to 1.29](#)
- [Upgrading a kubeadm cluster from 1.27 to 1.28](#)
- [Upgrading a kubeadm cluster from 1.26 to 1.27](#)
- [Upgrading a kubeadm cluster from 1.25 to 1.26](#)

The upgrade workflow at high level is the following:

1. Upgrade a primary control plane node.
2. Upgrade additional control plane nodes.
3. Upgrade worker nodes.

## Before you begin

- Make sure you read the [release notes](#) carefully.
- The cluster should use a static control plane and etcd pods or external etcd.
- Make sure to back up any important components, such as app-level state stored in a database. kubeadm upgrade does not touch your workloads, only components internal to Kubernetes, but backups are always a best practice.
- [Swap must be disabled](#).

## Additional information

- The instructions below outline when to drain each node during the upgrade process. If you are performing a **minor** version upgrade for any kubelet, you **must** first drain the node (or nodes) that you are upgrading. In the case of control plane nodes, they could be running CoreDNS Pods or other critical workloads. For more information see [Draining nodes](#).
- The Kubernetes project recommends that you match your kubelet and kubeadm versions. You can instead use a version of kubelet that is older than kubeadm, provided it is within the range of supported versions. For more details, please visit [kubeadm's skew against the kubelet](#).
- All containers are restarted after upgrade, because the container spec hash value is changed.
- To verify that the kubelet service has successfully restarted after the kubelet has been upgraded, you can execute `systemctl status kubelet` or view the service logs with `journalctl -xeu kubelet`.
- Usage of the `--config` flag of kubeadm upgrade with [kubeadm configuration API types](#) with the purpose of reconfiguring the cluster is not recommended and can have unexpected results. Follow the steps in [Reconfiguring a kubeadm cluster](#) instead.

## Considerations when upgrading etcd

Because the kube-apiserver static pod is running at all times (even if you have drained the node), when you perform a kubeadm upgrade which includes an etcd upgrade, in-flight requests to the server will stall while the new etcd static pod is restarting. As a workaround, it is possible to actively stop the kube-apiserver process a few seconds before starting the kubeadm upgrade apply command. This permits to complete in-flight requests and close existing connections, and minimizes the consequence of the etcd downtime. This can be done as follows on control plane nodes:

```
killall -s SIGTERM kube-apiserver # trigger a graceful kube-apiserver shutdown
sleep 20 # wait a little bit to permit completing in-flight requests
kubeadm upgrade ... # execute a kubeadm upgrade command
```

## Changing the package repository

If you're using the community-owned package repositories (`pkgs.k8s.io`), you need to enable the package repository for the desired Kubernetes minor release. This is explained in [Changing the Kubernetes package repository](#) document.

**Note:** The legacy package repositories (`apt.kubernetes.io` and `yum.kubernetes.io`) have been [deprecated and frozen starting from September 13, 2023](#). **Using the [new package repositories hosted at `pkgs.k8s.io`](#) is strongly recommended and required in order to install Kubernetes versions released after September 13, 2023.** The deprecated legacy repositories, and their contents, might be removed at any time in the future and without a further notice period. The new package repositories provide downloads for Kubernetes versions starting with v1.24.0.

## Determine which version to upgrade to

Find the latest patch release for Kubernetes 1.30 using the OS package manager:

- [Ubuntu, Debian or HyprionOS](#)
- [CentOS, RHEL or Fedora](#)

```
Find the latest 1.30 version in the list.
It should look like 1.30.x-*, where x is the latest patch.
sudo apt update
sudo apt-cache madison kubeadm
```

```
Find the latest 1.30 version in the list.
It should look like 1.30.x-*, where x is the latest patch.
sudo yum list --showduplicates kubeadm --disableexcludes=kubernetes
```

## Upgrading control plane nodes

The upgrade procedure on control plane nodes should be executed one node at a time. Pick a control plane node that you wish to upgrade first. It must have the `/etc/kubernetes/admin.conf` file.

### Call "kubeadm upgrade"

#### For the first control plane node

1. Upgrade kubeadm:

- [Ubuntu, Debian or HyprionOS](#)
- [CentOS, RHEL or Fedora](#)

```
replace x in 1.30.x-* with the latest patch version
sudo apt-mark unhold kubeadm && \
sudo apt-get update && sudo apt-get install -y kubeadm='1.30.x-*' && \
sudo apt-mark hold kubeadm
```

```
replace x in 1.30.x-* with the latest patch version
sudo yum install -y kubeadm-'1.30.x-*' --disableexcludes=kubernetes
```

2. Verify that the download works and has the expected version:

```
kubeadm version
```

3. Verify the upgrade plan:

```
sudo kubeadm upgrade plan
```

This command checks that your cluster can be upgraded, and fetches the versions you can upgrade to. It also shows a table with the component config version states.

**Note:**

kubeadm upgrade also automatically renews the certificates that it manages on this node. To opt-out of certificate renewal the flag `--certificate-renewal=false` can be used. For more information see the [certificate management guide](#).

**Note:**

If kubeadm upgrade plan shows any component configs that require manual upgrade, users must provide a config file with replacement configs to kubeadm upgrade apply via the `--config` command line flag. Failing to do so will cause kubeadm upgrade apply to exit with an error and not perform an upgrade.

4. Choose a version to upgrade to, and run the appropriate command. For example:

```
replace x with the patch version you picked for this upgrade
sudo kubeadm upgrade apply v1.30.x
```

Once the command finishes you should see:

```
[upgrade/successful] SUCCESS! Your cluster was upgraded to "v1.30.x". Enjoy!
```

```
[upgrade/kubelet] Now that your control plane is upgraded, please proceed with
upgrading your kubelets if you haven't already done so.
```

**Note:**

For versions earlier than v1.28, kubeadm defaulted to a mode that upgrades the addons (including CoreDNS and kube-proxy) immediately during kubeadm upgrade apply, regardless of whether there are other control plane instances that have not been upgraded. This may cause compatibility problems. Since v1.28, kubeadm defaults to a mode that checks whether all the control plane instances have been upgraded before starting to upgrade the addons. You must perform control plane instances upgrade sequentially or at least ensure that the last control plane instance upgrade is not started until all the other control plane instances have been upgraded completely, and the addons upgrade will be performed after the last control plane instance is upgraded. If you want to keep the old upgrade behavior, please enable the `UpgradeAddonsBeforeControlPlane` feature gate by `kubeadm upgrade apply --feature-gates=UpgradeAddonsBeforeControlPlane=true`. The Kubernetes project does not in general recommend enabling this feature gate, you should instead change your upgrade process or cluster addons so that you do not need to enable the legacy behavior. The `UpgradeAddonsBeforeControlPlane` feature gate will be removed in a future release.

5. Manually upgrade your CNI provider plugin.

Your Container Network Interface (CNI) provider may have its own upgrade instructions to follow. Check the [addons](#) page to find your CNI provider and see whether additional upgrade steps are required.

This step is not required on additional control plane nodes if the CNI provider runs as a DaemonSet.

**For the other control plane nodes**

Same as the first control plane node but use:

```
sudo kubeadm upgrade node
```

instead of:

```
sudo kubeadm upgrade apply
```

Also calling `kubeadm upgrade plan` and upgrading the CNI provider plugin is no longer needed.

## Drain the node

Prepare the node for maintenance by marking it unschedulable and evicting the workloads:

```
replace <node-to-drain> with the name of your node you are draining
kubectl drain <node-to-drain> --ignore-daemonsets
```

## Upgrade kubelet and kubectl

1. Upgrade the kubelet and kubectl:

- [Ubuntu, Debian or HypriotOS](#)
- [CentOS, RHEL or Fedora](#)

```
replace x in 1.30.x-* with the latest patch version
sudo apt-mark unhold kubelet kubectl && \
sudo apt-get update && sudo apt-get install -y kubelet='1.30.x-*' kubectl='1.30.x-*' && \
sudo apt-mark hold kubelet kubectl
```

```
replace x in 1.30.x-* with the latest patch version
sudo yum install -y kubelet-'1.30.x-*' kubectl-'1.30.x-*' --disableexcludes=kubernetes
```

2. Restart the kubelet:

```
sudo systemctl daemon-reload
sudo systemctl restart kubelet
```

## Uncordon the node

Bring the node back online by marking it schedulable:

```
replace <node-to-uncordon> with the name of your node
kubectl uncordon <node-to-uncordon>
```

## Upgrade worker nodes

The upgrade procedure on worker nodes should be executed one node at a time or few nodes at a time, without compromising the minimum required capacity for running your workloads.

The following pages show how to upgrade Linux and Windows worker nodes:

- [Upgrade Linux nodes](#)
- [Upgrade Windows nodes](#)

## Verify the status of the cluster

After the kubelet is upgraded on all nodes verify that all nodes are available again by running the following command from anywhere kubectl can access the cluster:

```
kubectl get nodes
```

The STATUS column should show Ready for all your nodes, and the version number should be updated.

## Recovering from a failure state

If kubeadm upgrade fails and does not roll back, for example because of an unexpected shutdown during execution, you can run kubeadm upgrade again. This command is idempotent and eventually makes sure that the actual state is the desired state you declare.

To recover from a bad state, you can also run `sudo kubeadm upgrade apply --force` without changing the version that your cluster is running.

During upgrade kubeadm writes the following backup folders under `/etc/kubernetes/tmp`:

- `kubeadm-backup-etcd-<date>--<time>`
- `kubeadm-backup-manifests-<date>--<time>`

`kubeadm-backup-etcd` contains a backup of the local etcd member data for this control plane Node. In case of an etcd upgrade failure and if the automatic rollback does not work, the contents of this folder can be manually restored in `/var/lib/etcd`. In case external etcd is used this backup folder will be empty.

`kubeadm-backup-manifests` contains a backup of the static Pod manifest files for this control plane Node. In case of a upgrade failure and if the automatic rollback does not work, the contents of this folder can be manually restored in `/etc/kubernetes/manifests`. If for some reason there is no difference between a pre-upgrade and post-upgrade manifest file for a certain component, a backup file for it will not be written.

## How it works

`kubeadm upgrade apply` does the following:

- Checks that your cluster is in an upgradeable state:
  - The API server is reachable
  - All nodes are in the Ready state
  - The control plane is healthy
- Enforces the version skew policies.
- Makes sure the control plane images are available or available to pull to the machine.
- Generates replacements and/or uses user supplied overwrites if component configs require version upgrades.
- Upgrades the control plane components or rollbacks if any of them fails to come up.
- Applies the new CoreDNS and kube-proxy manifests and makes sure that all necessary RBAC rules are created.
- Creates new certificate and key files of the API server and backs up old files if they're about to expire in 180 days.

kubeadm upgrade node does the following on additional control plane nodes:

- Fetches the kubeadm ClusterConfiguration from the cluster.
- Optionally backups the kube-apiserver certificate.
- Upgrades the static Pod manifests for the control plane components.
- Upgrades the kubelet configuration for this node.

kubeadm upgrade node does the following on worker nodes:

- Fetches the kubeadm ClusterConfiguration from the cluster.
- Upgrades the kubelet configuration for this node.

## Upgrading Linux nodes

This page explains how to upgrade a Linux Worker Nodes created with kubeadm.

### Before you begin

You need to have shell access to all the nodes, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts.

To check the version, enter kubectl version.

- Familiarize yourself with [the process for upgrading the rest of your kubeadm cluster](#). You will want to upgrade the control plane nodes before upgrading your Linux Worker nodes.

### Changing the package repository

If you're using the community-owned package repositories (pkgs.k8s.io), you need to enable the package repository for the desired Kubernetes minor release. This is explained in [Changing the Kubernetes package repository](#) document.

**Note:** The legacy package repositories (apt.kubernetes.io and yum.kubernetes.io) have been [deprecated and frozen starting from September 13, 2023](#). **Using the [new package repositories hosted at pkgs.k8s.io](#) is strongly recommended and required in order to install Kubernetes versions released after September 13, 2023.** The deprecated legacy repositories, and their contents, might be removed at any time in the future and without a further notice period. The new package repositories provide downloads for Kubernetes versions starting with v1.24.0.

## Upgrading worker nodes

### Upgrade kubeadm

Upgrade kubeadm:

- [Ubuntu, Debian or HypriotOS](#)
- [CentOS, RHEL or Fedora](#)

```
replace x in 1.30.x-* with the latest patch version
sudo apt-mark unhold kubeadm && \
sudo apt-get update && sudo apt-get install -y kubeadm='1.30.x-*' && \
sudo apt-mark hold kubeadm
```

```
replace x in 1.30.x-* with the latest patch version
sudo yum install -y kubeadm-'1.30.x-*' --disableexcludes=kubernetes
```

## Call "kubeadm upgrade"

For worker nodes this upgrades the local kubelet configuration:

```
sudo kubeadm upgrade node
```

## Drain the node

Prepare the node for maintenance by marking it unschedulable and evicting the workloads:

```
execute this command on a control plane node
replace <node-to-drain> with the name of your node you are draining
kubectl drain <node-to-drain> --ignore-daemonsets
```

## Upgrade kubelet and kubectl

1. Upgrade the kubelet and kubectl:

- [Ubuntu, Debian or HyprionOS](#)
- [CentOS, RHEL or Fedora](#)

```
replace x in 1.30.x-* with the latest patch version
sudo apt-mark unhold kubelet kubectl && \
sudo apt-get update && sudo apt-get install -y kubelet='1.30.x-*' kubectl='1.30.x-*' && \
sudo apt-mark hold kubelet kubectl
```

```
replace x in 1.30.x-* with the latest patch version
sudo yum install -y kubelet-'1.30.x-*' kubectl-'1.30.x-*' --disableexcludes=kubernetes
```

2. Restart the kubelet:

```
sudo systemctl daemon-reload
sudo systemctl restart kubelet
```

## Uncordon the node

Bring the node back online by marking it schedulable:

```
execute this command on a control plane node
replace <node-to-uncordon> with the name of your node
kubectl uncordon <node-to-uncordon>
```

## What's next

- See how to [Upgrade Windows nodes](#).

# Upgrading Windows nodes

FEATURE STATE: Kubernetes v1.18 [beta]

This page explains how to upgrade a Windows node created with kubeadm.

## Before you begin

You need to have shell access to all the nodes, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts.

Your Kubernetes server must be at or later than version 1.17. To check the version, enter kubectl version.

- Familiarize yourself with [the process for upgrading the rest of your kubeadm cluster](#). You will want to upgrade the control plane nodes before upgrading your Windows nodes.

## Upgrading worker nodes

### Upgrade kubeadm

1. From the Windows node, upgrade kubeadm:

```
replace 1.30.0 with your desired version
curl.exe -Lo <path-to-kubeadm.exe> "https://dl.k8s.io/v1.30.0/bin/windows/amd64/kubeadm.exe"
```

### Drain the node

1. From a machine with access to the Kubernetes API, prepare the node for maintenance by marking it unschedulable and evicting the workloads:

```
replace <node-to-drain> with the name of your node you are draining
kubectl drain <node-to-drain> --ignore-daemonsets
```

You should see output similar to this:

```
node/ip-172-31-85-18 cordoned
node/ip-172-31-85-18 drained
```

### Upgrade the kubelet configuration

1. From the Windows node, call the following command to sync new kubelet configuration:

```
kubeadm upgrade node
```

## Upgrade kubelet and kube-proxy

1. From the Windows node, upgrade and restart the kubelet:

```
stop-service kubelet
curl.exe -Lo <path-to-kubelet.exe> "https://dl.k8s.io/v1.30.0/bin/windows/amd64/
kubelet.exe"
restart-service kubelet
```

2. From the Windows node, upgrade and restart the kube-proxy.

```
stop-service kube-proxy
curl.exe -Lo <path-to-kube-proxy.exe> "https://dl.k8s.io/v1.30.0/bin/windows/amd64/
kube-proxy.exe"
restart-service kube-proxy
```

### Note:

If you are running kube-proxy in a HostProcess container within a Pod, and not as a Windows Service, you can upgrade kube-proxy by applying a newer version of your kube-proxy manifests.

## Uncordon the node

1. From a machine with access to the Kubernetes API, bring the node back online by marking it schedulable:

```
replace <node-to-drain> with the name of your node
kubectl uncordon <node-to-drain>
```

## What's next

- See how to [Upgrade Linux nodes](#).

# Changing The Kubernetes Package Repository

This page explains how to enable a package repository for the desired Kubernetes minor release upon upgrading a cluster. This is only needed for users of the community-owned package repositories hosted at [pkgs.k8s.io](https://pkgs.k8s.io). Unlike the legacy package repositories, the community-owned package repositories are structured in a way that there's a dedicated package repository for each Kubernetes minor version.

### Note:

This guide only covers a part of the Kubernetes upgrade process. Please see the [upgrade guide](#) for more information about upgrading Kubernetes clusters.

## Note:

This step is only needed upon upgrading a cluster to another **minor** release. If you're upgrading to another patch release within the same minor release (e.g. v1.30.5 to v1.30.7), you don't need to follow this guide. However, if you're still using the legacy package repositories, you'll need to migrate to the new community-owned package repositories before upgrading (see the next section for more details on how to do this).

## Before you begin

This document assumes that you're already using the community-owned package repositories (pkgs.k8s.io). If that's not the case, it's strongly recommended to migrate to the community-owned package repositories as described in the [official announcement](#).

**Note:** The legacy package repositories (apt.kubernetes.io and yum.kubernetes.io) have been [deprecated and frozen starting from September 13, 2023](#). **Using the [new package repositories hosted at pkgs.k8s.io](#) is strongly recommended and required in order to install Kubernetes versions released after September 13, 2023.** The deprecated legacy repositories, and their contents, might be removed at any time in the future and without a further notice period. The new package repositories provide downloads for Kubernetes versions starting with v1.24.0.

## Verifying if the Kubernetes package repositories are used

If you're unsure whether you're using the community-owned package repositories or the legacy package repositories, take the following steps to verify:

- [Ubuntu, Debian or HyprIoTOS](#)
- [CentOS, RHEL or Fedora](#)
- [openSUSE or SLES](#)

Print the contents of the file that defines the Kubernetes apt repository:

```
On your system, this configuration file could have a different name
pager /etc/apt/sources.list.d/kubernetes.list
```

If you see a line similar to:

```
deb [signed-by=/etc/apt/keyrings/kubernetes-apt-keyring.gpg] https://pkgs.k8s.io/core:/stable:/v1.29/deb/ /
```

**You're using the Kubernetes package repositories and this guide applies to you.**

Otherwise, it's strongly recommended to migrate to the Kubernetes package repositories as described in the [official announcement](#).

Print the contents of the file that defines the Kubernetes yum repository:

```
On your system, this configuration file could have a different name
cat /etc/yum.repos.d/kubernetes.repo
```

If you see a baseurl similar to the baseurl in the output below:

```
[kubernetes]
name=Kubernetes
baseurl=https://pkgs.k8s.io/core:/stable:/v1.29/rpm/
enabled=1
gpgcheck=1
gpgkey=https://pkgs.k8s.io/core:/stable:/v1.29/rpm/repodata/repomd.xml.key
exclude=kubelet kubeadm kubectl
```

**You're using the Kubernetes package repositories and this guide applies to you.**

Otherwise, it's strongly recommended to migrate to the Kubernetes package repositories as described in the [official announcement](#).

Print the contents of the file that defines the Kubernetes zypper repository:

```
On your system, this configuration file could have a different name
cat /etc/zypp/repos.d/kubernetes.repo
```

If you see a baseurl similar to the baseurl in the output below:

```
[kubernetes]
name=Kubernetes
baseurl=https://pkgs.k8s.io/core:/stable:/v1.29/rpm/
enabled=1
gpgcheck=1
gpgkey=https://pkgs.k8s.io/core:/stable:/v1.29/rpm/repodata/repomd.xml.key
exclude=kubelet kubeadm kubectl
```

**You're using the Kubernetes package repositories and this guide applies to you.**

Otherwise, it's strongly recommended to migrate to the Kubernetes package repositories as described in the [official announcement](#).

#### Note:

The URL used for the Kubernetes package repositories is not limited to `pkgs.k8s.io`, it can also be one of:

- `pkgs.k8s.io`
- `pkgs.kubernetes.io`
- `packages.kubernetes.io`

## Switching to another Kubernetes package repository

This step should be done upon upgrading from one to another Kubernetes minor release in order to get access to the packages of the desired Kubernetes minor version.

- [Ubuntu, Debian or HypriotOS](#)
- [CentOS, RHEL or Fedora](#)

1. Open the file that defines the Kubernetes apt repository using a text editor of your choice:

```
nano /etc/apt/sources.list.d/kubernetes.list
```

You should see a single line with the URL that contains your current Kubernetes minor version. For example, if you're using v1.29, you should see this:

```
deb [signed-by=/etc/apt/keyrings/kubernetes-apt-keyring.gpg] https://pkgs.k8s.io/core:/stable:/v1.29/deb/ /
```

2. Change the version in the URL to **the next available minor release**, for example:

```
deb [signed-by=/etc/apt/keyrings/kubernetes-apt-keyring.gpg] https://pkgs.k8s.io/core:/stable:/v1.30/deb/ /
```

3. Save the file and exit your text editor. Continue following the relevant upgrade instructions.

1. Open the file that defines the Kubernetes yum repository using a text editor of your choice:

```
nano /etc/yum.repos.d/kubernetes.repo
```

You should see a file with two URLs that contain your current Kubernetes minor version. For example, if you're using v1.29, you should see this:

```
[kubernetes]
name=Kubernetes
baseurl=https://pkgs.k8s.io/core:/stable:/v1.29/rpm/
enabled=1
gpgcheck=1
gpgkey=https://pkgs.k8s.io/core:/stable:/v1.29/rpm/repodata/repomd.xml.key
exclude=kubelet kubeadm kubectl cri-tools kubernetes-cni
```

2. Change the version in these URLs to **the next available minor release**, for example:

```
[kubernetes]
name=Kubernetes
baseurl=https://pkgs.k8s.io/core:/stable:/v1.30/rpm/
enabled=1
gpgcheck=1
gpgkey=https://pkgs.k8s.io/core:/stable:/v1.30/rpm/repodata/repomd.xml.key
exclude=kubelet kubeadm kubectl cri-tools kubernetes-cni
```

3. Save the file and exit your text editor. Continue following the relevant upgrade instructions.

## What's next

- See how to [Upgrade Linux nodes](#).
- See how to [Upgrade Windows nodes](#).

## Migrating from dockershim

This section presents information you need to know when migrating from dockershim to other container runtimes.

Since the announcement of [dockershim deprecation](#) in Kubernetes 1.20, there were questions on how this will affect various workloads and Kubernetes installations. Our [Dockershim Removal FAQ](#) is there to help you to understand the problem better.

Dockershim was removed from Kubernetes with the release of v1.24. If you use Docker Engine via dockershim as your container runtime and wish to upgrade to v1.24, it is recommended that you either migrate to another runtime or find an alternative means to obtain Docker Engine support. Check out the [container runtimes](#) section to know your options.

The version of Kubernetes with dockershim (1.23) is out of support and the v1.24 will run out of support [soon](#). Make sure to [report issues](#) you encountered with the migration so the issues can be fixed in a timely manner and your cluster would be ready for dockershim removal. After v1.24 running out of support, you will need to contact your Kubernetes provider for support or upgrade multiple versions at a time if there are critical issues affecting your cluster.

Your cluster might have more than one kind of node, although this is not a common configuration.

These tasks will help you to migrate:

- [Check whether Dockershim removal affects you](#)
- [Migrate Docker Engine nodes from dockershim to cri-dockerd](#)
- [Migrating telemetry and security agents from dockershim](#)

## What's next

- Check out [container runtimes](#) to understand your options for an alternative.
- If you find a defect or other technical concern relating to migrating away from dockershim, you can [report an issue](#) to the Kubernetes project.

# Changing the Container Runtime on a Node from Docker Engine to containerd

This task outlines the steps needed to update your container runtime to containerd from Docker. It is applicable for cluster operators running Kubernetes 1.23 or earlier. This also covers an example scenario for migrating from dockershim to containerd. Alternative container runtimes can be picked from this [page](#).

## Before you begin

**Note:** This section links to third party projects that provide functionality required by Kubernetes. The Kubernetes project authors aren't responsible for these projects, which are listed alphabetically. To add a project to this list, read the [content guide](#) before submitting a change. [More information](#).

Install containerd. For more information see [containerd's installation documentation](#) and for specific prerequisite follow [the containerd guide](#).

## Drain the node

```
kubectcl drain <node-to-drain> --ignore-daemonsets
```

Replace <node-to-drain> with the name of your node you are draining.

## Stop the Docker daemon

```
systemctl stop kubelet
systemctl disable docker.service --now
```

## Install Containerd

Follow the [guide](#) for detailed steps to install containerd.

- [Linux](#)
- [Windows \(PowerShell\)](#)

1. Install the containerd.io package from the official Docker repositories. Instructions for setting up the Docker repository for your respective Linux distribution and installing the containerd.io package can be found at [Getting started with containerd](#).

2. Configure containerd:

```
sudo mkdir -p /etc/containerd
containerd config default | sudo tee /etc/containerd/config.toml
```

3. Restart containerd:

```
sudo systemctl restart containerd
```

Start a Powershell session, set \$Version to the desired version (ex: \$Version="1.4.3"), and then run the following commands:

1. Download containerd:

```
curl.exe -L https://github.com/containerd/containerd/releases/download/v$Version/
containerd-$Version-windows-amd64.tar.gz -o containerd-windows-amd64.tar.gz
tar.exe xvf .\containerd-windows-amd64.tar.gz
```

2. Extract and configure:

```
Copy-Item -Path ".\bin\" -Destination "$Env:ProgramFiles\containerd" -Recurse -Force
cd $Env:ProgramFiles\containerd\
.\containerd.exe config default | Out-File config.toml -Encoding ascii
```

```
Review the configuration. Depending on setup you may want to adjust:
- the sandbox_image (Kubernetes pause image)
- cni bin_dir and conf_dir locations
Get-Content config.toml
```

```
(Optional - but highly recommended) Exclude containerd from Windows Defender
```

```
Scans
Add-MpPreference -ExclusionProcess "$Env:ProgramFiles\containerd\containerd.exe"
```

3. Start containerd:

```
.\containerd.exe --register-service
Start-Service containerd
```

## Configure the kubelet to use containerd as its container runtime

Edit the file `/var/lib/kubelet/kubeadm-flags.env` and add the containerd runtime to the flags; `--container-runtime-endpoint=unix:///run/containerd/containerd.sock`.

Users using kubeadm should be aware that the kubeadm tool stores the CRI socket for each host as an annotation in the Node object for that host. To change it you can execute the following command on a machine that has the kubeadm `/etc/kubernetes/admin.conf` file.

```
kubectrl edit no <node-name>
```

This will start a text editor where you can edit the Node object. To choose a text editor you can set the `KUBE_EDITOR` environment variable.

- Change the value of `kubeadm.alpha.kubernetes.io/cri-socket` from `/var/run/dockershim.sock` to the CRI socket path of your choice (for example `unix:///run/containerd/containerd.sock`).

Note that new CRI socket paths must be prefixed with `unix://` ideally.

- Save the changes in the text editor, which will update the Node object.

## Restart the kubelet

```
systemctl start kubelet
```

## Verify that the node is healthy

Run `kubectrl get nodes -o wide` and containerd appears as the runtime for the node we just changed.

## Remove Docker Engine

**Note:** This section links to third party projects that provide functionality required by Kubernetes. The Kubernetes project authors aren't responsible for these projects, which are listed alphabetically. To add a project to this list, read the [content guide](#) before submitting a change. [More information](#).

If the node appears healthy, remove Docker.

- [CentOS](#)
- [Debian](#)

- [Fedora](#)
- [Ubuntu](#)

```
sudo yum remove docker-ce docker-ce-cli
```

```
sudo apt-get purge docker-ce docker-ce-cli
```

```
sudo dnf remove docker-ce docker-ce-cli
```

```
sudo apt-get purge docker-ce docker-ce-cli
```

The preceding commands don't remove images, containers, volumes, or customized configuration files on your host. To delete them, follow Docker's instructions to [Uninstall Docker Engine](#).

### Caution:

Docker's instructions for uninstalling Docker Engine create a risk of deleting containerd. Be careful when executing commands.

## Uncordon the node

```
kubectrl uncordon <node-to-uncordon>
```

Replace `<node-to-uncordon>` with the name of your node you previously drained.

# Migrate Docker Engine nodes from dockershim to cri-dockerd

**Note:** This section links to third party projects that provide functionality required by Kubernetes. The Kubernetes project authors aren't responsible for these projects, which are listed alphabetically. To add a project to this list, read the [content guide](#) before submitting a change. [More information](#).

This page shows you how to migrate your Docker Engine nodes to use cri-dockerd instead of dockershim. You should follow these steps in these scenarios:

- You want to switch away from dockershim and still use Docker Engine to run containers in Kubernetes.
- You want to upgrade to Kubernetes v1.30 and your existing cluster relies on dockershim, in which case you must migrate from dockershim and cri-dockerd is one of your options.

To learn more about the removal of dockershim, read the [FAQ page](#).

## What is cri-dockerd?

In Kubernetes 1.23 and earlier, you could use Docker Engine with Kubernetes, relying on a built-in component of Kubernetes named *dockershim*. The dockershim component was removed in the Kubernetes 1.24 release; however, a third-party replacement, cri-dockerd, is available. The cri-dockerd adapter lets you use Docker Engine through the [Container Runtime Interface](#).

## Note:

If you already use `cri-dockerd`, you aren't affected by the dockershim removal. Before you begin, [Check whether your nodes use the dockershim](#).

If you want to migrate to `cri-dockerd` so that you can continue using Docker Engine as your container runtime, you should do the following for each affected node:

1. Install `cri-dockerd`.
2. Cordon and drain the node.
3. Configure the kubelet to use `cri-dockerd`.
4. Restart the kubelet.
5. Verify that the node is healthy.

Test the migration on non-critical nodes first.

You should perform the following steps for each node that you want to migrate to `cri-dockerd`.

## Before you begin

- [cri-dockerd](#) installed and started on each node.
- A [network plugin](#).

## Cordon and drain the node

1. Cordon the node to stop new Pods scheduling on it:

```
kubectl cordon <NODE_NAME>
```

Replace `<NODE_NAME>` with the name of the node.

2. Drain the node to safely evict running Pods:

```
kubectl drain <NODE_NAME> \
--ignore-daemonsets
```

## Configure the kubelet to use cri-dockerd

The following steps apply to clusters set up using the `kubeadm` tool. If you use a different tool, you should modify the kubelet using the configuration instructions for that tool.

1. Open `/var/lib/kubelet/kubeadm-flags.env` on each affected node.
2. Modify the `--container-runtime-endpoint` flag to `unix:///var/run/cri-dockerd.sock`.
3. Modify the `--container-runtime` flag to `remote` (unavailable in Kubernetes v1.27 and later).

The `kubeadm` tool stores the node's socket as an annotation on the Node object in the control plane. To modify this socket for each affected node:

1. Edit the YAML representation of the Node object:

```
KUBECONFIG=/path/to/admin.conf kubectl edit no <NODE_NAME>
```

Replace the following:

- `/path/to/admin.conf`: the path to the kubectl configuration file, `admin.conf`.
  - `<NODE_NAME>`: the name of the node you want to modify.
2. Change `kubeadm.alpha.kubernetes.io/cri-socket` from `/var/run/dockershim.sock` to `unix:///var/run/cri-dockerd.sock`.
  3. Save the changes. The Node object is updated on save.

## Restart the kubelet

```
systemctl restart kubelet
```

## Verify that the node is healthy

To check whether the node uses the cri-dockerd endpoint, follow the instructions in [Find out which runtime you use](#). The `--container-runtime-endpoint` flag for the kubelet should be `unix:///var/run/cri-dockerd.sock`.

## Uncordon the node

Uncordon the node to let Pods schedule on it:

```
kubectl uncordon <NODE_NAME>
```

## What's next

- Read the [dockershim removal FAQ](#).
- [Learn how to migrate from Docker Engine with dockershim to containerd](#).

# Find Out What Container Runtime is Used on a Node

This page outlines steps to find out what [container runtime](#) the nodes in your cluster use.

Depending on the way you run your cluster, the container runtime for the nodes may have been pre-configured or you need to configure it. If you're using a managed Kubernetes service, there might be vendor-specific ways to check what container runtime is configured for the nodes. The method described on this page should work whenever the execution of kubectl is allowed.

## Before you begin

Install and configure kubectl. See [Install Tools](#) section for details.

## Find out the container runtime used on a Node

Use `kubectl` to fetch and show node information:

```
kubectl get nodes -o wide
```

The output is similar to the following. The column `CONTAINER-RUNTIME` outputs the runtime and its version.

For Docker Engine, the output is similar to this:

| NAME   | STATUS | VERSION  | CONTAINER-RUNTIME |
|--------|--------|----------|-------------------|
| node-1 | Ready  | v1.16.15 | docker://19.3.1   |
| node-2 | Ready  | v1.16.15 | docker://19.3.1   |
| node-3 | Ready  | v1.16.15 | docker://19.3.1   |

If your runtime shows as Docker Engine, you still might not be affected by the removal of dockershim in Kubernetes v1.24. [Check the runtime endpoint](#) to see if you use dockershim. If you don't use dockershim, you aren't affected.

For containerd, the output is similar to this:

| NAME   | STATUS | VERSION | CONTAINER-RUNTIME  |
|--------|--------|---------|--------------------|
| node-1 | Ready  | v1.19.6 | containerd://1.4.1 |
| node-2 | Ready  | v1.19.6 | containerd://1.4.1 |
| node-3 | Ready  | v1.19.6 | containerd://1.4.1 |

Find out more information about container runtimes on [Container Runtimes](#) page.

## Find out what container runtime endpoint you use

The container runtime talks to the kubelet over a Unix socket using the [CRI protocol](#), which is based on the gRPC framework. The kubelet acts as a client, and the runtime acts as the server. In some cases, you might find it useful to know which socket your nodes use. For example, with the removal of dockershim in Kubernetes v1.24 and later, you might want to know whether you use Docker Engine with dockershim.

### Note:

If you currently use Docker Engine in your nodes with `cri-dockerd`, you aren't affected by the dockershim removal.

You can check which socket you use by checking the kubelet configuration on your nodes.

1. Read the starting commands for the kubelet process:

```
tr '\0 ' < /proc/"$(pgrep kubelet)"/cmdline
```

If you don't have `tr` or `pgrep`, check the command line for the kubelet process manually.

In the output, look for the `--container-runtime` flag and the `--container-runtime-endpoint` 2. flag.

- If your nodes use Kubernetes v1.23 and earlier and these flags aren't present or if the `--container-runtime` flag is not remote, you use the dockershim socket with Docker Engine. The `--container-runtime` command line argument is not available in Kubernetes v1.27 and later.
- If the `--container-runtime-endpoint` flag is present, check the socket name to find out which runtime you use. For example, `unix:///run/containerd/containerd.sock` is the containerd endpoint.

If you want to change the Container Runtime on a Node from Docker Engine to containerd, you can find out more information on [migrating from Docker Engine to containerd](#), or, if you want to continue using Docker Engine in Kubernetes v1.24 and later, migrate to a CRI-compatible adapter like [cri-dockerd](#).

## Troubleshooting CNI plugin-related errors

To avoid CNI plugin-related errors, verify that you are using or upgrading to a container runtime that has been tested to work correctly with your version of Kubernetes.

### About the "Incompatible CNI versions" and "Failed to destroy network for sandbox" errors

Service issues exist for pod CNI network setup and tear down in containerd v1.6.0-v1.6.3 when the CNI plugins have not been upgraded and/or the CNI config version is not declared in the CNI config files. The containerd team reports, "these issues are resolved in containerd v1.6.4."

With containerd v1.6.0-v1.6.3, if you do not upgrade the CNI plugins and/or declare the CNI config version, you might encounter the following "Incompatible CNI versions" or "Failed to destroy network for sandbox" error conditions.

#### Incompatible CNI versions error

If the version of your CNI plugin does not correctly match the plugin version in the config because the config version is later than the plugin version, the containerd log will likely show an error message on startup of a pod similar to:

```
incompatible CNI versions; config is \"1.0.0\", plugin supports [\"0.1.0\" \"0.2.0\" \"0.3.0\" \"0.3.1\" \"0.4.0\"]
```

To fix this issue, [update your CNI plugins and CNI config files](#).

#### Failed to destroy network for sandbox error

If the version of the plugin is missing in the CNI plugin config, the pod may run. However, stopping the pod generates an error similar to:

```
ERROR[2022-04-26T00:43:24.518165483Z] StopPodSandbox for "b" failed
error="failed to destroy network for sandbox"
```

```
\\"bbc85f891eaf060c5a879e27bba9b6b06450210161dfdecfb2732959fb6500a\\": invalid version \\"\\":
the version is empty"
```

This error leaves the pod in the not-ready state with a network namespace still attached. To recover from this problem, [edit the CNI config file](#) to add the missing version information. The next attempt to stop the pod should be successful.

## Updating your CNI plugins and CNI config files

If you're using containerd v1.6.0-v1.6.3 and encountered "Incompatible CNI versions" or "Failed to destroy network for sandbox" errors, consider updating your CNI plugins and editing the CNI config files.

Here's an overview of the typical steps for each node:

1. [Safely drain and cordon the node](#).
2. After stopping your container runtime and kubelet services, perform the following upgrade operations:
  - If you're running CNI plugins, upgrade them to the latest version.
  - If you're using non-CNI plugins, replace them with CNI plugins. Use the latest version of the plugins.
  - Update the plugin configuration file to specify or match a version of the CNI specification that the plugin supports, as shown in the following ["An example containerd configuration file"](#) section.
  - For containerd, ensure that you have installed the latest version (v1.0.0 or later) of the CNI loopback plugin.
  - Upgrade node components (for example, the kubelet) to Kubernetes v1.24
  - Upgrade to or install the most current version of the container runtime.
1. Bring the node back into your cluster by restarting your container runtime and kubelet. Uncordon the node (`kubectl uncordon <nodename>`).

## An example containerd configuration file

The following example shows a configuration for containerd runtime v1.6.x, which supports a recent version of the CNI specification (v1.0.0).

Please see the documentation from your plugin and networking provider for further instructions on configuring your system.

On Kubernetes, containerd runtime adds a loopback interface, `lo`, to pods as a default behavior. The containerd runtime configures the loopback interface via a CNI plugin, `loopback`. The `loopback` plugin is distributed as part of the containerd release packages that have the `cni` designation. containerd v1.6.0 and later includes a CNI v1.0.0-compatible loopback plugin as well as other default CNI plugins. The configuration for the loopback plugin is done internally by containerd, and is set to use CNI v1.0.0. This also means that the version of the loopback plugin must be v1.0.0 or later when this newer version containerd is started.

The following bash command generates an example CNI config. Here, the 1.0.0 value for the config version is assigned to the `cniVersion` field for use when containerd invokes the CNI bridge plugin.

```
cat << EOF | tee /etc/cni/net.d/10-containerd-net.conflist
{
 "cniVersion": "1.0.0",
 "name": "containerd-net",
 "plugins": [
 {
 "type": "bridge",
 "bridge": "cni0",
 "isGateway": true,
 "ipMasq": true,
 "promiscMode": true,
 "ipam": {
 "type": "host-local",
 "ranges": [
 [
 {
 "subnet": "10.88.0.0/16"
 }
],
 [
 {
 "subnet": "2001:db8:4860::/64"
 }
]
],
 "routes": [
 { "dst": "0.0.0.0/0" },
 { "dst": "::/0" }
]
 }
 },
 {
 "type": "portmap",
 "capabilities": {"portMappings": true},
 "externalSetMarkChain": "KUBE-MARK-MASQ"
 }
]
}
EOF
```

Update the IP address ranges in the preceding example with ones that are based on your use case and network addressing plan.

## Check whether dockershim removal affects you

The dockershim component of Kubernetes allows the use of Docker as a Kubernetes's [container runtime](#). Kubernetes' built-in dockershim component was removed in release v1.24.

This page explains how your cluster could be using Docker as a container runtime, provides details on the role that dockershim plays when in use, and shows steps you can take to check whether any workloads could be affected by dockershim removal.

# Finding if your app has a dependencies on Docker

If you are using Docker for building your application containers, you can still run these containers on any container runtime. This use of Docker does not count as a dependency on Docker as a container runtime.

When alternative container runtime is used, executing Docker commands may either not work or yield unexpected output. This is how you can find whether you have a dependency on Docker:

1. Make sure no privileged Pods execute Docker commands (like `docker ps`), restart the Docker service (commands such as `systemctl restart docker.service`), or modify Docker-specific files such as `/etc/docker/daemon.json`.
2. Check for any private registries or image mirror settings in the Docker configuration file (like `/etc/docker/daemon.json`). Those typically need to be reconfigured for another container runtime.
3. Check that scripts and apps running on nodes outside of your Kubernetes infrastructure do not execute Docker commands. It might be:
  - SSH to nodes to troubleshoot;
  - Node startup scripts;
  - Monitoring and security agents installed on nodes directly.
4. Third-party tools that perform above mentioned privileged operations. See [Migrating telemetry and security agents from dockershim](#) for more information.
5. Make sure there are no indirect dependencies on dockershim behavior. This is an edge case and unlikely to affect your application. Some tooling may be configured to react to Docker-specific behaviors, for example, raise alert on specific metrics or search for a specific log message as part of troubleshooting instructions. If you have such tooling configured, test the behavior on a test cluster before migration.

## Dependency on Docker explained

A [container runtime](#) is software that can execute the containers that make up a Kubernetes pod. Kubernetes is responsible for orchestration and scheduling of Pods; on each node, the [kubelet](#) uses the container runtime interface as an abstraction so that you can use any compatible container runtime.

In its earliest releases, Kubernetes offered compatibility with one container runtime: Docker. Later in the Kubernetes project's history, cluster operators wanted to adopt additional container runtimes. The CRI was designed to allow this kind of flexibility - and the kubelet began supporting CRI. However, because Docker existed before the CRI specification was invented, the Kubernetes project created an adapter component, `dockershim`. The `dockershim` adapter allows the kubelet to interact with Docker as if Docker were a CRI compatible runtime.

You can read about it in [Kubernetes Containerd integration goes GA](#) blog post.

### Dockershim vs. CRI with Containerd

Switching to Containerd as a container runtime eliminates the middleman. All the same containers can be run by container runtimes like Containerd as before. But now, since containers schedule directly with the container runtime, they are not visible to Docker. So any Docker tooling or fancy UI you might have used before to check on these containers is no longer available.

You cannot get container information using `docker ps` or `docker inspect` commands. As you cannot list containers, you cannot get logs, stop containers, or execute something inside a container using `docker exec`.

#### Note:

If you're running workloads via Kubernetes, the best way to stop a container is through the Kubernetes API rather than directly through the container runtime (this advice applies for all container runtimes, not only Docker).

You can still pull images or build them using `docker build` command. But images built or pulled by Docker would not be visible to container runtime and Kubernetes. They needed to be pushed to some registry to allow them to be used by Kubernetes.

## Known issues

### Some filesystem metrics are missing and the metrics format is different

The Kubelet `/metrics/cadvisor` endpoint provides Prometheus metrics, as documented in [Metrics for Kubernetes system components](#). If you install a metrics collector that depends on that endpoint, you might see the following issues:

- The metrics format on the Docker node is `k8s_<container-name>_<pod-name>_<namespace>_<pod-uid>_<restart-count>` but the format on other runtime is different. For example, on containerd node it is `<container-id>`.
- Some filesystem metrics are missing, as follows:

```
container_fs_inodes_free
container_fs_inodes_total
container_fs_io_current
container_fs_io_time_seconds_total
container_fs_io_time_weighted_seconds_total
container_fs_limit_bytes
container_fs_read_seconds_total
container_fs_reads_merged_total
container_fs_sector_reads_total
container_fs_sector_writes_total
container_fs_usage_bytes
container_fs_write_seconds_total
container_fs_writes_merged_total
```

### Workaround

You can mitigate this issue by using [cAdvisor](#) as a standalone daemonset.

1. Find the latest [cAdvisor release](#) with the name pattern `vX.Y.Z-containerd-cri` (for example, `v0.42.0-containerd-cri`).
2. Follow the steps in [cAdvisor Kubernetes Daemonset](#) to create the daemonset.
3. Point the installed metrics collector to use the cAdvisor `/metrics` endpoint which provides the full set of [Prometheus container metrics](#).

Alternatives:

- Use alternative third party metrics collection solution.
- Collect metrics from the Kubelet summary API that is served at `/stats/summary`.

## What's next

- Read [Migrating from dockershim](#) to understand your next steps
- Read the [dockershim deprecation FAQ](#) article for more information.

# Migrating telemetry and security agents from dockershim

**Note:** This section links to third party projects that provide functionality required by Kubernetes. The Kubernetes project authors aren't responsible for these projects, which are listed alphabetically. To add a project to this list, read the [content guide](#) before submitting a change. [More information](#).

Kubernetes' support for direct integration with Docker Engine is deprecated and has been removed. Most apps do not have a direct dependency on runtime hosting containers. However, there are still a lot of telemetry and monitoring agents that have a dependency on Docker to collect containers metadata, logs, and metrics. This document aggregates information on how to detect these dependencies as well as links on how to migrate these agents to use generic tools or alternative runtimes.

## Telemetry and security agents

Within a Kubernetes cluster there are a few different ways to run telemetry or security agents. Some agents have a direct dependency on Docker Engine when they run as DaemonSets or directly on nodes.

### Why do some telemetry agents communicate with Docker Engine?

Historically, Kubernetes was written to work specifically with Docker Engine. Kubernetes took care of networking and scheduling, relying on Docker Engine for launching and running containers (within Pods) on a node. Some information that is relevant to telemetry, such as a pod name, is only available from Kubernetes components. Other data, such as container metrics, is not the responsibility of the container runtime. Early telemetry agents needed to query the container runtime *and* Kubernetes to report an accurate picture. Over time, Kubernetes gained the ability to support multiple runtimes, and now supports any runtime that is compatible with the [container runtime interface](#).

Some telemetry agents rely specifically on Docker Engine tooling. For example, an agent might run a command such as [docker ps](#) or [docker top](#) to list containers and processes or [docker logs](#) to receive streamed logs. If nodes in your existing cluster use Docker Engine, and you switch to a different container runtime, these commands will not work any longer.

## Identify DaemonSets that depend on Docker Engine

If a pod wants to make calls to the dockerd running on the node, the pod must either:

- mount the filesystem containing the Docker daemon's privileged socket, as a [volume](#); or
- mount the specific path of the Docker daemon's privileged socket directly, also as a volume.

For example: on COS images, Docker exposes its Unix domain socket at `/var/run/docker.sock`. This means that the pod spec will include a `hostPath` volume mount of `/var/run/docker.sock`.

Here's a sample shell script to find Pods that have a mount directly mapping the Docker socket. This script outputs the namespace and name of the pod. You can remove the `grep '/var/run/docker.sock'` to review other mounts.

```
kubectl get pods --all-namespaces \
-o=jsonpath='{range .items[*]}{"\n"}{{.metadata.namespace}}{"\t"}{{.metadata.name}}{"\t"}\n{{range .spec.volumes[*]}}{{.hostPath.path}}", "{end}}{end}}' \
| sort \
| grep '/var/run/docker.sock'
```

### Note:

There are alternative ways for a pod to access Docker on the host. For instance, the parent directory `/var/run` may be mounted instead of the full path (like in [this example](#)). The script above only detects the most common uses.

## Detecting Docker dependency from node agents

If your cluster nodes are customized and install additional security and telemetry agents on the node, check with the agent vendor to verify whether it has any dependency on Docker.

## Telemetry and security agent vendors

This section is intended to aggregate information about various telemetry and security agents that may have a dependency on container runtimes.

We keep the work in progress version of migration instructions for various telemetry and security agent vendors in [Google doc](#). Please contact the vendor to get up to date instructions for migrating from dockershim.

## Migration from dockershim

### [Aqua](#)

No changes are needed: everything should work seamlessly on the runtime switch.

## Datadog

How to migrate: [Docker deprecation in Kubernetes](#) The pod that accesses Docker Engine may have a name containing any of:

- datadog-agent
- datadog
- dd-agent

## Dynatrace

How to migrate: [Migrating from Docker-only to generic container metrics in Dynatrace](#)

Containerd support announcement: [Get automated full-stack visibility into containerd-based Kubernetes environments](#)

CRI-O support announcement: [Get automated full-stack visibility into your CRI-O Kubernetes containers \(Beta\)](#)

The pod accessing Docker may have name containing:

- dynatrace-oneagent

## Falco

How to migrate:

[Migrate Falco from dockershim](#) Falco supports any CRI-compatible runtime (containerd is used in the default configuration); the documentation explains all details. The pod accessing Docker may have name containing:

- falco

## Prisma Cloud Compute

Check [documentation for Prisma Cloud](#), under the "Install Prisma Cloud on a CRI (non-Docker) cluster" section. The pod accessing Docker may be named like:

- twistlock-defender-ds

## SignalFx (Splunk)

The SignalFx Smart Agent (deprecated) uses several different monitors for Kubernetes including kubernetes-cluster, kubelet-stats/kubelet-metrics, and docker-container-stats. The kubelet-stats monitor was previously deprecated by the vendor, in favor of kubelet-metrics. The docker-container-stats monitor is the one affected by dockershim removal. Do not use the docker-container-stats with container runtimes other than Docker Engine.

How to migrate from dockershim-dependent agent:

1. Remove docker-container-stats from the list of [configured monitors](#). Note, keeping this monitor enabled with non-dockershim runtime will result in incorrect metrics being reported when docker is installed on node and no metrics when docker is not installed.

2. [Enable and configure kubelet-metrics](#) monitor.

**Note:**

The set of collected metrics will change. Review your alerting rules and dashboards.

The Pod accessing Docker may be named something like:

- `signalfx-agent`

## Yahoo Kubectl Flame

Flame does not support container runtimes other than Docker. See <https://github.com/yahoo/kubectl-flame/issues/51>

# Generate Certificates Manually

When using client certificate authentication, you can generate certificates manually through [easysrsa](#), [openssl](#) or [cfssl](#).

## easysrsa

**easysrsa** can manually generate certificates for your cluster.

1. Download, unpack, and initialize the patched version of easysrsa3.

```
curl -LO https://dl.k8s.io/easy-rsa/easy-rsa.tar.gz
tar xzf easy-rsa.tar.gz
cd easy-rsa-master/easysrsa3
./easysrsa init-pki
```

2. Generate a new certificate authority (CA). `--batch` sets automatic mode; `--req-cn` specifies the Common Name (CN) for the CA's new root certificate.

```
./easysrsa --batch "--req-cn=${MASTER_IP}@`date +%s`" build-ca nopass
```

3. Generate server certificate and key.

The argument `--subject-alt-name` sets the possible IPs and DNS names the API server will be accessed with. The `MASTER_CLUSTER_IP` is usually the first IP from the service CIDR that is specified as the `--service-cluster-ip-range` argument for both the API server and the controller manager component. The argument `--days` is used to set the number of days after which the certificate expires. The sample below also assumes that you are using `cluster.local` as the default DNS domain name.

```
./easysrsa --subject-alt-name="IP:${MASTER_IP},\
"IP:${MASTER_CLUSTER_IP},\
"DNS:kubernetes,\
"DNS:kubernetes.default,\
"DNS:kubernetes.default.svc,\
"DNS:kubernetes.default.svc.cluster,\
"DNS:kubernetes.default.svc.cluster.local" \
```

```
--days=10000 \
build-server-full server nopass
```

4. Copy pki/ca.crt, pki/issued/server.crt, and pki/private/server.key to your directory.
5. Fill in and add the following parameters into the API server start parameters:

```
--client-ca-file=/yourdirectory/ca.crt
--tls-cert-file=/yourdirectory/server.crt
--tls-private-key-file=/yourdirectory/server.key
```

## openssl

**openssl** can manually generate certificates for your cluster.

1. Generate a ca.key with 2048bit:

```
openssl genrsa -out ca.key 2048
```

2. According to the ca.key generate a ca.crt (use -days to set the certificate effective time):

```
openssl req -x509 -new -nodes -key ca.key -subj "/CN=${MASTER_IP}" -days 10000 -out
ca.crt
```

3. Generate a server.key with 2048bit:

```
openssl genrsa -out server.key 2048
```

4. Create a config file for generating a Certificate Signing Request (CSR).

Be sure to substitute the values marked with angle brackets (e.g. <MASTER\_IP>) with real values before saving this to a file (e.g. csr.conf). Note that the value for MASTER\_CLUSTER\_IP is the service cluster IP for the API server as described in previous subsection. The sample below also assumes that you are using cluster.local as the default DNS domain name.

```
[req]
default_bits = 2048
prompt = no
default_md = sha256
req_extensions = req_ext
distinguished_name = dn

[dn]
C = <country>
ST = <state>
L = <city>
O = <organization>
OU = <organization unit>
CN = <MASTER_IP>

[req_ext]
subjectAltName = @alt_names
```

```
[alt_names]
DNS.1 = kubernetes
DNS.2 = kubernetes.default
DNS.3 = kubernetes.default.svc
DNS.4 = kubernetes.default.svc.cluster
DNS.5 = kubernetes.default.svc.cluster.local
IP.1 = <MASTER_IP>
IP.2 = <MASTER_CLUSTER_IP>

[v3_ext]
authorityKeyIdentifier=keyid,issuer:always
basicConstraints=CA:FALSE
keyUsage=keyEncipherment,dataEncipherment
extendedKeyUsage=serverAuth,clientAuth
subjectAltName=@alt_names
```

5. Generate the certificate signing request based on the config file:

```
openssl req -new -key server.key -out server.csr -config csr.conf
```

6. Generate the server certificate using the ca.key, ca.crt and server.csr:

```
openssl x509 -req -in server.csr -CA ca.crt -CAkey ca.key \
-CACreateserial -out server.crt -days 10000 \
-extensions v3_ext -extfile csr.conf -sha256
```

7. View the certificate signing request:

```
openssl req -noout -text -in ./server.csr
```

8. View the certificate:

```
openssl x509 -noout -text -in ./server.crt
```

Finally, add the same parameters into the API server start parameters.

## cfssl

**cfssl** is another tool for certificate generation.

1. Download, unpack and prepare the command line tools as shown below.

Note that you may need to adapt the sample commands based on the hardware architecture and cfssl version you are using.

```
curl -L https://github.com/cloudflare/cfssl/releases/download/v1.5.0/
cfssl_1.5.0_linux_amd64 -o cfssl
chmod +x cfssl
curl -L https://github.com/cloudflare/cfssl/releases/download/v1.5.0/
cfssljson_1.5.0_linux_amd64 -o cfssljson
chmod +x cfssljson
curl -L https://github.com/cloudflare/cfssl/releases/download/v1.5.0/cfssl-
certinfo_1.5.0_linux_amd64 -o cfssl-certinfo
chmod +x cfssl-certinfo
```

Create a directory to hold the artifacts and initialize cfssl:

2.

```
mkdir cert
cd cert
../cfssl print-defaults config > config.json
../cfssl print-defaults csr > csr.json
```

3. Create a JSON config file for generating the CA file, for example, `ca-config.json`:

```
{
 "signing": {
 "default": {
 "expiry": "8760h"
 },
 "profiles": {
 "kubernetes": {
 "usages": [
 "signing",
 "key encipherment",
 "server auth",
 "client auth"
],
 "expiry": "8760h"
 }
 }
 }
}
```

4. Create a JSON config file for CA certificate signing request (CSR), for example, `ca-csr.json`. Be sure to replace the values marked with angle brackets with real values you want to use.

```
{
 "CN": "kubernetes",
 "key": {
 "algo": "rsa",
 "size": 2048
 },
 "names": [{
 "C": "<country>",
 "ST": "<state>",
 "L": "<city>",
 "O": "<organization>",
 "OU": "<organization unit>"
 }]
}
```

5. Generate CA key (`ca-key.pem`) and certificate (`ca.pem`):

```
../cfssl gencert -initca ca-csr.json | ../cfssljason -bare ca
```

6. Create a JSON config file for generating keys and certificates for the API server, for example, `server-csr.json`. Be sure to replace the values in angle brackets with real values you want to use. The `<MASTER_CLUSTER_IP>` is the service cluster IP for the API server

as described in previous subsection. The sample below also assumes that you are using cluster.local as the default DNS domain name.

```
{
 "CN": "kubernetes",
 "hosts": [
 "127.0.0.1",
 "<MASTER_IP>",
 "<MASTER_CLUSTER_IP>",
 "kubernetes",
 "kubernetes.default",
 "kubernetes.default.svc",
 "kubernetes.default.svc.cluster",
 "kubernetes.default.svc.cluster.local"
],
 "key": {
 "algo": "rsa",
 "size": 2048
 },
 "names": [{
 "C": "<country>",
 "ST": "<state>",
 "L": "<city>",
 "O": "<organization>",
 "OU": "<organization unit>"
 }]
}
```

7. Generate the key and certificate for the API server, which are by default saved into file server-key.pem and server.pem respectively:

```
../cfssl gencert -ca=ca.pem -ca-key=ca-key.pem \
 --config=ca-config.json -profile=kubernetes \
 server-csr.json | ../cfssljson -bare server
```

## Distributing Self-Signed CA Certificate

A client node may refuse to recognize a self-signed CA certificate as valid. For a non-production deployment, or for a deployment that runs behind a company firewall, you can distribute a self-signed CA certificate to all clients and refresh the local list for valid certificates.

On each client, perform the following operations:

```
sudo cp ca.crt /usr/local/share/ca-certificates/kubernetes.crt
sudo update-ca-certificates
```

```
Updating certificates in /etc/ssl/certs...
1 added, 0 removed; done.
Running hooks in /etc/ca-certificates/update.d....
done.
```

## Certificates API

You can use the `certificates.k8s.io` API to provision x509 certificates to use for authentication as documented in the [Managing TLS in a cluster](#) task page.

# Manage Memory, CPU, and API Resources

---

### [Configure Default Memory Requests and Limits for a Namespace](#)

Define a default memory resource limit for a namespace, so that every new Pod in that namespace has a memory resource limit configured.

### [Configure Default CPU Requests and Limits for a Namespace](#)

Define a default CPU resource limits for a namespace, so that every new Pod in that namespace has a CPU resource limit configured.

### [Configure Minimum and Maximum Memory Constraints for a Namespace](#)

Define a range of valid memory resource limits for a namespace, so that every new Pod in that namespace falls within the range you configure.

### [Configure Minimum and Maximum CPU Constraints for a Namespace](#)

Define a range of valid CPU resource limits for a namespace, so that every new Pod in that namespace falls within the range you configure.

### [Configure Memory and CPU Quotas for a Namespace](#)

Define overall memory and CPU resource limits for a namespace.

### [Configure a Pod Quota for a Namespace](#)

Restrict how many Pods you can create within a namespace.

## Configure Default Memory Requests and Limits for a Namespace

Define a default memory resource limit for a namespace, so that every new Pod in that namespace has a memory resource limit configured.

This page shows how to configure default memory requests and limits for a [namespace](#).

A Kubernetes cluster can be divided into namespaces. Once you have a namespace that has a default memory [limit](#), and you then try to create a Pod with a container that does not specify its own memory limit, then the [control plane](#) assigns the default memory limit to that container.

Kubernetes assigns a default memory request under certain conditions that are explained later in this topic.

## Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

You must have access to create namespaces in your cluster.

Each node in your cluster must have at least 2 GiB of memory.

## Create a namespace

Create a namespace so that the resources you create in this exercise are isolated from the rest of your cluster.

```
kubectl create namespace default-mem-example
```

## Create a LimitRange and a Pod

Here's a manifest for an example [LimitRange](#). The manifest specifies a default memory request and a default memory limit.

[admin/resource/memory-defaults.yaml](#)

```
apiVersion: v1
kind: LimitRange
metadata:
 name: mem-limit-range
spec:
 limits:
 - default:
 memory: 512Mi
 defaultRequest:
 memory: 256Mi
 type: Container
```

Create the `LimitRange` in the `default-mem-example` namespace:

```
kubectl apply -f https://k8s.io/examples/admin/resource/memory-defaults.yaml --namespace=default-mem-example
```

Now if you create a Pod in the `default-mem-example` namespace, and any container within that Pod does not specify its own values for memory request and memory limit, then the [control plane](#) applies default values: a memory request of 256MiB and a memory limit of 512MiB.

Here's an example manifest for a Pod that has one container. The container does not specify a memory request and limit.

[admin/resource/memory-defaults-pod.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: default-mem-demo
spec:
 containers:
 - name: default-mem-demo-ctr
 image: nginx
```

Create the Pod.

```
kubectl apply -f https://k8s.io/examples/admin/resource/memory-defaults-pod.yaml --
namespace=default-mem-example
```

View detailed information about the Pod:

```
kubectl get pod default-mem-demo --output=yaml --namespace=default-mem-example
```

The output shows that the Pod's container has a memory request of 256 MiB and a memory limit of 512 MiB. These are the default values specified by the LimitRange.

```
containers:
- image: nginx
 imagePullPolicy: Always
 name: default-mem-demo-ctr
 resources:
 limits:
 memory: 512Mi
 requests:
 memory: 256Mi
```

Delete your Pod:

```
kubectl delete pod default-mem-demo --namespace=default-mem-example
```

## What if you specify a container's limit, but not its request?

Here's a manifest for a Pod that has one container. The container specifies a memory limit, but not a request:

[admin/resource/memory-defaults-pod-2.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: default-mem-demo-2
spec:
```

```
containers:
- name: default-mem-demo-2-ctr
 image: nginx
 resources:
 limits:
 memory: "1Gi"
```

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/admin/resource/memory-defaults-pod-2.yaml --
namespace=default-mem-example
```

View detailed information about the Pod:

```
kubectl get pod default-mem-demo-2 --output=yaml --namespace=default-mem-example
```

The output shows that the container's memory request is set to match its memory limit. Notice that the container was not assigned the default memory request value of 256Mi.

```
resources:
 limits:
 memory: 1Gi
 requests:
 memory: 1Gi
```

## What if you specify a container's request, but not its limit?

Here's a manifest for a Pod that has one container. The container specifies a memory request, but not a limit:

[admin/resource/memory-defaults-pod-3.yaml](https://k8s.io/examples/admin/resource/memory-defaults-pod-3.yaml)

```
apiVersion: v1
kind: Pod
metadata:
 name: default-mem-demo-3
spec:
 containers:
 - name: default-mem-demo-3-ctr
 image: nginx
 resources:
 requests:
 memory: "128Mi"
```

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/admin/resource/memory-defaults-pod-3.yaml --
namespace=default-mem-example
```

View the Pod's specification:

```
kubectl get pod default-mem-demo-3 --output=yaml --namespace=default-mem-example
```

The output shows that the container's memory request is set to the value specified in the container's manifest. The container is limited to use no more than 512MiB of memory, which matches the default memory limit for the namespace.

```
resources:
 limits:
 memory: 512Mi
 requests:
 memory: 128Mi
```

#### Note:

A LimitRange does **not** check the consistency of the default values it applies. This means that a default value for the *limit* that is set by LimitRange may be less than the *request* value specified for the container in the spec that a client submits to the API server. If that happens, the final Pod will not be scheduleable. See [Constraints on resource limits and requests](#) for more details.

## Motivation for default memory limits and requests

If your namespace has a memory [resource quota](#) configured, it is helpful to have a default value in place for memory limit. Here are three of the restrictions that a resource quota imposes on a namespace:

- For every Pod that runs in the namespace, the Pod and each of its containers must have a memory limit. (If you specify a memory limit for every container in a Pod, Kubernetes can infer the Pod-level memory limit by adding up the limits for its containers).
- Memory limits apply a resource reservation on the node where the Pod in question is scheduled. The total amount of memory reserved for all Pods in the namespace must not exceed a specified limit.
- The total amount of memory actually used by all Pods in the namespace must also not exceed a specified limit.

When you add a LimitRange:

If any Pod in that namespace that includes a container does not specify its own memory limit, the control plane applies the default memory limit to that container, and the Pod can be allowed to run in a namespace that is restricted by a memory ResourceQuota.

## Clean up

Delete your namespace:

```
kubectl delete namespace default-mem-example
```

## What's next

# Configure Default CPU Requests and Limits for a Namespace

Define a default CPU resource limits for a namespace, so that every new Pod in that namespace has a CPU resource limit configured.

This page shows how to configure default CPU requests and limits for a [namespace](#).

A Kubernetes cluster can be divided into namespaces. If you create a Pod within a namespace that has a default CPU [limit](#), and any container in that Pod does not specify its own CPU limit, then the [control plane](#) assigns the default CPU limit to that container.

Kubernetes assigns a default CPU [request](#), but only under certain conditions that are explained later in this page.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

You must have access to create namespaces in your cluster.

If you're not already familiar with what Kubernetes means by 1.0 CPU, read [meaning of CPU](#).

## Create a namespace

Create a namespace so that the resources you create in this exercise are isolated from the rest of your cluster.

```
kubectl create namespace default-cpu-example
```

## Create a LimitRange and a Pod

Here's a manifest for an example [LimitRange](#). The manifest specifies a default CPU request and a default CPU limit.

[admin/resource/cpu-defaults.yaml](#)

```
apiVersion: v1
kind: LimitRange
metadata:
 name: cpu-limit-range
spec:
 limits:
 - default:
 cpu: 1
 defaultRequest:
 cpu: 0.5
 type: Container
```

Create the LimitRange in the default-cpu-example namespace:

```
kubectl apply -f https://k8s.io/examples/admin/resource/cpu-defaults.yaml --namespace=default-cpu-example
```

Now if you create a Pod in the default-cpu-example namespace, and any container in that Pod does not specify its own values for CPU request and CPU limit, then the control plane applies default values: a CPU request of 0.5 and a default CPU limit of 1.

Here's a manifest for a Pod that has one container. The container does not specify a CPU request and limit.

[admin/resource/cpu-defaults-pod.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: default-cpu-demo
spec:
 containers:
 - name: default-cpu-demo-ctr
 image: nginx
```

Create the Pod.

```
kubectl apply -f https://k8s.io/examples/admin/resource/cpu-defaults-pod.yaml --namespace=default-cpu-example
```

View the Pod's specification:

```
kubectl get pod default-cpu-demo --output=yaml --namespace=default-cpu-example
```

The output shows that the Pod's only container has a CPU request of 500m cpu (which you can read as "500 millicpu"), and a CPU limit of 1 cpu. These are the default values specified by the LimitRange.

```
containers:
- image: nginx
 imagePullPolicy: Always
 name: default-cpu-demo-ctr
 resources:
 limits:
 cpu: "1"
 requests:
 cpu: 500m
```

## What if you specify a container's limit, but not its request?

Here's a manifest for a Pod that has one container. The container specifies a CPU limit, but not a request:

[admin/resource/cpu-defaults-pod-2.yaml](https://k8s.io/examples/admin/resource/cpu-defaults-pod-2.yaml)

```
apiVersion: v1
kind: Pod
metadata:
 name: default-cpu-demo-2
spec:
 containers:
 - name: default-cpu-demo-2-ctr
 image: nginx
 resources:
 limits:
 cpu: "1"
```

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/admin/resource/cpu-defaults-pod-2.yaml --
namespace=default-cpu-example
```

View the [specification](#) of the Pod that you created:

```
kubectl get pod default-cpu-demo-2 --output=yaml --namespace=default-cpu-example
```

The output shows that the container's CPU request is set to match its CPU limit. Notice that the container was not assigned the default CPU request value of 0.5 cpu:

```
resources:
 limits:
 cpu: "1"
 requests:
 cpu: "1"
```

# What if you specify a container's request, but not its limit?

Here's an example manifest for a Pod that has one container. The container specifies a CPU request, but not a limit:

[admin/resource/cpu-defaults-pod-3.yaml](https://k8s.io/examples/admin/resource/cpu-defaults-pod-3.yaml)

```
apiVersion: v1
kind: Pod
metadata:
 name: default-cpu-demo-3
spec:
 containers:
 - name: default-cpu-demo-3-ctr
 image: nginx
 resources:
 requests:
 cpu: "0.75"
```

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/admin/resource/cpu-defaults-pod-3.yaml --
namespace=default-cpu-example
```

View the specification of the Pod that you created:

```
kubectl get pod default-cpu-demo-3 --output=yaml --namespace=default-cpu-example
```

The output shows that the container's CPU request is set to the value you specified at the time you created the Pod (in other words: it matches the manifest). However, the same container's CPU limit is set to 1 cpu, which is the default CPU limit for that namespace.

```
resources:
 limits:
 cpu: "1"
 requests:
 cpu: 750m
```

## Motivation for default CPU limits and requests

If your namespace has a CPU [resource quota](#) configured, it is helpful to have a default value in place for CPU limit. Here are two of the restrictions that a CPU resource quota imposes on a namespace:

- For every Pod that runs in the namespace, each of its containers must have a CPU limit.
- CPU limits apply a resource reservation on the node where the Pod in question is scheduled. The total amount of CPU that is reserved for use by all Pods in the namespace must not exceed a specified limit.

When you add a LimitRange:

If any Pod in that namespace that includes a container does not specify its own CPU limit, the control plane applies the default CPU limit to that container, and the Pod can be allowed to run in a namespace that is restricted by a CPU ResourceQuota.

## Clean up

Delete your namespace:

```
kubectl delete namespace default-cpu-example
```

## What's next

### For cluster administrators

- [Configure Default Memory Requests and Limits for a Namespace](#)
- [Configure Minimum and Maximum Memory Constraints for a Namespace](#)
- [Configure Minimum and Maximum CPU Constraints for a Namespace](#)
- [Configure Memory and CPU Quotas for a Namespace](#)

# Configure Minimum and Maximum Memory Constraints for a Namespace

Define a range of valid memory resource limits for a namespace, so that every new Pod in that namespace falls within the range you configure.

This page shows how to set minimum and maximum values for memory used by containers running in a [namespace](#). You specify minimum and maximum memory values in a [LimitRange](#) object. If a Pod does not meet the constraints imposed by the LimitRange, it cannot be created in the namespace.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at

least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

You must have access to create namespaces in your cluster.

Each node in your cluster must have at least 1 GiB of memory available for Pods.

## Create a namespace

Create a namespace so that the resources you create in this exercise are isolated from the rest of your cluster.

```
kubectl create namespace constraints-mem-example
```

## Create a LimitRange and a Pod

Here's an example manifest for a LimitRange:

[admin/resource/memory-constraints.yaml](#)

```
apiVersion: v1
kind: LimitRange
metadata:
 name: mem-min-max-demo-lr
spec:
 limits:
 - max:
 memory: 1Gi
 min:
 memory: 500Mi
 type: Container
```

Create the LimitRange:

```
kubectl apply -f https://k8s.io/examples/admin/resource/memory-constraints.yaml --
namespace=constraints-mem-example
```

View detailed information about the LimitRange:

```
kubectl get limitrange mem-min-max-demo-lr --namespace=constraints-mem-example --
output=yaml
```

The output shows the minimum and maximum memory constraints as expected. But notice that even though you didn't specify default values in the configuration file for the LimitRange, they were created automatically.

```
limits:
- default:
 memory: 1Gi
 defaultRequest:
```

```
memory: 1Gi
max:
 memory: 1Gi
min:
 memory: 500Mi
type: Container
```

Now whenever you define a Pod within the constraints-mem-example namespace, Kubernetes performs these steps:

- If any container in that Pod does not specify its own memory request and limit, the control plane assigns the default memory request and limit to that container.
- Verify that every container in that Pod requests at least 500 MiB of memory.
- Verify that every container in that Pod requests no more than 1024 MiB (1 GiB) of memory.

Here's a manifest for a Pod that has one container. Within the Pod spec, the sole container specifies a memory request of 600 MiB and a memory limit of 800 MiB. These satisfy the minimum and maximum memory constraints imposed by the LimitRange.

[admin/resource/memory-constraints-pod.yaml](https://k8s.io/examples/admin/resource/memory-constraints-pod.yaml)

```
apiVersion: v1
kind: Pod
metadata:
 name: constraints-mem-demo
spec:
 containers:
 - name: constraints-mem-demo-ctr
 image: nginx
 resources:
 limits:
 memory: "800Mi"
 requests:
 memory: "600Mi"
```

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/admin/resource/memory-constraints-pod.yaml --
namespace=constraints-mem-example
```

Verify that the Pod is running and that its container is healthy:

```
kubectl get pod constraints-mem-demo --namespace=constraints-mem-example
```

View detailed information about the Pod:

```
kubectl get pod constraints-mem-demo --output=yaml --namespace=constraints-mem-example
```

The output shows that the container within that Pod has a memory request of 600 MiB and a memory limit of 800 MiB. These satisfy the constraints imposed by the LimitRange for this namespace:

```
resources:
 limits:
 memory: 800Mi
 requests:
 memory: 600Mi
```

Delete your Pod:

```
kubectl delete pod constraints-mem-demo --namespace=constraints-mem-example
```

## Attempt to create a Pod that exceeds the maximum memory constraint

Here's a manifest for a Pod that has one container. The container specifies a memory request of 800 MiB and a memory limit of 1.5 GiB.

[admin/resource/memory-constraints-pod-2.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: constraints-mem-demo-2
spec:
 containers:
 - name: constraints-mem-demo-2-ctr
 image: nginx
 resources:
 limits:
 memory: "1.5Gi"
 requests:
 memory: "800Mi"
```

Attempt to create the Pod:

```
kubectl apply -f https://k8s.io/examples/admin/resource/memory-constraints-pod-2.yaml --namespace=constraints-mem-example
```

The output shows that the Pod does not get created, because it defines a container that requests more memory than is allowed:

```
Error from server (Forbidden): error when creating "examples/admin/resource/memory-constraints-pod-2.yaml":
pods "constraints-mem-demo-2" is forbidden: maximum memory usage per Container is 1Gi, but limit is 1536Mi.
```

## Attempt to create a Pod that does not meet the minimum memory request

Here's a manifest for a Pod that has one container. That container specifies a memory request of 100 MiB and a memory limit of 800 MiB.

[admin/resource/memory-constraints-pod-3.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: constraints-mem-demo-3
spec:
 containers:
 - name: constraints-mem-demo-3-ctr
 image: nginx
 resources:
 limits:
 memory: "800Mi"
 requests:
 memory: "100Mi"
```

Attempt to create the Pod:

```
kubectl apply -f https://k8s.io/examples/admin/resource/memory-constraints-pod-3.yaml --
namespace=constraints-mem-example
```

The output shows that the Pod does not get created, because it defines a container that requests less memory than the enforced minimum:

Error from server (Forbidden): error when creating "examples/admin/resource/memory-constraints-pod-3.yaml":  
pods "constraints-mem-demo-3" is forbidden: minimum memory usage per Container is 500Mi, but request is 100Mi.

## Create a Pod that does not specify any memory request or limit

Here's a manifest for a Pod that has one container. The container does not specify a memory request, and it does not specify a memory limit.

[admin/resource/memory-constraints-pod-4.yaml](https://k8s.io/examples/admin/resource/memory-constraints-pod-4.yaml)

```
apiVersion: v1
kind: Pod
metadata:
 name: constraints-mem-demo-4
spec:
 containers:
 - name: constraints-mem-demo-4-ctr
 image: nginx
```

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/admin/resource/memory-constraints-pod-4.yaml --
namespace=constraints-mem-example
```

View detailed information about the Pod:

```
kubectl get pod constraints-mem-demo-4 --namespace=constraints-mem-example --output=yaml
```

The output shows that the Pod's only container has a memory request of 1 GiB and a memory limit of 1 GiB. How did that container get those values?

```
resources:
 limits:
 memory: 1Gi
 requests:
 memory: 1Gi
```

Because your Pod did not define any memory request and limit for that container, the cluster applied a [default memory request and limit](#) from the LimitRange.

This means that the definition of that Pod shows those values. You can check it using `kubectl describe`:

```
Look for the "Requests:" section of the output
kubectl describe pod constraints-mem-demo-4 --namespace=constraints-mem-example
```

At this point, your Pod might be running or it might not be running. Recall that a prerequisite for this task is that your Nodes have at least 1 GiB of memory. If each of your Nodes has only 1 GiB of memory, then there is not enough allocatable memory on any Node to accommodate a memory request of 1 GiB. If you happen to be using Nodes with 2 GiB of memory, then you probably have enough space to accommodate the 1 GiB request.

Delete your Pod:

```
kubectl delete pod constraints-mem-demo-4 --namespace=constraints-mem-example
```

## Enforcement of minimum and maximum memory constraints

The maximum and minimum memory constraints imposed on a namespace by a LimitRange are enforced only when a Pod is created or updated. If you change the LimitRange, it does not affect Pods that were created previously.

## Motivation for minimum and maximum memory constraints

As a cluster administrator, you might want to impose restrictions on the amount of memory that Pods can use. For example:

- Each Node in a cluster has 2 GiB of memory. You do not want to accept any Pod that requests more than 2 GiB of memory, because no Node in the cluster can support the request.
- A cluster is shared by your production and development departments. You want to allow production workloads to consume up to 8 GiB of memory, but you want development workloads to be limited to 512 MiB. You create separate namespaces for production and development, and you apply memory constraints to each namespace.

## Clean up

Delete your namespace:

```
kubectrl delete namespace constraints-mem-example
```

## What's next

### For cluster administrators

- [Configure Default Memory Requests and Limits for a Namespace](#)
- [Configure Default CPU Requests and Limits for a Namespace](#)
- [Configure Minimum and Maximum CPU Constraints for a Namespace](#)
- [Configure Memory and CPU Quotas for a Namespace](#)
- [Configure a Pod Quota for a Namespace](#)
- [Configure Quotas for API Objects](#)

### For app developers

- [Assign Memory Resources to Containers and Pods](#)
- [Assign CPU Resources to Containers and Pods](#)
- [Configure Quality of Service for Pods](#)

# Configure Minimum and Maximum CPU Constraints for a Namespace

Define a range of valid CPU resource limits for a namespace, so that every new Pod in that namespace falls within the range you configure.

This page shows how to set minimum and maximum values for the CPU resources used by containers and Pods in a [namespace](#). You specify minimum and maximum CPU values in a [LimitRange](#) object. If a Pod does not meet the constraints imposed by the LimitRange, it cannot be created in the namespace.

## Before you begin

You need to have a Kubernetes cluster, and the kubectrl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)

- [Play with Kubernetes](#)

You must have access to create namespaces in your cluster.

Each node in your cluster must have at least 1.0 CPU available for Pods. See [meaning of CPU](#) to learn what Kubernetes means by “1 CPU”.

## Create a namespace

Create a namespace so that the resources you create in this exercise are isolated from the rest of your cluster.

```
kubectl create namespace constraints-cpu-example
```

## Create a LimitRange and a Pod

Here's a manifest for an example [LimitRange](#):

[admin/resource/cpu-constraints.yaml](#)

```
apiVersion: v1
kind: LimitRange
metadata:
 name: cpu-min-max-demo-lr
spec:
 limits:
 - max:
 cpu: "800m"
 min:
 cpu: "200m"
 type: Container
```

Create the LimitRange:

```
kubectl apply -f https://k8s.io/examples/admin/resource/cpu-constraints.yaml --namespace=constraints-cpu-example
```

View detailed information about the LimitRange:

```
kubectl get limitrange cpu-min-max-demo-lr --output=yaml --namespace=constraints-cpu-example
```

The output shows the minimum and maximum CPU constraints as expected. But notice that even though you didn't specify default values in the configuration file for the LimitRange, they were created automatically.

```
limits:
- default:
 cpu: 800m
 defaultRequest:
 cpu: 800m
 max:
 cpu: 800m
```

```
min:
 cpu: 200m
type: Container
```

Now whenever you create a Pod in the constraints-cpu-example namespace (or some other client of the Kubernetes API creates an equivalent Pod), Kubernetes performs these steps:

- If any container in that Pod does not specify its own CPU request and limit, the control plane assigns the default CPU request and limit to that container.
- Verify that every container in that Pod specifies a CPU request that is greater than or equal to 200 millicpu.
- Verify that every container in that Pod specifies a CPU limit that is less than or equal to 800 millicpu.

**Note:**

When creating a LimitRange object, you can specify limits on huge-pages or GPUs as well. However, when both default and defaultRequest are specified on these resources, the two values must be the same.

Here's a manifest for a Pod that has one container. The container manifest specifies a CPU request of 500 millicpu and a CPU limit of 800 millicpu. These satisfy the minimum and maximum CPU constraints imposed by the LimitRange for this namespace.

[admin/resource/cpu-constraints-pod.yaml](https://k8s.io/examples/admin/resource/cpu-constraints-pod.yaml)

```
apiVersion: v1
kind: Pod
metadata:
 name: constraints-cpu-demo
spec:
 containers:
 - name: constraints-cpu-demo-ctr
 image: nginx
 resources:
 limits:
 cpu: "800m"
 requests:
 cpu: "500m"
```

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/admin/resource/cpu-constraints-pod.yaml --
namespace=constraints-cpu-example
```

Verify that the Pod is running and that its container is healthy:

```
kubectl get pod constraints-cpu-demo --namespace=constraints-cpu-example
```

View detailed information about the Pod:

```
kubectl get pod constraints-cpu-demo --output=yaml --namespace=constraints-cpu-example
```

The output shows that the Pod's only container has a CPU request of 500 millicpu and CPU limit of 800 millicpu. These satisfy the constraints imposed by the LimitRange.

```
resources:
 limits:
 cpu: 800m
 requests:
 cpu: 500m
```

## Delete the Pod

```
kubectl delete pod constraints-cpu-demo --namespace=constraints-cpu-example
```

## Attempt to create a Pod that exceeds the maximum CPU constraint

Here's a manifest for a Pod that has one container. The container specifies a CPU request of 500 millicpu and a cpu limit of 1.5 cpu.

[admin/resource/cpu-constraints-pod-2.yaml](https://k8s.io/examples/admin/resource/cpu-constraints-pod-2.yaml)

```
apiVersion: v1
kind: Pod
metadata:
 name: constraints-cpu-demo-2
spec:
 containers:
 - name: constraints-cpu-demo-2-ctr
 image: nginx
 resources:
 limits:
 cpu: "1.5"
 requests:
 cpu: "500m"
```

Attempt to create the Pod:

```
kubectl apply -f https://k8s.io/examples/admin/resource/cpu-constraints-pod-2.yaml --namespace=constraints-cpu-example
```

The output shows that the Pod does not get created, because it defines an unacceptable container. That container is not acceptable because it specifies a CPU limit that is too large:

```
Error from server (Forbidden): error when creating "examples/admin/resource/cpu-constraints-pod-2.yaml":
pods "constraints-cpu-demo-2" is forbidden: maximum cpu usage per Container is 800m, but
limit is 1500m.
```

## Attempt to create a Pod that does not meet the minimum CPU request

Here's a manifest for a Pod that has one container. The container specifies a CPU request of 100 millicpu and a CPU limit of 800 millicpu.

[admin/resource/cpu-constraints-pod-3.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: constraints-cpu-demo-3
spec:
 containers:
 - name: constraints-cpu-demo-3-ctr
 image: nginx
 resources:
 limits:
 cpu: "800m"
 requests:
 cpu: "100m"
```

Attempt to create the Pod:

```
kubectl apply -f https://k8s.io/examples/admin/resource/cpu-constraints-pod-3.yaml --
namespace=constraints-cpu-example
```

The output shows that the Pod does not get created, because it defines an unacceptable container. That container is not acceptable because it specifies a CPU request that is lower than the enforced minimum:

```
Error from server (Forbidden): error when creating "examples/admin/resource/cpu-constraints-
pod-3.yaml":
pods "constraints-cpu-demo-3" is forbidden: minimum cpu usage per Container is 200m, but
request is 100m.
```

## Create a Pod that does not specify any CPU request or limit

Here's a manifest for a Pod that has one container. The container does not specify a CPU request, nor does it specify a CPU limit.

[admin/resource/cpu-constraints-pod-4.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: constraints-cpu-demo-4
spec:
 containers:
 - name: constraints-cpu-demo-4-ctr
 image: vish/stress
```

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/admin/resource/cpu-constraints-pod-4.yaml --namespace=constraints-cpu-example
```

View detailed information about the Pod:

```
kubectl get pod constraints-cpu-demo-4 --namespace=constraints-cpu-example --output=yaml
```

The output shows that the Pod's single container has a CPU request of 800 millicpu and a CPU limit of 800 millicpu. How did that container get those values?

```
resources:
 limits:
 cpu: 800m
 requests:
 cpu: 800m
```

Because that container did not specify its own CPU request and limit, the control plane applied the [default CPU request and limit](#) from the LimitRange for this namespace.

At this point, your Pod may or may not be running. Recall that a prerequisite for this task is that your Nodes must have at least 1 CPU available for use. If each of your Nodes has only 1 CPU, then there might not be enough allocatable CPU on any Node to accommodate a request of 800 millicpu. If you happen to be using Nodes with 2 CPU, then you probably have enough CPU to accommodate the 800 millicpu request.

Delete your Pod:

```
kubectl delete pod constraints-cpu-demo-4 --namespace=constraints-cpu-example
```

## Enforcement of minimum and maximum CPU constraints

The maximum and minimum CPU constraints imposed on a namespace by a LimitRange are enforced only when a Pod is created or updated. If you change the LimitRange, it does not affect Pods that were created previously.

## Motivation for minimum and maximum CPU constraints

As a cluster administrator, you might want to impose restrictions on the CPU resources that Pods can use. For example:

- Each Node in a cluster has 2 CPU. You do not want to accept any Pod that requests more than 2 CPU, because no Node in the cluster can support the request.
- A cluster is shared by your production and development departments. You want to allow production workloads to consume up to 3 CPU, but you want development workloads to be limited to 1 CPU. You create separate namespaces for production and development, and you apply CPU constraints to each namespace.

## Clean up

Delete your namespace:

```
kubectrl delete namespace constraints-cpu-example
```

## What's next

### For cluster administrators

# Configure Memory and CPU Quotas for a Namespace

Define overall memory and CPU resource limits for a namespace.

This page shows how to set quotas for the total amount memory and CPU that can be used by all Pods running in a [namespace](#). You specify quotas in a [ResourceQuota](#) object.

## Before you begin

You need to have a Kubernetes cluster, and the kubectrl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

You must have access to create namespaces in your cluster.

Each node in your cluster must have at least 1 GiB of memory.

## Create a namespace

Create a namespace so that the resources you create in this exercise are isolated from the rest of your cluster.

```
kubectl create namespace quota-mem-cpu-example
```

## Create a ResourceQuota

Here is a manifest for an example ResourceQuota:

[admin/resource/quota-mem-cpu.yaml](https://k8s.io/examples/admin/resource/quota-mem-cpu.yaml)

```
apiVersion: v1
kind: ResourceQuota
metadata:
 name: mem-cpu-demo
spec:
 hard:
 requests.cpu: "1"
 requests.memory: 1Gi
 limits.cpu: "2"
 limits.memory: 2Gi
```

Create the ResourceQuota:

```
kubectl apply -f https://k8s.io/examples/admin/resource/quota-mem-cpu.yaml --namespace=quota-mem-cpu-example
```

View detailed information about the ResourceQuota:

```
kubectl get resourcequota mem-cpu-demo --namespace=quota-mem-cpu-example --output=yaml
```

The ResourceQuota places these requirements on the quota-mem-cpu-example namespace:

- For every Pod in the namespace, each container must have a memory request, memory limit, cpu request, and cpu limit.
- The memory request total for all Pods in that namespace must not exceed 1 GiB.
- The memory limit total for all Pods in that namespace must not exceed 2 GiB.
- The CPU request total for all Pods in that namespace must not exceed 1 cpu.
- The CPU limit total for all Pods in that namespace must not exceed 2 cpu.

See [meaning of CPU](#) to learn what Kubernetes means by “1 CPU”.

## Create a Pod

Here is a manifest for an example Pod:

[admin/resource/quota-mem-cpu-pod.yaml](https://k8s.io/examples/admin/resource/quota-mem-cpu-pod.yaml)

```
apiVersion: v1
kind: Pod
metadata:
 name: quota-mem-cpu-demo
spec:
 containers:
 - name: quota-mem-cpu-demo-ctr
 image: nginx
 resources:
 limits:
 memory: "800Mi"
 cpu: "800m"
 requests:
 memory: "600Mi"
 cpu: "400m"
```

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/admin/resource/quota-mem-cpu-pod.yaml --
namespace=quota-mem-cpu-example
```

Verify that the Pod is running and that its (only) container is healthy:

```
kubectl get pod quota-mem-cpu-demo --namespace=quota-mem-cpu-example
```

Once again, view detailed information about the ResourceQuota:

```
kubectl get resourcequota mem-cpu-demo --namespace=quota-mem-cpu-example --output=ya
ml
```

The output shows the quota along with how much of the quota has been used. You can see that the memory and CPU requests and limits for your Pod do not exceed the quota.

```
status:
 hard:
 limits.cpu: "2"
 limits.memory: 2Gi
 requests.cpu: "1"
 requests.memory: 1Gi
 used:
 limits.cpu: 800m
 limits.memory: 800Mi
 requests.cpu: 400m
 requests.memory: 600Mi
```

If you have the jq tool, you can also query (using [JSONPath](#)) for just the used values, **and** pretty-print that that of the output. For example:

```
kubectl get resourcequota mem-cpu-demo --namespace=quota-mem-cpu-example -o jsonpath='
{.status.used }' | jq .
```

## Attempt to create a second Pod

Here is a manifest for a second Pod:

[admin/resource/quota-mem-cpu-pod-2.yaml](https://k8s.io/examples/admin/resource/quota-mem-cpu-pod-2.yaml)

```
apiVersion: v1
kind: Pod
metadata:
 name: quota-mem-cpu-demo-2
spec:
 containers:
 - name: quota-mem-cpu-demo-2-ctr
 image: redis
 resources:
 limits:
 memory: "1Gi"
 cpu: "800m"
 requests:
 memory: "700Mi"
 cpu: "400m"
```

In the manifest, you can see that the Pod has a memory request of 700 MiB. Notice that the sum of the used memory request and this new memory request exceeds the memory request quota: 600 MiB + 700 MiB > 1 GiB.

Attempt to create the Pod:

```
kubectl apply -f https://k8s.io/examples/admin/resource/quota-mem-cpu-pod-2.yaml --
namespace=quota-mem-cpu-example
```

The second Pod does not get created. The output shows that creating the second Pod would cause the memory request total to exceed the memory request quota.

```
Error from server (Forbidden): error when creating "examples/admin/resource/quota-mem-cpu-
pod-2.yaml":
pods "quota-mem-cpu-demo-2" is forbidden: exceeded quota: mem-cpu-demo,
requested: requests.memory=700Mi,used: requests.memory=600Mi, limited:
requests.memory=1Gi
```

## Discussion

As you have seen in this exercise, you can use a ResourceQuota to restrict the memory request total for all Pods running in a namespace. You can also restrict the totals for memory limit, cpu request, and cpu limit.

Instead of managing total resource use within a namespace, you might want to restrict individual Pods, or the containers in those Pods. To achieve that kind of limiting, use a [LimitRange](#).

## Clean up

Delete your namespace:

```
kubectrl delete namespace quota-mem-cpu-example
```

## What's next

### For cluster administrators

- [Configure Default Memory Requests and Limits for a Namespace](#)
- [Configure Default CPU Requests and Limits for a Namespace](#)
- [Configure Minimum and Maximum Memory Constraints for a Namespace](#)
- [Configure Minimum and Maximum CPU Constraints for a Namespace](#)
- [Configure a Pod Quota for a Namespace](#)
- [Configure Quotas for API Objects](#)

### For app developers

- [Assign Memory Resources to Containers and Pods](#)
- [Assign CPU Resources to Containers and Pods](#)
- [Configure Quality of Service for Pods](#)

## Configure a Pod Quota for a Namespace

Restrict how many Pods you can create within a namespace.

This page shows how to set a quota for the total number of Pods that can run in a [Namespace](#). You specify quotas in a [ResourceQuota](#) object.

## Before you begin

You need to have a Kubernetes cluster, and the kubectrl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

You must have access to create namespaces in your cluster.

## Create a namespace

Create a namespace so that the resources you create in this exercise are isolated from the rest of your cluster.

```
kubectl create namespace quota-pod-example
```

## Create a ResourceQuota

Here is an example manifest for a ResourceQuota:

[admin/resource/quota-pod.yaml](#)

```
apiVersion: v1
kind: ResourceQuota
metadata:
 name: pod-demo
spec:
 hard:
 pods: "2"
```

Create the ResourceQuota:

```
kubectl apply -f https://k8s.io/examples/admin/resource/quota-pod.yaml --namespace=quota-pod-example
```

View detailed information about the ResourceQuota:

```
kubectl get resourcequota pod-demo --namespace=quota-pod-example --output=yaml
```

The output shows that the namespace has a quota of two Pods, and that currently there are no Pods; that is, none of the quota is used.

```
spec:
 hard:
 pods: "2"
status:
 hard:
 pods: "2"
 used:
 pods: "0"
```

Here is an example manifest for a [Deployment](#):

[admin/resource/quota-pod-deployment.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
 name: pod-quota-demo
spec:
 selector:
 matchLabels:
```

```
 purpose: quota-demo
replicas: 3
template:
 metadata:
 labels:
 purpose: quota-demo
 spec:
 containers:
 - name: pod-quota-demo
 image: nginx
```

In that manifest, `replicas: 3` tells Kubernetes to attempt to create three new Pods, all running the same application.

Create the Deployment:

```
kubectl apply -f https://k8s.io/examples/admin/resource/quota-pod-deployment.yaml --
namespace=quota-pod-example
```

View detailed information about the Deployment:

```
kubectl get deployment pod-quota-demo --namespace=quota-pod-example --output=yaml
```

The output shows that even though the Deployment specifies three replicas, only two Pods were created because of the quota you defined earlier:

```
spec:
 ...
 replicas: 3
 ...
status:
 availableReplicas: 2
 ...
lastUpdateTime: 2021-04-02T20:57:05Z
 message: 'unable to create pods: pods "pod-quota-demo-1650323038-" is forbidden:
 exceeded quota: pod-demo, requested: pods=1, used: pods=2, limited: pods=2'
```

## Choice of resource

In this task you have defined a `ResourceQuota` that limited the total number of Pods, but you could also limit the total number of other kinds of object. For example, you might decide to limit how many [CronJobs](#) that can live in a single namespace.

## Clean up

Delete your namespace:

```
kubectl delete namespace quota-pod-example
```

## What's next

## Install a Network Policy Provider

---

[Use Antrea for NetworkPolicy](#)

[Use Calico for NetworkPolicy](#)

[Use Cilium for NetworkPolicy](#)

[Use Kube-router for NetworkPolicy](#)

[Romana for NetworkPolicy](#)

[Weave Net for NetworkPolicy](#)

## Use Antrea for NetworkPolicy

This page shows how to install and use Antrea CNI plugin on Kubernetes. For background on Project Antrea, read the [Introduction to Antrea](#).

### Before you begin

You need to have a Kubernetes cluster. Follow the [kubeadm getting started guide](#) to bootstrap one.

# Deploying Antrea with kubeadm

Follow [Getting Started](#) guide to deploy Antrea for kubeadm.

## What's next

Once your cluster is running, you can follow the [Declare Network Policy](#) to try out Kubernetes NetworkPolicy.

# Use Calico for NetworkPolicy

This page shows a couple of quick ways to create a Calico cluster on Kubernetes.

## Before you begin

Decide whether you want to deploy a [cloud](#) or [local](#) cluster.

## Creating a Calico cluster with Google Kubernetes Engine (GKE)

**Prerequisite:** [gcloud](#).

1. To launch a GKE cluster with Calico, include the `--enable-network-policy` flag.

### Syntax

```
gcloud container clusters create [CLUSTER_NAME] --enable-network-policy
```

### Example

```
gcloud container clusters create my-calico-cluster --enable-network-policy
```

2. To verify the deployment, use the following command.

```
kubectl get pods --namespace=kube-system
```

The Calico pods begin with `calico`. Check to make sure each one has a status of `Running`.

## Creating a local Calico cluster with kubeadm

To get a local single-host Calico cluster in fifteen minutes using kubeadm, refer to the [Calico Quickstart](#).

## What's next

Once your cluster is running, you can follow the [Declare Network Policy](#) to try out Kubernetes NetworkPolicy.

# Use Cilium for NetworkPolicy

This page shows how to use Cilium for NetworkPolicy.

For background on Cilium, read the [Introduction to Cilium](#).

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter kubectl version.

## Deploying Cilium on Minikube for Basic Testing

To get familiar with Cilium easily you can follow the [Cilium Kubernetes Getting Started Guide](#) to perform a basic DaemonSet installation of Cilium in minikube.

To start minikube, minimal version required is  $\geq v1.5.2$ , run the with the following arguments:

```
minikube version
```

```
minikube version: v1.5.2
```

```
minikube start --network-plugin=cni
```

For minikube you can install Cilium using its CLI tool. To do so, first download the latest version of the CLI with the following command:

```
curl -LO https://github.com/cilium/cilium-cli/releases/latest/download/cilium-linux-amd64.tar.gz
```

Then extract the downloaded file to your `/usr/local/bin` directory with the following command:

```
sudo tar xzvfC cilium-linux-amd64.tar.gz /usr/local/bin
rm cilium-linux-amd64.tar.gz
```

After running the above commands, you can now install Cilium with the following command:

```
cilium install
```

Cilium will then automatically detect the cluster configuration and create and install the appropriate components for a successful installation. The components are:

- Certificate Authority (CA) in Secret `cilium-ca` and certificates for Hubble (Cilium's observability layer).
- Service accounts.

- Cluster roles.
- ConfigMap.
- Agent DaemonSet and an Operator Deployment.

After the installation, you can view the overall status of the Cilium deployment with the `cilium status` command. See the expected output of the status command [here](#).

The remainder of the Getting Started Guide explains how to enforce both L3/L4 (i.e., IP address + port) security policies, as well as L7 (e.g., HTTP) security policies using an example application.

## Deploying Cilium for Production Use

For detailed instructions around deploying Cilium for production, see: [Cilium Kubernetes Installation Guide](#) This documentation includes detailed requirements, instructions and example production DaemonSet files.

## Understanding Cilium components

Deploying a cluster with Cilium adds Pods to the kube-system namespace. To see this list of Pods run:

```
kubectl get pods --namespace=kube-system -l k8s-app=cilium
```

You'll see a list of Pods similar to this:

| NAME         | READY | STATUS  | RESTARTS | AGE   |
|--------------|-------|---------|----------|-------|
| cilium-kkdhz | 1/1   | Running | 0        | 3m23s |
| ...          |       |         |          |       |

A cilium Pod runs on each node in your cluster and enforces network policy on the traffic to/from Pods on that node using Linux BPF.

## What's next

Once your cluster is running, you can follow the [Declare Network Policy](#) to try out Kubernetes NetworkPolicy with Cilium. Have fun, and if you have questions, contact us using the [Cilium Slack Channel](#).

## Use Kube-router for NetworkPolicy

This page shows how to use [Kube-router](#) for NetworkPolicy.

## Before you begin

You need to have a Kubernetes cluster running. If you do not already have a cluster, you can create one by using any of the cluster installers like Kops, Bootkube, Kubeadm etc.

## Installing Kube-router addon

The Kube-router Addon comes with a Network Policy Controller that watches Kubernetes API server for any NetworkPolicy and pods updated and configures iptables rules and ipsets to allow or block traffic as directed by the policies. Please follow the [trying Kube-router with cluster installers](#) guide to install Kube-router addon.

### What's next

Once you have installed the Kube-router addon, you can follow the [Declare Network Policy](#) to try out Kubernetes NetworkPolicy.

## Romana for NetworkPolicy

This page shows how to use Romana for NetworkPolicy.

### Before you begin

Complete steps 1, 2, and 3 of the [kubeadm getting started guide](#).

### Installing Romana with kubeadm

Follow the [containerized installation guide](#) for kubeadm.

### Applying network policies

To apply network policies use one of the following:

- [Romana network policies](#).
  - [Example of Romana network policy](#).
- The NetworkPolicy API.

### What's next

Once you have installed Romana, you can follow the [Declare Network Policy](#) to try out Kubernetes NetworkPolicy.

## Weave Net for NetworkPolicy

This page shows how to use Weave Net for NetworkPolicy.

### Before you begin

You need to have a Kubernetes cluster. Follow the [kubeadm getting started guide](#) to bootstrap one.

## Install the Weave Net addon

Follow the [Integrating Kubernetes via the Addon](#) guide.

The Weave Net addon for Kubernetes comes with a [Network Policy Controller](#) that automatically monitors Kubernetes for any NetworkPolicy annotations on all namespaces and configures iptables rules to allow or block traffic as directed by the policies.

## Test the installation

Verify that the weave works.

Enter the following command:

```
kubectl get pods -n kube-system -o wide
```

The output is similar to this:

| NAME            | READY | STATUS  | RESTARTS | AGE | IP            | NODE        |
|-----------------|-------|---------|----------|-----|---------------|-------------|
| weave-net-1t1qg | 2/2   | Running | 0        | 9d  | 192.168.2.10  | worknode3   |
| weave-net-231d7 | 2/2   | Running | 1        | 7d  | 10.2.0.17     | worknodegpu |
| weave-net-7nmwt | 2/2   | Running | 3        | 9d  | 192.168.2.131 | masternode  |
| weave-net-pmw8w | 2/2   | Running | 0        | 9d  | 192.168.2.216 | worknode2   |

Each Node has a weave Pod, and all Pods are Running and 2/2 READY. (2/2 means that each Pod has weave and weave-npc.)

## What's next

Once you have installed the Weave Net addon, you can follow the [Declare Network Policy](#) to try out Kubernetes NetworkPolicy. If you have any question, contact us at [#weave-community on Slack or Weave User Group](#).

## Access Clusters Using the Kubernetes API

This page shows how to access clusters using the Kubernetes API.

### Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

# Accessing the Kubernetes API

## Accessing for the first time with kubectl

When accessing the Kubernetes API for the first time, use the Kubernetes command-line tool, kubectl.

To access a cluster, you need to know the location of the cluster and have credentials to access it. Typically, this is automatically set-up when you work through a [Getting started guide](#), or someone else set up the cluster and provided you with credentials and a location.

Check the location and credentials that kubectl knows about with this command:

```
kubectl config view
```

Many of the [examples](#) provide an introduction to using kubectl. Complete documentation is found in the [kubectl manual](#).

## Directly accessing the REST API

kubectl handles locating and authenticating to the API server. If you want to directly access the REST API with an http client like curl or wget, or a browser, there are multiple ways you can locate and authenticate against the API server:

1. Run kubectl in proxy mode (recommended). This method is recommended, since it uses the stored API server location and verifies the identity of the API server using a self-signed certificate. No man-in-the-middle (MITM) attack is possible using this method.
2. Alternatively, you can provide the location and credentials directly to the http client. This works with client code that is confused by proxies. To protect against man in the middle attacks, you'll need to import a root cert into your browser.

Using the Go or Python client libraries provides accessing kubectl in proxy mode.

## Using kubectl proxy

The following command runs kubectl in a mode where it acts as a reverse proxy. It handles locating the API server and authenticating.

Run it like this:

```
kubectl proxy --port=8080 &
```

See [kubectl proxy](#) for more details.

Then you can explore the API with curl, wget, or a browser, like so:

```
curl http://localhost:8080/api/
```

The output is similar to this:

```
{
 "versions": [
 "v1"
```

```

],
"serverAddressByClientCIDRs": [
 {
 "clientCIDR": "0.0.0.0/0",
 "serverAddress": "10.0.1.149:443"
 }
]
}

```

## Without kubectl proxy

It is possible to avoid using kubectl proxy by passing an authentication token directly to the API server, like this:

Using grep/cut approach:

```

Check all possible clusters, as your .KUBECONFIG may have multiple contexts:
kubectl config view -o jsonpath='{ "Cluster name\tServer\n" }{range .clusters[*]}{.name}{ "\t" }{.cluster.server}{ "\n" }{end}'

Select name of cluster you want to interact with from above output:
export CLUSTER_NAME="some_server_name"

Point to the API server referring the cluster name
APISERVER=$(kubectl config view -o jsonpath="{.clusters[?(@.name==\"$CLUSTER_NAME\")].cluster.server}")

Create a secret to hold a token for the default service account
kubectl apply -f - <<EOF
apiVersion: v1
kind: Secret
metadata:
 name: default-token
 annotations:
 kubernetes.io/service-account.name: default
type: kubernetes.io/service-account-token
EOF

Wait for the token controller to populate the secret with a token:
while ! kubectl describe secret default-token | grep -E '^token' >/dev/null; do
 echo "waiting for token..." >&2
 sleep 1
done

Get the token value
TOKEN=$(kubectl get secret default-token -o jsonpath='{.data.token}' | base64 --decode)

Explore the API with TOKEN
curl -X GET $APISERVER/api --header "Authorization: Bearer $TOKEN" --insecure

```

The output is similar to this:

```
{
 "kind": "APIVersions",
 "versions": [
 "v1"
],
 "serverAddressByClientCIDRs": [
 {
 "clientCIDR": "0.0.0.0/0",
 "serverAddress": "10.0.1.149:443"
 }
]
}
```

The above example uses the `--insecure` flag. This leaves it subject to MITM attacks. When `kubectl` accesses the cluster it uses a stored root certificate and client certificates to access the server. (These are installed in the `~/.kube` directory). Since cluster certificates are typically self-signed, it may take special configuration to get your http client to use root certificate.

On some clusters, the API server does not require authentication; it may serve on localhost, or be protected by a firewall. There is not a standard for this. [Controlling Access to the Kubernetes API](#) describes how you can configure this as a cluster administrator.

## Programmatic access to the API

Kubernetes officially supports client libraries for [Go](#), [Python](#), [Java](#), [dotnet](#), [JavaScript](#), and [Haskell](#). There are other client libraries that are provided and maintained by their authors, not the Kubernetes team. See [client libraries](#) for accessing the API from other languages and how they authenticate.

### Go client

- To get the library, run the following command: `go get k8s.io/client-go@kubernetes-<kubernetes-version-number>` See <https://github.com/kubernetes/client-go/releases> to see which versions are supported.
- Write an application atop of the client-go clients.

#### Note:

`client-go` defines its own API objects, so if needed, import API definitions from `client-go` rather than from the main repository. For example, `import "k8s.io/client-go/kubernetes"` is correct.

The Go client can use the same [kubeconfig file](#) as the `kubectl` CLI does to locate and authenticate to the API server. See this [example](#):

```
package main

import (
 "context"
 "fmt"
 "k8s.io/apimachinery/pkg/apis/meta/v1"
 "k8s.io/client-go/kubernetes"
 "k8s.io/client-go/tools/clientcmd"
```

```

)

func main() {
 // uses the current context in kubeconfig
 // path-to-kubeconfig -- for example, /root/.kube/config
 config, _ := clientcmd.BuildConfigFromFlags("", "<path-to-kubeconfig>")
 // creates the clientset
 clientset, _ := kubernetes.NewForConfig(config)
 // access the API to list pods
 pods, _ := clientset.CoreV1().Pods("").List(context.TODO(), v1.ListOptions{})
 fmt.Printf("There are %d pods in the cluster\n", len(pods.Items))
}

```

If the application is deployed as a Pod in the cluster, see [Accessing the API from within a Pod](#).

## Python client

To use [Python client](#), run the following command: `pip install kubernetes`. See [Python Client Library page](#) for more installation options.

The Python client can use the same [kubeconfig file](#) as the kubectl CLI does to locate and authenticate to the API server. See this [example](#):

```

from kubernetes import client, config

config.load_kube_config()

v1=client.CoreV1Api()
print("Listing pods with their IPs:")
ret = v1.list_pod_for_all_namespaces(watch=False)
for i in ret.items:
 print("%s\t%s\t%s" % (i.status.pod_ip, i.metadata.namespace, i.metadata.name))

```

## Java client

To install the [Java Client](#), run:

```

Clone java library
git clone --recursive https://github.com/kubernetes-client/java

Installing project artifacts, POM etc:
cd java
mvn install

```

See <https://github.com/kubernetes-client/java/releases> to see which versions are supported.

The Java client can use the same [kubeconfig file](#) as the kubectl CLI does to locate and authenticate to the API server. See this [example](#):

```

package io.kubernetes.client.examples;

import io.kubernetes.client.ApiClient;
import io.kubernetes.client.ApiException;

```

```

import io.kubernetes.client.Configuration;
import io.kubernetes.client.apis.CoreV1Api;
import io.kubernetes.client.models.V1Pod;
import io.kubernetes.client.models.V1PodList;
import io.kubernetes.client.util.ClientBuilder;
import io.kubernetes.client.util.KubeConfig;
import java.io.FileReader;
import java.io.IOException;

/**
 * A simple example of how to use the Java API from an application outside a kubernetes cluster
 *
 * <p>Easiest way to run this: mvn exec:java
 * -Dexec.mainClass="io.kubernetes.client.examples.KubeConfigFileClientExample"
 *
 */
public class KubeConfigFileClientExample {
 public static void main(String[] args) throws IOException, ApiException {

 // file path to your KubeConfig
 String kubeConfigPath = "~/.kube/config";

 // loading the out-of-cluster config, a kubeconfig from file-system
 ApiClient client =
 ClientBuilder.kubeconfig(KubeConfig.loadKubeConfig(new FileReader(kubeConfigPath))).build();

 // set the global default api-client to the in-cluster one from above
 Configuration.setDefaultApiClient(client);

 // the CoreV1Api loads default api-client from global configuration.
 CoreV1Api api = new CoreV1Api();

 // invokes the CoreV1Api client
 V1PodList list = api.listPodForAllNamespaces(null, null, null, null, null, null, null, null, null);
 System.out.println("Listing all pods: ");
 for (V1Pod item : list.getItems()) {
 System.out.println(item.getMetadata().getName());
 }
 }
}

```

## dotnet client

To use [dotnet client](#), run the following command: `dotnet add package KubernetesClient --version 1.6.1`. See [dotnet Client Library page](#) for more installation options. See <https://github.com/kubernetes-client/csharp/releases> to see which versions are supported.

The dotnet client can use the same [kubeconfig file](#) as the kubectl CLI does to locate and authenticate to the API server. See this [example](#):

```

using System;
using k8s;

```

```
namespace simple
{
 internal class PodList
 {
 private static void Main(string[] args)
 {
 var config = KubernetesClientConfiguration.BuildDefaultConfig();
 IKubernetes client = new Kubernetes(config);
 Console.WriteLine("Starting Request!");

 var list = client.ListNamespacedPod("default");
 foreach (var item in list.Items)
 {
 Console.WriteLine(item.Metadata.Name);
 }
 if (list.Items.Count == 0)
 {
 Console.WriteLine("Empty!");
 }
 }
 }
}
```

## JavaScript client

To install [JavaScript client](#), run the following command: `npm install @kubernetes/client-node`. See <https://github.com/kubernetes-client/javascript/releases> to see which versions are supported.

The JavaScript client can use the same [kubeconfig file](#) as the kubectl CLI does to locate and authenticate to the API server. See this [example](#):

```
const k8s = require('@kubernetes/client-node');

const kc = new k8s.KubeConfig();
kc.loadFromDefault();

const k8sApi = kc.makeApiClient(k8s.CoreV1Api);

k8sApi.listNamespacedPod('default').then((res) => {
 console.log(res.body);
});
```

## Haskell client

See <https://github.com/kubernetes-client/haskell/releases> to see which versions are supported.

The [Haskell client](#) can use the same [kubeconfig file](#) as the kubectl CLI does to locate and authenticate to the API server. See this [example](#):

```
exampleWithKubeConfig :: IO ()
exampleWithKubeConfig = do
```

```
oidcCache <- atomically $ newTVar $ Map.fromList []
(mgr, kcfg) <- mkKubeClientConfig oidcCache $ KubeConfigFile "/path/to/kubeconfig"
dispatchMime
 mgr
 kcfg
 (CoreV1.listPodForAllNamespaces (Accept MIMEJSON))
>>= print
```

## What's next

- [Accessing the Kubernetes API from a Pod](#)

# Advertise Extended Resources for a Node

This page shows how to specify extended resources for a Node. Extended resources allow cluster administrators to advertise node-level resources that would otherwise be unknown to Kubernetes.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

To check the version, enter kubectl version.

## Get the names of your Nodes

```
kubectl get nodes
```

Choose one of your Nodes to use for this exercise.

## Advertise a new extended resource on one of your Nodes

To advertise a new extended resource on a Node, send an HTTP PATCH request to the Kubernetes API server. For example, suppose one of your Nodes has four dongles attached. Here's an example of a PATCH request that advertises four dongle resources for your Node.

```
PATCH /api/v1/nodes/<your-node-name>/status HTTP/1.1
Accept: application/json
Content-Type: application/json-patch+json
Host: k8s-master:8080
```

```
[
{
```

```
[{"op": "add",
 "path": "/status/capacity/example.com~1dongle",
 "value": "4"}]
```

Note that Kubernetes does not need to know what a dongle is or what a dongle is for. The preceding PATCH request tells Kubernetes that your Node has four things that you call dongles.

Start a proxy, so that you can easily send requests to the Kubernetes API server:

```
kubectrl proxy
```

In another command window, send the HTTP PATCH request. Replace `<your-node-name>` with the name of your Node:

```
curl --header "Content-Type: application/json-patch+json" \
--request PATCH \
--data '[{"op": "add", "path": "/status/capacity/example.com~1dongle", "value": "4"}]' \
http://localhost:8001/api/v1/nodes/<your-node-name>/status
```

#### **Note:**

In the preceding request, `~1` is the encoding for the character `/` in the patch path. The operation path value in JSON-Patch is interpreted as a JSON-Pointer. For more details, see [IETF RFC 6901](https://tools.ietf.org/html/rfc6901), section 3.

The output shows that the Node has a capacity of 4 dongles:

```
"capacity": {
 "cpu": "2",
 "memory": "2049008Ki",
 "example.com/dongle": "4",
```

Describe your Node:

```
kubectrl describe node <your-node-name>
```

Once again, the output shows the dongle resource:

```
Capacity:
cpu: 2
memory: 2049008Ki
example.com/dongle: 4
```

Now, application developers can create Pods that request a certain number of dongles. See [Assign Extended Resources to a Container](#).

## **Discussion**

Extended resources are similar to memory and CPU resources. For example, just as a Node has a certain amount of memory and CPU to be shared by all components running on the Node, it

can have a certain number of dongles to be shared by all components running on the Node. And just as application developers can create Pods that request a certain amount of memory and CPU, they can create Pods that request a certain number of dongles.

Extended resources are opaque to Kubernetes; Kubernetes does not know anything about what they are. Kubernetes knows only that a Node has a certain number of them. Extended resources must be advertised in integer amounts. For example, a Node can advertise four dongles, but not 4.5 dongles.

## Storage example

Suppose a Node has 800 GiB of a special kind of disk storage. You could create a name for the special storage, say `example.com/special-storage`. Then you could advertise it in chunks of a certain size, say 100 GiB. In that case, your Node would advertise that it has eight resources of type `example.com/special-storage`.

Capacity:

...

`example.com/special-storage: 8`

If you want to allow arbitrary requests for special storage, you could advertise special storage in chunks of size 1 byte. In that case, you would advertise 800Gi resources of type `example.com/special-storage`.

Capacity:

...

`example.com/special-storage: 800Gi`

Then a Container could request any number of bytes of special storage, up to 800Gi.

## Clean up

Here is a PATCH request that removes the dongle advertisement from a Node.

```
PATCH /api/v1/nodes/<your-node-name>/status HTTP/1.1
```

```
Accept: application/json
```

```
Content-Type: application/json-patch+json
```

```
Host: k8s-master:8080
```

```
[
 {
 "op": "remove",
 "path": "/status/capacity/example.com~1dongle",
 }
]
```

Start a proxy, so that you can easily send requests to the Kubernetes API server:

```
kubectrl proxy
```

In another command window, send the HTTP PATCH request. Replace `<your-node-name>` with the name of your Node:

```
curl --header "Content-Type: application/json-patch+json" \
--request PATCH \
--data ' [{"op": "remove", "path": "/status/capacity/example.com~1dongle"}]' \
http://localhost:8001/api/v1/nodes/<your-node-name>/status
```

Verify that the dongle advertisement has been removed:

```
kubectl describe node <your-node-name> | grep dongle
```

(you should not see any output)

## What's next

### For application developers

- [Assign Extended Resources to a Container](#)

### For cluster administrators

- [Configure Minimum and Maximum Memory Constraints for a Namespace](#)
- [Configure Minimum and Maximum CPU Constraints for a Namespace](#)

# Autoscale the DNS Service in a Cluster

This page shows how to enable and configure autoscaling of the DNS service in your Kubernetes cluster.

## Before you begin

- You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercoda](#)
- [Play with Kubernetes](#)

To check the version, enter kubectl version.

- This guide assumes your nodes use the AMD64 or Intel 64 CPU architecture.
- Make sure [Kubernetes DNS](#) is enabled.

## Determine whether DNS horizontal autoscaling is already enabled

List the [Deployments](#) in your cluster in the kube-system [namespace](#):

```
kubectl get deployment --namespace=kube-system
```

The output is similar to this:

```
NAME READY UP-TO-DATE AVAILABLE AGE
...
kube-dns-autoscaler 1/1 1 1 ...
...
```

If you see "kube-dns-autoscaler" in the output, DNS horizontal autoscaling is already enabled, and you can skip to [Tuning autoscaling parameters](#).

## Get the name of your DNS Deployment

List the DNS deployments in your cluster in the kube-system namespace:

```
kubectl get deployment -l k8s-app=kube-dns --namespace=kube-system
```

The output is similar to this:

```
NAME READY UP-TO-DATE AVAILABLE AGE
...
coredns 2/2 2 2 ...
...
```

If you don't see a Deployment for DNS services, you can also look for it by name:

```
kubectl get deployment --namespace=kube-system
```

and look for a deployment named coredns or kube-dns.

Your scale target is

```
Deployment/<your-deployment-name>
```

where <your-deployment-name> is the name of your DNS Deployment. For example, if the name of your Deployment for DNS is coredns, your scale target is Deployment/coredns.

### Note:

CoreDNS is the default DNS service for Kubernetes. CoreDNS sets the label k8s-app=kube-dns so that it can work in clusters that originally used kube-dns.

## Enable DNS horizontal autoscaling

In this section, you create a new Deployment. The Pods in the Deployment run a container based on the cluster-proportional-autoscaler-amd64 image.

Create a file named dns-horizontal-autoscaler.yaml with this content:

[admin/dns/dns-horizontal-autoscaler.yaml](#)

```
kind: ServiceAccount
apiVersion: v1
metadata:
```

```

name: kube-dns-autoscaler
namespace: kube-system

kind: ClusterRole
apiVersion: rbac.authorization.k8s.io/v1
metadata:
 name: system:kube-dns-autoscaler
rules:
 - apiGroups: [""]
 resources: ["nodes"]
 verbs: ["list", "watch"]
 - apiGroups: [""]
 resources: ["replicationcontrollers/scale"]
 verbs: ["get", "update"]
 - apiGroups: ["apps"]
 resources: ["deployments/scale", "replicasets/scale"]
 verbs: ["get", "update"]
Remove the configmaps rule once below issue is fixed:
kubernetes-incubator/cluster-proportional-autoscaler#16
 - apiGroups: [""]
 resources: ["configmaps"]
 verbs: ["get", "create"]

kind: ClusterRoleBinding
apiVersion: rbac.authorization.k8s.io/v1
metadata:
 name: system:kube-dns-autoscaler
subjects:
 - kind: ServiceAccount
 name: kube-dns-autoscaler
 namespace: kube-system
roleRef:
 kind: ClusterRole
 name: system:kube-dns-autoscaler
 apiGroup: rbac.authorization.k8s.io

apiVersion: apps/v1
kind: Deployment
metadata:
 name: kube-dns-autoscaler
 namespace: kube-system
 labels:
 k8s-app: kube-dns-autoscaler
 kubernetes.io/cluster-service: "true"
spec:
 selector:
 matchLabels:
 k8s-app: kube-dns-autoscaler
 template:
 metadata:
 labels:
 k8s-app: kube-dns-autoscaler

```

```

spec:
 priorityClassName: system-cluster-critical
 securityContext:
 seccompProfile:
 type: RuntimeDefault
 supplementalGroups: [65534]
 fsGroup: 65534
 nodeSelector:
 kubernetes.io/os: linux
 containers:
 - name: autoscaler
 image: registry.k8s.io/cpa/cluster-proportional-autoscaler:1.8.4
 resources:
 requests:
 cpu: "20m"
 memory: "10Mi"
 command:
 - /cluster-proportional-autoscaler
 - --namespace=kube-system
 - --configmap=kube-dns-autoscaler
 # Should keep target in sync with cluster/addons/dns/kube-dns.yaml.base
 - --target=<SCALE_TARGET>
 # When cluster is using large nodes(with more cores), "coresPerReplica" should dominate.
 # If using small nodes, "nodesPerReplica" should dominate.
 - --default-params={"linear":{"coresPerReplica":256,"nodesPerReplica":
16,"preventSinglePointFailure":true,"includeUnschedulableNodes":true}}
 - --logtostderr=true
 - --v=2
 tolerations:
 - key: "CriticalAddonsOnly"
 operator: "Exists"
 serviceAccountName: kube-dns-autoscaler

```

In the file, replace `<SCALE_TARGET>` with your scale target.

Go to the directory that contains your configuration file, and enter this command to create the Deployment:

```
kubectl apply -f dns-horizontal-autoscaler.yaml
```

The output of a successful command is:

```
deployment.apps/kube-dns-autoscaler created
```

DNS horizontal autoscaling is now enabled.

## Tune DNS autoscaling parameters

Verify that the kube-dns-autoscaler [ConfigMap](#) exists:

```
kubectl get configmap --namespace=kube-system
```

The output is similar to this:

| NAME                | DATA | AGE |
|---------------------|------|-----|
| ...                 |      |     |
| kube-dns-autoscaler | 1    | ... |
| ...                 |      |     |

Modify the data in the ConfigMap:

```
kubectrl edit configmap kube-dns-autoscaler --namespace=kube-system
```

Look for this line:

```
linear: '{"coresPerReplica":256,"min":1,"nodesPerReplica":16}'
```

Modify the fields according to your needs. The "min" field indicates the minimal number of DNS backends. The actual number of backends is calculated using this equation:

$$\text{replicas} = \max(\text{ceil}(\text{cores} \times 1/\text{coresPerReplica}), \text{ceil}(\text{nodes} \times 1/\text{nodesPerReplica}))$$

Note that the values of both `coresPerReplica` and `nodesPerReplica` are floats.

The idea is that when a cluster is using nodes that have many cores, `coresPerReplica` dominates. When a cluster is using nodes that have fewer cores, `nodesPerReplica` dominates.

There are other supported scaling patterns. For details, see [cluster-proportional-autoscaler](#).

## Disable DNS horizontal autoscaling

There are a few options for tuning DNS horizontal autoscaling. Which option to use depends on different conditions.

### Option 1: Scale down the kube-dns-autoscaler deployment to 0 replicas

This option works for all situations. Enter this command:

```
kubectrl scale deployment --replicas=0 kube-dns-autoscaler --namespace=kube-system
```

The output is:

```
deployment.apps/kube-dns-autoscaler scaled
```

Verify that the replica count is zero:

```
kubectrl get rs --namespace=kube-system
```

The output displays 0 in the DESIRED and CURRENT columns:

| NAME                           | DESIRED | CURRENT | READY | AGE |
|--------------------------------|---------|---------|-------|-----|
| ...                            |         |         |       |     |
| kube-dns-autoscaler-6b59789fc8 | 0       | 0       | 0     | ... |
| ...                            |         |         |       |     |

## Option 2: Delete the kube-dns-autoscaler deployment

This option works if kube-dns-autoscaler is under your own control, which means no one will re-create it:

```
kubectl delete deployment kube-dns-autoscaler --namespace=kube-system
```

The output is:

```
deployment.apps "kube-dns-autoscaler" deleted
```

## Option 3: Delete the kube-dns-autoscaler manifest file from the master node

This option works if kube-dns-autoscaler is under control of the (deprecated) [Addon Manager](#), and you have write access to the master node.

Sign in to the master node and delete the corresponding manifest file. The common path for this kube-dns-autoscaler is:

```
/etc/kubernetes/addons/dns-horizontal-autoscaler/dns-horizontal-autoscaler.yaml
```

After the manifest file is deleted, the Addon Manager will delete the kube-dns-autoscaler Deployment.

## Understanding how DNS horizontal autoscaling works

- The cluster-proportional-autoscaler application is deployed separately from the DNS service.
- An autoscaler Pod runs a client that polls the Kubernetes API server for the number of nodes and cores in the cluster.
- A desired replica count is calculated and applied to the DNS backends based on the current schedulable nodes and cores and the given scaling parameters.
- The scaling parameters and data points are provided via a ConfigMap to the autoscaler, and it refreshes its parameters table every poll interval to be up to date with the latest desired scaling parameters.
- Changes to the scaling parameters are allowed without rebuilding or restarting the autoscaler Pod.
- The autoscaler provides a controller interface to support two control patterns: *linear* and *ladder*.

- Learn more about the [implementation of cluster-proportional-autoscaler](#).

# Change the Access Mode of a PersistentVolume to ReadWriteOncePod

This page shows how to change the access mode on an existing PersistentVolume to use ReadWriteOncePod.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version v1.22. To check the version, enter kubectl version.

### Note:

The ReadWriteOncePod access mode graduated to stable in the Kubernetes v1.29 release. If you are running a version of Kubernetes older than v1.29, you might need to enable a feature gate. Check the documentation for your version of Kubernetes.

### Note:

The ReadWriteOncePod access mode is only supported for [CSI](#) volumes. To use this volume access mode you will need to update the following [CSI sidecars](#) to these versions or greater:

- [csi-provisioner:v3.0.0+](#)
- [csi-attacher:v3.3.0+](#)
- [csi-resizer:v1.3.0+](#)

## Why should I use ReadWriteOncePod?

Prior to Kubernetes v1.22, the ReadWriteOnce access mode was commonly used to restrict PersistentVolume access for workloads that required single-writer access to storage. However, this access mode had a limitation: it restricted volume access to a single *node*, allowing multiple pods on the same node to read from and write to the same volume simultaneously. This could pose a risk for applications that demand strict single-writer access for data safety.

If ensuring single-writer access is critical for your workloads, consider migrating your volumes to ReadWriteOncePod.

# Migrating existing PersistentVolumes

If you have existing PersistentVolumes, they can be migrated to use ReadWriteOncePod. Only migrations from ReadWriteOnce to ReadWriteOncePod are supported.

In this example, there is already a ReadWriteOnce "cat-pictures-pvc" PersistentVolumeClaim that is bound to a "cat-pictures-pv" PersistentVolume, and a "cat-pictures-writer" Deployment that uses this PersistentVolumeClaim.

## Note:

If your storage plugin supports [Dynamic provisioning](#), the "cat-pictures-pv" will be created for you, but its name may differ. To get your PersistentVolume's name run:

```
kubectl get pvc cat-pictures-pvc -o jsonpath='{.spec.volumeName}'
```

And you can view the PVC before you make changes. Either view the manifest locally, or run `kubectl get pvc <name-of-pvc> -o yaml`. The output is similar to:

```
cat-pictures-pvc.yaml
kind: PersistentVolumeClaim
apiVersion: v1
metadata:
 name: cat-pictures-pvc
spec:
 accessModes:
 - ReadWriteOnce
 resources:
 requests:
 storage: 1Gi
```

Here's an example Deployment that relies on that PersistentVolumeClaim:

```
cat-pictures-writer-deployment.yaml
apiVersion: apps/v1
kind: Deployment
metadata:
 name: cat-pictures-writer
spec:
 replicas: 3
 selector:
 matchLabels:
 app: cat-pictures-writer
 template:
 metadata:
 labels:
 app: cat-pictures-writer
 spec:
 containers:
 - name: nginx
 image: nginx:1.14.2
 ports:
 - containerPort: 80
```

```
volumeMounts:
- name: cat-pictures
 mountPath: /mnt
volumes:
- name: cat-pictures
 persistentVolumeClaim:
 claimName: cat-pictures-pvc
 readOnly: false
```

As a first step, you need to edit your PersistentVolume's `spec.persistentVolumeReclaimPolicy` and set it to `Retain`. This ensures your PersistentVolume will not be deleted when you delete the corresponding PersistentVolumeClaim:

```
kubectl patch pv cat-pictures-pv -p '{"spec":{"persistentVolumeReclaimPolicy":"Retain"}}'
```

Next you need to stop any workloads that are using the PersistentVolumeClaim bound to the PersistentVolume you want to migrate, and then delete the PersistentVolumeClaim. Avoid making any other changes to the PersistentVolumeClaim, such as volume resizes, until after the migration is complete.

Once that is done, you need to clear your PersistentVolume's `spec.claimRef.uid` to ensure PersistentVolumeClaims can bind to it upon recreation:

```
kubectl scale --replicas=0 deployment cat-pictures-writer
kubectl delete pvc cat-pictures-pvc
kubectl patch pv cat-pictures-pv -p '{"spec":{"claimRef":{"uid":""}}}'
```

After that, replace the PersistentVolume's list of valid access modes to be (only) `ReadWriteOncePod`:

```
kubectl patch pv cat-pictures-pv -p '{"spec":{"accessModes":["ReadWriteOncePod"]}}'
```

### **Note:**

The `ReadWriteOncePod` access mode cannot be combined with other access modes. Make sure `ReadWriteOncePod` is the only access mode on the PersistentVolume when updating, otherwise the request will fail.

Next you need to modify your PersistentVolumeClaim to set `ReadWriteOncePod` as the only access mode. You should also set the PersistentVolumeClaim's `spec.volumeName` to the name of your PersistentVolume to ensure it binds to this specific PersistentVolume.

Once this is done, you can recreate your PersistentVolumeClaim and start up your workloads:

```
IMPORTANT: Make sure to edit your PVC in cat-pictures-pvc.yaml before applying. You need
to:
- Set ReadWriteOncePod as the only access mode
- Set spec.volumeName to "cat-pictures-pv"

kubectl apply -f cat-pictures-pvc.yaml
kubectl apply -f cat-pictures-writer-deployment.yaml
```

Lastly you may edit your PersistentVolume's `spec.persistentVolumeReclaimPolicy` and set it back to `Delete` if you previously changed it.

```
kubectl patch pv cat-pictures-pv -p '{"spec":{"persistentVolumeReclaimPolicy":"Delete"}}'
```

## What's next

- Learn more about [PersistentVolumeClaims](#).
- Learn more about [Configuring a Pod to Use a PersistentVolume for Storage](#)

# Change the default StorageClass

This page shows how to change the default Storage Class that is used to provision volumes for PersistentVolumeClaims that have no special requirements.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

## Why change the default storage class?

Depending on the installation method, your Kubernetes cluster may be deployed with an existing StorageClass that is marked as default. This default StorageClass is then used to dynamically provision storage for PersistentVolumeClaims that do not require any specific storage class. See [PersistentVolumeClaim documentation](#) for details.

The pre-installed default StorageClass may not fit well with your expected workload; for example, it might provision storage that is too expensive. If this is the case, you can either change the default StorageClass or disable it completely to avoid dynamic provisioning of storage.

Deleting the default StorageClass may not work, as it may be re-created automatically by the addon manager running in your cluster. Please consult the docs for your installation for details about addon manager and how to disable individual addons.

## Changing the default StorageClass

1. List the StorageClasses in your cluster:

```
kubectl get storageclass
```

The output is similar to this:

| NAME               | PROVISIONER          | AGE |
|--------------------|----------------------|-----|
| standard (default) | kubernetes.io/gce-pd | 1d  |
| gold               | kubernetes.io/gce-pd | 1d  |

The default StorageClass is marked by (default).

## 2. Mark the default StorageClass as non-default:

The default StorageClass has an annotation `storageclass.kubernetes.io/is-default-class` set to `true`. Any other value or absence of the annotation is interpreted as `false`.

To mark a StorageClass as non-default, you need to change its value to `false`:

```
kubectrl patch storageclass standard -p '{"metadata": {"annotations": {"storageclass.kubernetes.io/is-default-class": "false"}}}'
```

where `standard` is the name of your chosen StorageClass.

## 3. Mark a StorageClass as default:

Similar to the previous step, you need to add/set the annotation `storageclass.kubernetes.io/is-default-class=true`.

```
kubectrl patch storageclass gold -p '{"metadata": {"annotations": {"storageclass.kubernetes.io/is-default-class": "true"}}}'
```

Please note that at most one StorageClass can be marked as default. If two or more of them are marked as default, a `PersistentVolumeClaim` without `storageClassName` explicitly specified cannot be created.

## 4. Verify that your chosen StorageClass is default:

```
kubectrl get storageclass
```

The output is similar to this:

| NAME           | PROVISIONER          | AGE |
|----------------|----------------------|-----|
| standard       | kubernetes.io/gce-pd | 1d  |
| gold (default) | kubernetes.io/gce-pd | 1d  |

## What's next

- Learn more about [PersistentVolumes](#).

# Switching from Polling to CRI Event-based Updates to Container Status

FEATURE STATE: Kubernetes v1.27 [beta]

This page shows how to migrate nodes to use event based updates for container status. The event-based implementation reduces node resource consumption by the kubelet, compared to the legacy approach that relies on polling. You may know this feature as *evented Pod lifecycle*

*event generator (PLEG)*. That's the name used internally within the Kubernetes project for a key implementation detail.

The polling based approach is referred to as *generic PLEG*.

## Before you begin

- You need to run a version of Kubernetes that provides this feature. Kubernetes v1.27 includes beta support for event-based container status updates. The feature is beta but is *disabled* by default because it requires support from the container runtime.
- Your Kubernetes server must be at or later than version 1.26. To check the version, enter `kubectl version`. If you are running a different version of Kubernetes, check the documentation for that release.
- The container runtime in use must support container lifecycle events. The kubelet automatically switches back to the legacy generic PLEG mechanism if the container runtime does not announce support for container lifecycle events, even if you have this feature gate enabled.

## Why switch to Evented PLEG?

- The *Generic PLEG* incurs non-negligible overhead due to frequent polling of container statuses.
- This overhead is exacerbated by Kubelet's parallelized polling of container states, thus limiting its scalability and causing poor performance and reliability problems.
- The goal of *Evented PLEG* is to reduce unnecessary work during inactivity by replacing periodic polling.

## Switching to Evented PLEG

1. Start the Kubelet with the [feature gate](#) `EventedPLEG` enabled. You can manage the kubelet feature gates editing the kubelet [config file](#) and restarting the kubelet service. You need to do this on each node where you are using this feature.
2. Make sure the node is [drained](#) before proceeding.
3. Start the container runtime with the container event generation enabled.
  - [Containerd](#)
  - [CRI-O](#)

Version 1.7+

Version 1.26+

Check if the CRI-O is already configured to emit CRI events by verifying the configuration,

```
crio config | grep enable_pod_events
```

If it is enabled, the output should be similar to the following:

```
enable_pod_events = true
```

To enable it, start the CRI-O daemon with the flag `--enable-pod-events=true` or use a dropin config with the following lines:

```
[crio.runtime]
enable_pod_events: true
```

Your Kubernetes server must be at or later than version 1.26. To check the version, enter `kubectl version`.

4. Verify that the kubelet is using event-based container stage change monitoring. To check, look for the term `EventedPLEG` in the kubelet logs.

The output should be similar to this:

```
I0314 11:10:13.909915 1105457 feature_gate.go:249] feature gates:
&{map[EventedPLEG:true]}
```

If you have set `--v` to 4 and above, you might see more entries that indicate that the kubelet is using event-based container state monitoring.

```
I0314 11:12:42.009542 1110177 evented.go:238] "Evented PLEG: Generated pod status from
the received event" podUID=3b2c6172-b112-447a-ba96-94e7022912dc
I0314 11:12:44.623326 1110177 evented.go:238] "Evented PLEG: Generated pod status from
the received event" podUID=b3fba5ea-a8c5-4b76-8f43-481e17e8ec40
I0314 11:12:44.714564 1110177 evented.go:238] "Evented PLEG: Generated pod status from
the received event" podUID=b3fba5ea-a8c5-4b76-8f43-481e17e8ec40
```

# Change the Reclaim Policy of a PersistentVolume

This page shows how to change the reclaim policy of a Kubernetes PersistentVolume.

## Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercoda](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

# Why change reclaim policy of a PersistentVolume

PersistentVolumes can have various reclaim policies, including "Retain", "Recycle", and "Delete". For dynamically provisioned PersistentVolumes, the default reclaim policy is "Delete". This means that a dynamically provisioned volume is automatically deleted when a user deletes the corresponding PersistentVolumeClaim. This automatic behavior might be inappropriate if the volume contains precious data. In that case, it is more appropriate to use the "Retain" policy. With the "Retain" policy, if a user deletes a PersistentVolumeClaim, the corresponding PersistentVolume will not be deleted. Instead, it is moved to the Released phase, where all of its data can be manually recovered.

## Changing the reclaim policy of a PersistentVolume

1. List the PersistentVolumes in your cluster:

```
kubectl get pv
```

The output is similar to this:

| NAME                                     |        | CAPACITY     | ACCESSMODES | RECLAIMPOLICY |       |
|------------------------------------------|--------|--------------|-------------|---------------|-------|
| STATUS                                   | CLAIM  | STORAGECLASS | REASON      | AGE           |       |
| pvc-b6efd8da-b7b5-11e6-9d58-0ed433a7dd94 |        | 4Gi          | RWO         | Delete        | Bound |
| default/claim1                           | manual | 10s          |             |               |       |
| pvc-b95650f8-b7b5-11e6-9d58-0ed433a7dd94 |        | 4Gi          | RWO         | Delete        | Bound |
| default/claim2                           | manual | 6s           |             |               |       |
| pvc-bb3ca71d-b7b5-11e6-9d58-0ed433a7dd94 |        | 4Gi          | RWO         | Delete        | Bound |
| default/claim3                           | manual | 3s           |             |               |       |

This list also includes the name of the claims that are bound to each volume for easier identification of dynamically provisioned volumes.

2. Choose one of your PersistentVolumes and change its reclaim policy:

```
kubectl patch pv <your-pv-name> -p '{"spec":{"persistentVolumeReclaimPolicy":"Retain"}}'
```

where <your-pv-name> is the name of your chosen PersistentVolume.

### Note:

On Windows, you must *double* quote any JSONPath template that contains spaces (not single quote as shown above for bash). This in turn means that you must use a single quote or escaped double quote around any literals in the template. For example:

```
kubectl patch pv <your-pv-name> -p '{"spec":{"persistentVolumeReclaimPolicy":"Retain\\\""}}'
```

3. Verify that your chosen PersistentVolume has the right policy:

```
kubectl get pv
```

The output is similar to this:

| NAME                                     |        | CAPACITY     | ACCESSMODES | RECLAIMPOLICY |       |
|------------------------------------------|--------|--------------|-------------|---------------|-------|
| STATUS                                   | CLAIM  | STORAGECLASS | REASON      | AGE           |       |
| pvc-b6efd8da-b7b5-11e6-9d58-0ed433a7dd94 |        | 4Gi          | RWO         | Delete        | Bound |
| default/claim1                           | manual | 40s          |             |               |       |
| pvc-b95650f8-b7b5-11e6-9d58-0ed433a7dd94 |        | 4Gi          | RWO         | Delete        | Bound |
| default/claim2                           | manual | 36s          |             |               |       |
| pvc-bb3ca71d-b7b5-11e6-9d58-0ed433a7dd94 |        | 4Gi          | RWO         | Retain        | Bound |
| default/claim3                           | manual | 33s          |             |               |       |

In the preceding output, you can see that the volume bound to claim default/claim3 has reclaim policy Retain. It will not be automatically deleted when a user deletes claim default/claim3.

# Cloud Controller Manager Administration

FEATURE STATE: Kubernetes v1.11 [beta]

Since cloud providers develop and release at a different pace compared to the Kubernetes project, abstracting the provider-specific code to the [cloud-controller-manager](#) binary allows cloud vendors to evolve independently from the core Kubernetes code.

The cloud-controller-manager can be linked to any cloud provider that satisfies [cloudprovider.Interface](#). For backwards compatibility, the [cloud-controller-manager](#) provided in the core Kubernetes project uses the same cloud libraries as kube-controller-manager. Cloud providers already supported in Kubernetes core are expected to use the in-tree cloud-controller-manager to transition out of Kubernetes core.

## Administration

### Requirements

Every cloud has their own set of requirements for running their own cloud provider integration, it should not be too different from the requirements when running kube-controller-manager. As a general rule of thumb you'll need:

- cloud authentication/authorization: your cloud may require a token or IAM rules to allow access to their APIs
- kubernetes authentication/authorization: cloud-controller-manager may need RBAC rules set to speak to the kubernetes apiserver

- high availability: like kube-controller-manager, you may want a high available setup for cloud controller manager using leader election (on by default).

## Running cloud-controller-manager

Successfully running cloud-controller-manager requires some changes to your cluster configuration.

- kubelet, kube-apiserver, and kube-controller-manager must be set according to the user's usage of external CCM. If the user has an external CCM (not the internal cloud controller loops in the Kubernetes Controller Manager), then `--cloud-provider=external` must be specified. Otherwise, it should not be specified.

Keep in mind that setting up your cluster to use cloud controller manager will change your cluster behaviour in a few ways:

- Components that specify `--cloud-provider=external` will add a taint `node.cloudprovider.kubernetes.io/uninitialized` with an effect `NoSchedule` during initialization. This marks the node as needing a second initialization from an external controller before it can be scheduled work. Note that in the event that cloud controller manager is not available, new nodes in the cluster will be left unschedulable. The taint is important since the scheduler may require cloud specific information about nodes such as their region or type (high cpu, gpu, high memory, spot instance, etc).
- cloud information about nodes in the cluster will no longer be retrieved using local metadata, but instead all API calls to retrieve node information will go through cloud controller manager. This may mean you can restrict access to your cloud API on the kubelets for better security. For larger clusters you may want to consider if cloud controller manager will hit rate limits since it is now responsible for almost all API calls to your cloud from within the cluster.

The cloud controller manager can implement:

- Node controller - responsible for updating kubernetes nodes using cloud APIs and deleting kubernetes nodes that were deleted on your cloud.
- Service controller - responsible for loadbalancers on your cloud against services of type `LoadBalancer`.
- Route controller - responsible for setting up network routes on your cloud
- any other features you would like to implement if you are running an out-of-tree provider.

## Examples

If you are using a cloud that is currently supported in Kubernetes core and would like to adopt cloud controller manager, see the [cloud controller manager in kubernetes core](#).

For cloud controller managers not in Kubernetes core, you can find the respective projects in repositories maintained by cloud vendors or by SIGs.

For providers already in Kubernetes core, you can run the in-tree cloud controller manager as a DaemonSet in your cluster, use the following as a guideline:

[admin/cloud/ccm-example.yaml](#)

```
This is an example of how to set up cloud-controller-manager as a Daemonset in your cluster.
It assumes that your masters can run pods and has the role node-role.kubernetes.io/master
Note that this Daemonset will not work straight out of the box for your cloud, this is
meant to be a guideline.
```

```

```

```

- key: node-role.kubernetes.io/master
 operator: Exists
 effect: NoSchedule
this is to restrict CCM to only run on master nodes
the node selector may vary depending on your cluster setup
nodeSelector:
 node-role.kubernetes.io/master: ""
```

## Limitations

Running cloud controller manager comes with a few possible limitations. Although these limitations are being addressed in upcoming releases, it's important that you are aware of these limitations for production workloads.

## Support for Volumes

Cloud controller manager does not implement any of the volume controllers found in kube-controller-manager as the volume integrations also require coordination with kubelets. As we evolve CSI (container storage interface) and add stronger support for flex volume plugins, necessary support will be added to cloud controller manager so that clouds can fully integrate with volumes. Learn more about out-of-tree CSI volume plugins [here](#).

## Scalability

The cloud-controller-manager queries your cloud provider's APIs to retrieve information for all nodes. For very large clusters, consider possible bottlenecks such as resource requirements and API rate limiting.

## Chicken and Egg

The goal of the cloud controller manager project is to decouple development of cloud features from the core Kubernetes project. Unfortunately, many aspects of the Kubernetes project has assumptions that cloud provider features are tightly integrated into the project. As a result, adopting this new architecture can create several situations where a request is being made for information from a cloud provider, but the cloud controller manager may not be able to return that information without the original request being complete.

A good example of this is the TLS bootstrapping feature in the Kubelet. TLS bootstrapping assumes that the Kubelet has the ability to ask the cloud provider (or a local metadata service)

for all its address types (private, public, etc) but cloud controller manager cannot set a node's address types without being initialized in the first place which requires that the kubelet has TLS certificates to communicate with the apiserver.

As this initiative evolves, changes will be made to address these issues in upcoming releases.

## What's next

To build and develop your own cloud controller manager, read [Developing Cloud Controller Manager](#).

# Configure a kubelet image credential provider

FEATURE STATE: Kubernetes v1.26 [stable]

Starting from Kubernetes v1.20, the kubelet can dynamically retrieve credentials for a container image registry using exec plugins. The kubelet and the exec plugin communicate through stdio (stdin, stdout, and stderr) using Kubernetes versioned APIs. These plugins allow the kubelet to request credentials for a container registry dynamically as opposed to storing static credentials on disk. For example, the plugin may talk to a local metadata server to retrieve short-lived credentials for an image that is being pulled by the kubelet.

You may be interested in using this capability if any of the below are true:

- API calls to a cloud provider service are required to retrieve authentication information for a registry.
- Credentials have short expiration times and requesting new credentials frequently is required.
- Storing registry credentials on disk or in `imagePullSecrets` is not acceptable.

This guide demonstrates how to configure the kubelet's image credential provider plugin mechanism.

## Before you begin

- You need a Kubernetes cluster with nodes that support kubelet credential provider plugins. This support is available in Kubernetes 1.30; Kubernetes v1.24 and v1.25 included this as a beta feature, enabled by default.
- A working implementation of a credential provider exec plugin. You can build your own plugin or use one provided by cloud providers.

Your Kubernetes server must be at or later than version v1.26. To check the version, enter `kubectl version`.

# Installing Plugins on Nodes

A credential provider plugin is an executable binary that will be run by the kubelet. Ensure that the plugin binary exists on every node in your cluster and stored in a known directory. The directory will be required later when configuring kubelet flags.

## Configuring the Kubelet

In order to use this feature, the kubelet expects two flags to be set:

- `--image-credential-provider-config` - the path to the credential provider plugin config file.
- `--image-credential-provider-bin-dir` - the path to the directory where credential provider plugin binaries are located.

### Configure a kubelet credential provider

The configuration file passed into `--image-credential-provider-config` is read by the kubelet to determine which exec plugins should be invoked for which container images. Here's an example configuration file you may end up using if you are using the [ECR-based plugin](#):

```
apiVersion: kubelet.config.k8s.io/v1
kind: CredentialProviderConfig
providers is a list of credential provider helper plugins that will be enabled by the kubelet.
Multiple providers may match against a single image, in which case credentials
from all providers will be returned to the kubelet. If multiple providers are called
for a single image, the results are combined. If providers return overlapping
auth keys, the value from the provider earlier in this list is used.
providers:
 # name is the required name of the credential provider. It must match the name of the
 # provider executable as seen by the kubelet. The executable must be in the kubelet's
 # bin directory (set by the --image-credential-provider-bin-dir flag).
 - name: ecr-credential-provider
 # matchImages is a required list of strings used to match against images in order to
 # determine if this provider should be invoked. If one of the strings matches the
 # requested image from the kubelet, the plugin will be invoked and given a chance
 # to provide credentials. Images are expected to contain the registry domain
 # and URL path.
 #
 # Each entry in matchImages is a pattern which can optionally contain a port and a path.
 # Globs can be used in the domain, but not in the port or the path. Globs are supported
 # as subdomains like '*.k8s.io' or 'k8s*.io', and top-level-domains such as 'k8s.*'.
 # Matching partial subdomains like 'app*.k8s.io' is also supported. Each glob can only match
 # a single subdomain segment, so '*.io' does not match '*.k8s.io'.
 #
 # A match exists between an image and a matchImage when all of the below are true:
 # - Both contain the same number of domain parts and each part matches.
 # - The URL path of an matchImages must be a prefix of the target image URL path.
 # - If the matchImages contains a port, then the port must match in the image as well.
 #
 # Example values of matchImages:
 # - 123456789.dkr.ecr.us-east-1.amazonaws.com
 # - *.azurecr.io
```

```

- gcr.io
- *.registry.io
- registry.io:8080/path
matchImages:
 - "*.dkr.ecr.*.amazonaws.com"
 - "*.dkr.ecr.*.amazonaws.com.cn"
 - "*.dkr.ecr-fips.*.amazonaws.com"
 - "*.dkr.ecr.us-iso-east-1.c2s.ic.gov"
 - "*.dkr.ecr.us-isob-east-1.sc2s.sgov.gov"
defaultCacheDuration is the default duration the plugin will cache credentials in-memory
if a cache duration is not provided in the plugin response. This field is required.
defaultCacheDuration: "12h"
Required input version of the exec CredentialProviderRequest. The returned
CredentialProviderResponse
MUST use the same encoding version as the input. Current supported values are:
- credentialprovider.kubelet.k8s.io/v1
apiVersion: credentialprovider.kubelet.k8s.io/v1
Arguments to pass to the command when executing it.
+optional
args:
- --example-argument
Env defines additional environment variables to expose to the process. These
are unioned with the host's environment, as well as variables client-go uses
to pass argument to the plugin.
+optional
env:
 - name: AWS_PROFILE
 value: example_profile

```

The providers field is a list of enabled plugins used by the kubelet. Each entry has a few required fields:

- **name**: the name of the plugin which MUST match the name of the executable binary that exists in the directory passed into `--image-credential-provider-bin-dir`.
- **matchImages**: a list of strings used to match against images in order to determine if this provider should be invoked. More on this below.
- **defaultCacheDuration**: the default duration the kubelet will cache credentials in-memory if a cache duration was not specified by the plugin.
- **apiVersion**: the API version that the kubelet and the exec plugin will use when communicating.

Each credential provider can also be given optional args and environment variables as well. Consult the plugin implementors to determine what set of arguments and environment variables are required for a given plugin.

## Configure image matching

The `matchImages` field for each credential provider is used by the kubelet to determine whether a plugin should be invoked for a given image that a Pod is using. Each entry in `matchImages` is an image pattern which can optionally contain a port and a path. Globs can be used in the domain, but not in the port or the path. Globs are supported as subdomains like `*.k8s.io` or `k8s*.io`, and top-level domains such as `k8s.*`. Matching partial subdomains like `app*.k8s.io` is also

supported. Each glob can only match a single subdomain segment, so \*.io does NOT match \*.k8s.io.

A match exists between an image name and a matchImage entry when all of the below are true:

- Both contain the same number of domain parts and each part matches.
- The URL path of match image must be a prefix of the target image URL path.
- If the matchImages contains a port, then the port must match in the image as well.

Some example values of matchImages patterns are:

- 123456789.dkr.ecr.us-east-1.amazonaws.com
- \*.azurecr.io
- gcr.io
- \*.registry.io
- foo.registry.io:8080/path

- Read the [kubelet credential provider API reference \(v1\)](#).

# Configure Quotas for API Objects

This page shows how to configure quotas for API objects, including PersistentVolumeClaims and Services. A quota restricts the number of objects, of a particular type, that can be created in a namespace. You specify quotas in a [ResourceQuota](#) object.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter kubectl version.

## Create a namespace

Create a namespace so that the resources you create in this exercise are isolated from the rest of your cluster.

```
kubectl create namespace quota-object-example
```

## Create a ResourceQuota

Here is the configuration file for a ResourceQuota object:

[admin/resource/quota-objects.yaml](https://k8s.io/examples/admin/resource/quota-objects.yaml)

```
apiVersion: v1
kind: ResourceQuota
metadata:
 name: object-quota-demo
spec:
 hard:
 persistentvolumeclaims: "1"
 services.loadbalancers: "2"
 services.nodeports: "0"
```

Create the ResourceQuota:

```
kubectl apply -f https://k8s.io/examples/admin/resource/quota-objects.yaml --namespace=quota-object-example
```

View detailed information about the ResourceQuota:

```
kubectl get resourcequota object-quota-demo --namespace=quota-object-example --output=yaml
```

The output shows that in the quota-object-example namespace, there can be at most one PersistentVolumeClaim, at most two Services of type LoadBalancer, and no Services of type NodePort.

```
status:
 hard:
 persistentvolumeclaims: "1"
 services.loadbalancers: "2"
 services.nodeports: "0"
 used:
 persistentvolumeclaims: "0"
 services.loadbalancers: "0"
 services.nodeports: "0"
```

## Create a PersistentVolumeClaim

Here is the configuration file for a PersistentVolumeClaim object:

[admin/resource/quota-objects-pvc.yaml](https://k8s.io/examples/admin/resource/quota-objects-pvc.yaml)

```
apiVersion: v1
kind: PersistentVolumeClaim
metadata:
 name: pvc-quota-demo
spec:
 storageClassName: manual
 accessModes:
```

```
- ReadWriteOnce
resources:
 requests:
 storage: 3Gi
```

Create the PersistentVolumeClaim:

```
kubectl apply -f https://k8s.io/examples/admin/resource/quota-objects-pvc.yaml --namespace=quota-object-example
```

Verify that the PersistentVolumeClaim was created:

```
kubectl get persistentvolumeclaims --namespace=quota-object-example
```

The output shows that the PersistentVolumeClaim exists and has status Pending:

| NAME           | STATUS  |
|----------------|---------|
| pvc-quota-demo | Pending |

## Attempt to create a second PersistentVolumeClaim

Here is the configuration file for a second PersistentVolumeClaim:

[admin/resource/quota-objects-pvc-2.yaml](https://k8s.io/examples/admin/resource/quota-objects-pvc-2.yaml)

```
apiVersion: v1
kind: PersistentVolumeClaim
metadata:
 name: pvc-quota-demo-2
spec:
 storageClassName: manual
 accessModes:
 - ReadWriteOnce
 resources:
 requests:
 storage: 4Gi
```

Attempt to create the second PersistentVolumeClaim:

```
kubectl apply -f https://k8s.io/examples/admin/resource/quota-objects-pvc-2.yaml --namespace=quota-object-example
```

The output shows that the second PersistentVolumeClaim was not created, because it would have exceeded the quota for the namespace.

```
persistentvolumeclaims "pvc-quota-demo-2" is forbidden:
exceeded quota: object-quota-demo, requested: persistentvolumeclaims=1,
used: persistentvolumeclaims=1, limited: persistentvolumeclaims=1
```

## Notes

These are the strings used to identify API resources that can be constrained by quotas:

| String                   | API Object                   |
|--------------------------|------------------------------|
| "pods"                   | Pod                          |
| "services"               | Service                      |
| "replicationcontrollers" | ReplicationController        |
| "resourcequotas"         | ResourceQuota                |
| "secrets"                | Secret                       |
| "configmaps"             | ConfigMap                    |
| "persistentvolumeclaims" | PersistentVolumeClaim        |
| "services.nodeports"     | Service of type NodePort     |
| "services.loadbalancers" | Service of type LoadBalancer |

## Clean up

Delete your namespace:

```
kubectl delete namespace quota-object-example
```

# Control CPU Management Policies on the Node

FEATURE STATE: Kubernetes v1.26 [stable]

Kubernetes keeps many aspects of how pods execute on nodes abstracted from the user. This is by design. However, some workloads require stronger guarantees in terms of latency and/or

performance in order to operate acceptably. The kubelet provides methods to enable more complex workload placement policies while keeping the abstraction free from explicit placement directives.

For detailed information on resource management, please refer to the [Resource Management for Pods and Containers](#) documentation.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version v1.26. To check the version, enter kubectl version.

If you are running an older version of Kubernetes, please look at the documentation for the version you are actually running.

## CPU Management Policies

By default, the kubelet uses [CFS quota](#) to enforce pod CPU limits. When the node runs many CPU-bound pods, the workload can move to different CPU cores depending on whether the pod is throttled and which CPU cores are available at scheduling time. Many workloads are not sensitive to this migration and thus work fine without any intervention.

However, in workloads where CPU cache affinity and scheduling latency significantly affect workload performance, the kubelet allows alternative CPU management policies to determine some placement preferences on the node.

## Configuration

The CPU Manager policy is set with the `--cpu-manager-policy` kubelet flag or the `cpuManagerPolicy` field in [KubeletConfiguration](#). There are two supported policies:

- [none](#): the default policy.
- [static](#): allows pods with certain resource characteristics to be granted increased CPU affinity and exclusivity on the node.

The CPU manager periodically writes resource updates through the CRI in order to reconcile in-memory CPU assignments with cgroups. The reconcile frequency is set through a new Kubelet configuration value `--cpu-manager-reconcile-period`. If not specified, it defaults to the same duration as `--node-status-update-frequency`.

The behavior of the static policy can be fine-tuned using the `--cpu-manager-policy-options` flag. The flag takes a comma-separated list of key=value policy options. If you disable the `CPUManagerPolicyOptions` [feature gate](#) then you cannot fine-tune CPU manager policies. In that case, the CPU manager operates only using its default settings.

In addition to the top-level `CPUManagerPolicyOptions` feature gate, the policy options are split into two groups: alpha quality (hidden by default) and beta quality (visible by default). The groups are guarded respectively by the `CPUManagerPolicyAlphaOptions` and `CPUManagerPolicyBetaOptions` feature gates. Diverging from the Kubernetes standard, these feature gates guard groups of options, because it would have been too cumbersome to add a feature gate for each individual option.

## Changing the CPU Manager Policy

Since the CPU manager policy can only be applied when kubelet spawns new pods, simply changing from "none" to "static" won't apply to existing pods. So in order to properly change the CPU manager policy on a node, perform the following steps:

1. [Drain](#) the node.
2. Stop kubelet.
3. Remove the old CPU manager state file. The path to this file is `/var/lib/kubelet/cpu_manager_state` by default. This clears the state maintained by the `CPUManager` so that the `cpu-sets` set up by the new policy won't conflict with it.
4. Edit the kubelet configuration to change the CPU manager policy to the desired value.
5. Start kubelet.

Repeat this process for every node that needs its CPU manager policy changed. Skipping this process will result in kubelet crashlooping with the following error:

```
could not restore state from checkpoint: configured policy "static" differs from state checkpoint policy "none", please drain this node and delete the CPU manager checkpoint file "/var/lib/kubelet/cpu_manager_state" before restarting Kubelet
```

## None policy

The none policy explicitly enables the existing default CPU affinity scheme, providing no affinity beyond what the OS scheduler does automatically. Limits on CPU usage for [Guaranteed pods](#) and [Burstable pods](#) are enforced using CFS quota.

## Static policy

The static policy allows containers in `Guaranteed` pods with integer CPU requests access to exclusive CPUs on the node. This exclusivity is enforced using the [cpuset cgroup controller](#).

### Note:

System services such as the container runtime and the kubelet itself can continue to run on these exclusive CPUs. The exclusivity only extends to other pods.

### Note:

CPU Manager doesn't support offlining and onlining of CPUs at runtime. Also, if the set of online CPUs changes on the node, the node must be drained and CPU manager manually reset by deleting the state file `cpu_manager_state` in the kubelet root directory.

This policy manages a shared pool of CPUs that initially contains all CPUs in the node. The amount of exclusively allocatable CPUs is equal to the total number of CPUs in the node minus

any CPU reservations by the kubelet `--kube-reserved` or `--system-reserved` options. From 1.17, the CPU reservation list can be specified explicitly by kubelet `--reserved-cpus` option. The explicit CPU list specified by `--reserved-cpus` takes precedence over the CPU reservation specified by `--kube-reserved` and `--system-reserved`. CPUs reserved by these options are taken, in integer quantity, from the initial shared pool in ascending order by physical core ID. This shared pool is the set of CPUs on which any containers in BestEffort and Burstable pods run. Containers in Guaranteed pods with fractional CPU requests also run on CPUs in the shared pool. Only containers that are both part of a Guaranteed pod and have integer CPU requests are assigned exclusive CPUs.

**Note:**

The kubelet requires a CPU reservation greater than zero be made using either `--kube-reserved` and/or `--system-reserved` or `--reserved-cpus` when the static policy is enabled. This is because zero CPU reservation would allow the shared pool to become empty.

As Guaranteed pods whose containers fit the requirements for being statically assigned are scheduled to the node, CPUs are removed from the shared pool and placed in the cpuset for the container. CFS quota is not used to bound the CPU usage of these containers as their usage is bound by the scheduling domain itself. In other words, the number of CPUs in the container cpuset is equal to the integer CPU limit specified in the pod spec. This static assignment increases CPU affinity and decreases context switches due to throttling for the CPU-bound workload.

Consider the containers in the following pod specs:

```
spec:
 containers:
 - name: nginx
 image: nginx
```

This pod runs in the BestEffort QoS class because no resource requests or limits are specified. It runs in the shared pool.

```
spec:
 containers:
 - name: nginx
 image: nginx
 resources:
 limits:
 memory: "200Mi"
 requests:
 memory: "100Mi"
```

This pod runs in the Burstable QoS class because resource requests do not equal limits and the cpu quantity is not specified. It runs in the shared pool.

```
spec:
 containers:
 - name: nginx
 image: nginx
 resources:
 limits:
```

```
memory: "200Mi"
cpu: "2"
requests:
 memory: "100Mi"
 cpu: "1"
```

This pod runs in the **Burstable QoS** class because resource requests do not equal limits. It runs in the shared pool.

```
spec:
 containers:
 - name: nginx
 image: nginx
 resources:
 limits:
 memory: "200Mi"
 cpu: "2"
 requests:
 memory: "200Mi"
 cpu: "2"
```

This pod runs in the **Guaranteed QoS** class because requests are equal to limits. And the container's resource limit for the CPU resource is an integer greater than or equal to one. The nginx container is granted 2 exclusive CPUs.

```
spec:
 containers:
 - name: nginx
 image: nginx
 resources:
 limits:
 memory: "200Mi"
 cpu: "1.5"
 requests:
 memory: "200Mi"
 cpu: "1.5"
```

This pod runs in the **Guaranteed QoS** class because requests are equal to limits. But the container's resource limit for the CPU resource is a fraction. It runs in the shared pool.

```
spec:
 containers:
 - name: nginx
 image: nginx
 resources:
 limits:
 memory: "200Mi"
 cpu: "2"
```

This pod runs in the **Guaranteed QoS** class because only limits are specified and requests are set equal to limits when not explicitly specified. And the container's resource limit for the CPU resource is an integer greater than or equal to one. The nginx container is granted 2 exclusive CPUs.

## Static policy options

You can toggle groups of options on and off based upon their maturity level using the following feature gates:

- `CPUManagerPolicyBetaOptions` default enabled. Disable to hide beta-level options.
- `CPUManagerPolicyAlphaOptions` default disabled. Enable to show alpha-level options. You will still have to enable each option using the `CPUManagerPolicyOptions` kubelet option.

The following policy options exist for the static `CPUManager` policy:

- `full-pcpus-only` (beta, visible by default) (1.22 or higher)
- `distribute-cpus-across-numa` (alpha, hidden by default) (1.23 or higher)
- `align-by-socket` (alpha, hidden by default) (1.25 or higher)

If the `full-pcpus-only` policy option is specified, the static policy will always allocate full physical cores. By default, without this option, the static policy allocates CPUs using a topology-aware best-fit allocation. On SMT enabled systems, the policy can allocate individual virtual cores, which correspond to hardware threads. This can lead to different containers sharing the same physical cores; this behaviour in turn contributes to the [noisy neighbours problem](#). With the option enabled, the pod will be admitted by the kubelet only if the CPU request of all its containers can be fulfilled by allocating full physical cores. If the pod does not pass the admission, it will be put in Failed state with the message `SMTAlignmentError`.

If the `distribute-cpus-across-numa` policy option is specified, the static policy will evenly distribute CPUs across NUMA nodes in cases where more than one NUMA node is required to satisfy the allocation. By default, the `CPUManager` will pack CPUs onto one NUMA node until it is filled, with any remaining CPUs simply spilling over to the next NUMA node. This can cause undesired bottlenecks in parallel code relying on barriers (and similar synchronization primitives), as this type of code tends to run only as fast as its slowest worker (which is slowed down by the fact that fewer CPUs are available on at least one NUMA node). By distributing CPUs evenly across NUMA nodes, application developers can more easily ensure that no single worker suffers from NUMA effects more than any other, improving the overall performance of these types of applications.

If the `align-by-socket` policy option is specified, CPUs will be considered aligned at the socket boundary when deciding how to allocate CPUs to a container. By default, the `CPUManager` aligns CPU allocations at the NUMA boundary, which could result in performance degradation if CPUs need to be pulled from more than one NUMA node to satisfy the allocation. Although it tries to ensure that all CPUs are allocated from the *minimum* number of NUMA nodes, there is no guarantee that those NUMA nodes will be on the same socket. By directing the `CPUManager` to explicitly align CPUs at the socket boundary rather than the NUMA boundary, we are able to avoid such issues. Note, this policy option is not compatible with `TopologyManager` `single-numa-node` policy and does not apply to hardware where the number of sockets is greater than number of NUMA nodes.

The `full-pcpus-only` option can be enabled by adding `full-pcpus-only=true` to the `CPUManager` policy options. Likewise, the `distribute-cpus-across-numa` option can be enabled by adding `distribute-cpus-across-numa=true` to the `CPUManager` policy options. When both are set, they are "additive" in the sense that CPUs will be distributed across NUMA nodes in chunks of full-pcpus rather than individual cores. The `align-by-socket` policy option can be enabled by adding `align-by-socket=true` to the `CPUManager` policy options. It is also additive to the `full-pcpus-only` and `distribute-cpus-across-numa` policy options.

# Control Topology Management Policies on a node

FEATURE STATE: Kubernetes v1.27 [stable]

An increasing number of systems leverage a combination of CPUs and hardware accelerators to support latency-critical execution and high-throughput parallel computation. These include workloads in fields such as telecommunications, scientific computing, machine learning, financial services and data analytics. Such hybrid systems comprise a high performance environment.

In order to extract the best performance, optimizations related to CPU isolation, memory and device locality are required. However, in Kubernetes, these optimizations are handled by a disjoint set of components.

*Topology Manager* is a Kubelet component that aims to coordinate the set of components that are responsible for these optimizations.

## Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercoda](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version v1.18. To check the version, enter `kubectl version`.

## How Topology Manager Works

Prior to the introduction of Topology Manager, the CPU and Device Manager in Kubernetes make resource allocation decisions independently of each other. This can result in undesirable allocations on multiple-socketed systems, performance/latency sensitive applications will suffer due to these undesirable allocations. Undesirable in this case meaning for example, CPUs and devices being allocated from different NUMA Nodes thus, incurring additional latency.

The Topology Manager is a Kubelet component, which acts as a source of truth so that other Kubelet components can make topology aligned resource allocation choices.

The Topology Manager provides an interface for components, called *Hint Providers*, to send and receive topology information. Topology Manager has a set of node level policies which are explained below.

The Topology manager receives Topology information from the *Hint Providers* as a bitmask denoting NUMA Nodes available and a preferred allocation indication. The Topology Manager policies perform a set of operations on the hints provided and converge on the hint determined by the policy to give the optimal result, if an undesirable hint is stored the preferred field for

the hint will be set to false. In the current policies preferred is the narrowest preferred mask. The selected hint is stored as part of the Topology Manager. Depending on the policy configured the pod can be accepted or rejected from the node based on the selected hint. The hint is then stored in the Topology Manager for use by the *Hint Providers* when making the resource allocation decisions.

## Topology Manager Scopes and Policies

The Topology Manager currently:

- Aligns Pods of all QoS classes.
- Aligns the requested resources that Hint Provider provides topology hints for.

If these conditions are met, the Topology Manager will align the requested resources.

In order to customise how this alignment is carried out, the Topology Manager provides two distinct knobs: scope and policy.

The scope defines the granularity at which you would like resource alignment to be performed (e.g. at the pod or container level). And the policy defines the actual strategy used to carry out the alignment (e.g. best-effort, restricted, single-numa-node, etc.). Details on the various scopes and policies available today can be found below.

### Note:

To align CPU resources with other requested resources in a Pod Spec, the CPU Manager should be enabled and proper CPU Manager policy should be configured on a Node. See [control CPU Management Policies](#).

### Note:

To align memory (and hugepages) resources with other requested resources in a Pod Spec, the Memory Manager should be enabled and proper Memory Manager policy should be configured on a Node. Examine [Memory Manager](#) documentation.

## Topology Manager Scopes

The Topology Manager can deal with the alignment of resources in a couple of distinct scopes:

- container (default)
- pod

Either option can be selected at a time of the kubelet startup, with `--topology-manager-scope` flag.

### container scope

The container scope is used by default.

Within this scope, the Topology Manager performs a number of sequential resource alignments, i.e., for each container (in a pod) a separate alignment is computed. In other words, there is no notion of grouping the containers to a specific set of NUMA nodes, for this particular scope. In

effect, the Topology Manager performs an arbitrary alignment of individual containers to NUMA nodes.

The notion of grouping the containers was endorsed and implemented on purpose in the following scope, for example the pod scope.

## pod scope

To select the pod scope, start the kubelet with the command line option `--topology-manager-scope=pod`.

This scope allows for grouping all containers in a pod to a common set of NUMA nodes. That is, the Topology Manager treats a pod as a whole and attempts to allocate the entire pod (all containers) to either a single NUMA node or a common set of NUMA nodes. The following examples illustrate the alignments produced by the Topology Manager on different occasions:

- all containers can be and are allocated to a single NUMA node;
- all containers can be and are allocated to a shared set of NUMA nodes.

The total amount of particular resource demanded for the entire pod is calculated according to [effective requests/limits](#) formula, and thus, this total value is equal to the maximum of:

- the sum of all app container requests,
- the maximum of init container requests,

for a resource.

Using the pod scope in tandem with single-numa-node Topology Manager policy is specifically valuable for workloads that are latency sensitive or for high-throughput applications that perform IPC. By combining both options, you are able to place all containers in a pod onto a single NUMA node; hence, the inter-NUMA communication overhead can be eliminated for that pod.

In the case of single-numa-node policy, a pod is accepted only if a suitable set of NUMA nodes is present among possible allocations. Reconsider the example above:

- a set containing only a single NUMA node - it leads to pod being admitted,
- whereas a set containing more NUMA nodes - it results in pod rejection (because instead of one NUMA node, two or more NUMA nodes are required to satisfy the allocation).

To recap, Topology Manager first computes a set of NUMA nodes and then tests it against Topology Manager policy, which either leads to the rejection or admission of the pod.

## Topology Manager Policies

Topology Manager supports four allocation policies. You can set a policy via a Kubelet flag, `--topology-manager-policy`. There are four supported policies:

- none (default)
- best-effort
- restricted
- single-numa-node

**Note:**

If Topology Manager is configured with the **pod** scope, the container, which is considered by the policy, is reflecting requirements of the entire pod, and thus each container from the pod will result with **the same** topology alignment decision.

**none policy**

This is the default policy and does not perform any topology alignment.

**best-effort policy**

For each container in a Pod, the kubelet, with best-effort topology management policy, calls each Hint Provider to discover their resource availability. Using this information, the Topology Manager stores the preferred NUMA Node affinity for that container. If the affinity is not preferred, Topology Manager will store this and admit the pod to the node anyway.

The *Hint Providers* can then use this information when making the resource allocation decision.

**restricted policy**

For each container in a Pod, the kubelet, with restricted topology management policy, calls each Hint Provider to discover their resource availability. Using this information, the Topology Manager stores the preferred NUMA Node affinity for that container. If the affinity is not preferred, Topology Manager will reject this pod from the node. This will result in a pod in a Terminated state with a pod admission failure.

Once the pod is in a Terminated state, the Kubernetes scheduler will **not** attempt to reschedule the pod. It is recommended to use a ReplicaSet or Deployment to trigger a redeploy of the pod. An external control loop could be also implemented to trigger a redeployment of pods that have the Topology Affinity error.

If the pod is admitted, the *Hint Providers* can then use this information when making the resource allocation decision.

**single-numa-node policy**

For each container in a Pod, the kubelet, with single-numa-node topology management policy, calls each Hint Provider to discover their resource availability. Using this information, the Topology Manager determines if a single NUMA Node affinity is possible. If it is, Topology Manager will store this and the *Hint Providers* can then use this information when making the resource allocation decision. If, however, this is not possible then the Topology Manager will reject the pod from the node. This will result in a pod in a Terminated state with a pod admission failure.

Once the pod is in a Terminated state, the Kubernetes scheduler will **not** attempt to reschedule the pod. It is recommended to use a Deployment with replicas to trigger a redeploy of the Pod. An external control loop could be also implemented to trigger a redeployment of pods that have the Topology Affinity error.

## Topology manager policy options

Support for the Topology Manager policy options requires `TopologyManagerPolicyOptions` [feature gate](#) to be enabled (it is enabled by default).

You can toggle groups of options on and off based upon their maturity level using the following feature gates:

- `TopologyManagerPolicyBetaOptions` default enabled. Enable to show beta-level options.
- `TopologyManagerPolicyAlphaOptions` default disabled. Enable to show alpha-level options.

You will still have to enable each option using the `TopologyManagerPolicyOptions` kubelet option.

The following policy options exists:

- `prefer-closest-numa-nodes` (beta, visible by default; `TopologyManagerPolicyOptions` and `TopologyManagerPolicyBetaOptions` feature gates have to be enabled). The `prefer-closest-numa-nodes` policy option is beta in Kubernetes 1.30.

If the `prefer-closest-numa-nodes` policy option is specified, the best-effort and restricted policies will favor sets of NUMA nodes with shorter distance between them when making admission decisions. You can enable this option by adding `prefer-closest-numa-nodes=true` to the Topology Manager policy options. By default, without this option, Topology Manager aligns resources on either a single NUMA node or the minimum number of NUMA nodes (in cases where more than one NUMA node is required). However, the TopologyManager is not aware of NUMA distances and does not take them into account when making admission decisions. This limitation surfaces in multi-socket, as well as single-socket multi NUMA systems, and can cause significant performance degradation in latency-critical execution and high-throughput applications if the Topology Manager decides to align resources on non-adjacent NUMA nodes.

## Pod Interactions with Topology Manager Policies

Consider the containers in the following pod specs:

```
spec:
 containers:
 - name: nginx
 image: nginx
```

This pod runs in the BestEffort QoS class because no resource requests or limits are specified.

```
spec:
 containers:
 - name: nginx
 image: nginx
 resources:
 limits:
 memory: "200Mi"
 requests:
 memory: "100Mi"
```

This pod runs in the Burstable QoS class because requests are less than limits.

If the selected policy is anything other than none, Topology Manager would consider these Pod specifications. The Topology Manager would consult the Hint Providers to get topology hints. In the case of the static, the CPU Manager policy would return default topology hint, because these Pods do not have explicitly request CPU resources.

```
spec:
 containers:
 - name: nginx
 image: nginx
 resources:
 limits:
 memory: "200Mi"
 cpu: "2"
 example.com/device: "1"
 requests:
 memory: "200Mi"
 cpu: "2"
 example.com/device: "1"
```

This pod with integer CPU request runs in the Guaranteed QoS class because requests are equal to limits.

```
spec:
 containers:
 - name: nginx
 image: nginx
 resources:
 limits:
 memory: "200Mi"
 cpu: "300m"
 example.com/device: "1"
 requests:
 memory: "200Mi"
 cpu: "300m"
 example.com/device: "1"
```

This pod with sharing CPU request runs in the Guaranteed QoS class because requests are equal to limits.

```
spec:
 containers:
 - name: nginx
 image: nginx
 resources:
 limits:
 example.com/deviceA: "1"
 example.com/deviceB: "1"
 requests:
 example.com/deviceA: "1"
 example.com/deviceB: "1"
```

This pod runs in the BestEffort QoS class because there are no CPU and memory requests.

The Topology Manager would consider the above pods. The Topology Manager would consult the Hint Providers, which are CPU and Device Manager to get topology hints for the pods.

In the case of the Guaranteed pod with integer CPU request, the static CPU Manager policy would return topology hints relating to the exclusive CPU and the Device Manager would send back hints for the requested device.

In the case of the Guaranteed pod with sharing CPU request, the static CPU Manager policy would return default topology hint as there is no exclusive CPU request and the Device Manager would send back hints for the requested device.

In the above two cases of the Guaranteed pod, the none CPU Manager policy would return default topology hint.

In the case of the BestEffort pod, the static CPU Manager policy would send back the default topology hint as there is no CPU request and the Device Manager would send back the hints for each of the requested devices.

Using this information the Topology Manager calculates the optimal hint for the pod and stores this information, which will be used by the Hint Providers when they are making their resource assignments.

## Known Limitations

1. The maximum number of NUMA nodes that Topology Manager allows is 8. With more than 8 NUMA nodes there will be a state explosion when trying to enumerate the possible NUMA affinities and generating their hints.
2. The scheduler is not topology-aware, so it is possible to be scheduled on a node and then fail on the node due to the Topology Manager.

# Customizing DNS Service

This page explains how to configure your DNS [Pod\(s\)](#) and customize the DNS resolution process in your cluster.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Your cluster must be running the CoreDNS add-on.

Your Kubernetes server must be at or later than version v1.12. To check the version, enter kubectl version.

# Introduction

DNS is a built-in Kubernetes service launched automatically using the *addon manager* [cluster add-on](#).

## Note:

The CoreDNS Service is named kube-dns in the metadata.name field.

The intent is to ensure greater interoperability with workloads that relied on the legacy kube-dns Service name to resolve addresses internal to the cluster. Using a Service named kube-dns abstracts away the implementation detail of which DNS provider is running behind that common name.

If you are running CoreDNS as a Deployment, it will typically be exposed as a Kubernetes Service with a static IP address. The kubelet passes DNS resolver information to each container with the `--cluster-dns=<dns-service-ip>` flag.

DNS names also need domains. You configure the local domain in the kubelet with the flag `--cluster-domain=<default-local-domain>`.

The DNS server supports forward lookups (A and AAAA records), port lookups (SRV records), reverse IP address lookups (PTR records), and more. For more information, see [DNS for Services and Pods](#).

If a Pod's dnsPolicy is set to default, it inherits the name resolution configuration from the node that the Pod runs on. The Pod's DNS resolution should behave the same as the node. But see [Known issues](#).

If you don't want this, or if you want a different DNS config for pods, you can use the kubelet's `--resolv-conf` flag. Set this flag to `""` to prevent Pods from inheriting DNS. Set it to a valid file path to specify a file other than `/etc/resolv.conf` for DNS inheritance.

## CoreDNS

CoreDNS is a general-purpose authoritative DNS server that can serve as cluster DNS, complying with the [DNS specifications](#).

### CoreDNS ConfigMap options

CoreDNS is a DNS server that is modular and pluggable, with plugins adding new functionalities. The CoreDNS server can be configured by maintaining a [Corefile](#), which is the CoreDNS configuration file. As a cluster administrator, you can modify the [ConfigMap](#) for the CoreDNS Corefile to change how DNS service discovery behaves for that cluster.

In Kubernetes, CoreDNS is installed with the following default Corefile configuration:

```
apiVersion: v1
kind: ConfigMap
metadata:
 name: coredns
 namespace: kube-system
data:
```

```
Corefile: |
.:53 {
 errors
 health {
 lameduck 5s
 }
 ready
 kubernetes cluster.local in-addr.arpa ip6.arpa {
 pods insecure
 fallthrough in-addr.arpa ip6.arpa
 ttl 30
 }
 prometheus :9153
 forward . /etc/resolv.conf
 cache 30
 loop
 reload
 loadbalance
}
```

The Corefile configuration includes the following [plugins](#) of CoreDNS:

- [errors](#): Errors are logged to stdout.
- [health](#): Health of CoreDNS is reported to <http://localhost:8080/health>. In this extended syntax lameduck will make the process unhealthy then wait for 5 seconds before the process is shut down.
- [ready](#): An HTTP endpoint on port 8181 will return 200 OK, when all plugins that are able to signal readiness have done so.
- [kubernetes](#): CoreDNS will reply to DNS queries based on IP of the Services and Pods. You can find [more details](#) about this plugin on the CoreDNS website.
  - ttl allows you to set a custom TTL for responses. The default is 5 seconds. The minimum TTL allowed is 0 seconds, and the maximum is capped at 3600 seconds. Setting TTL to 0 will prevent records from being cached.
  - The pods insecure option is provided for backward compatibility with kube-dns.
  - You can use the pods verified option, which returns an A record only if there exists a pod in the same namespace with a matching IP.
  - The pods disabled option can be used if you don't use pod records.
- [prometheus](#): Metrics of CoreDNS are available at <http://localhost:9153/metrics> in the [Prometheus](#) format (also known as OpenMetrics).
- [forward](#): Any queries that are not within the Kubernetes cluster domain are forwarded to predefined resolvers (/etc/resolv.conf).
- [cache](#): This enables a frontend cache.
- [loop](#): Detects simple forwarding loops and halts the CoreDNS process if a loop is found.
- [reload](#): Allows automatic reload of a changed Corefile. After you edit the ConfigMap configuration, allow two minutes for your changes to take effect.
- [loadbalance](#): This is a round-robin DNS loadbalancer that randomizes the order of A, AAAA, and MX records in the answer.

You can modify the default CoreDNS behavior by modifying the ConfigMap.

## Configuration of Stub-domain and upstream nameserver using CoreDNS

CoreDNS has the ability to configure stub-domains and upstream nameservers using the [forward plugin](#).

### Example

If a cluster operator has a [Consul](#) domain server located at "10.150.0.1", and all Consul names have the suffix ".consul.local". To configure it in CoreDNS, the cluster administrator creates the following stanza in the CoreDNS ConfigMap.

```
consul.local:53 {
 errors
 cache 30
 forward . 10.150.0.1
}
```

To explicitly force all non-cluster DNS lookups to go through a specific nameserver at 172.16.0.1, point the forward to the nameserver instead of /etc/resolv.conf

```
forward . 172.16.0.1
```

The final ConfigMap along with the default Corefile configuration looks like:

```
apiVersion: v1
kind: ConfigMap
metadata:
 name: coredns
 namespace: kube-system
data:
 Corefile: |
 .:53 {
 errors
 health
 kubernetes cluster.local in-addr.arpa ip6.arpa {
 pods insecure
 fallthrough in-addr.arpa ip6.arpa
 }
 prometheus :9153
 forward . 172.16.0.1
 cache 30
 loop
 reload
 loadbalance
 }
 consul.local:53 {
 errors
 cache 30
 forward . 10.150.0.1
 }
```

## Note:

CoreDNS does not support FQDNs for stub-domains and nameservers (eg: "ns.foo.com"). During translation, all FQDN nameservers will be omitted from the CoreDNS config.

## What's next

- Read [Debugging DNS Resolution](#)

# Debugging DNS Resolution

This page provides hints on diagnosing DNS problems.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Your cluster must be configured to use the CoreDNS [addon](#) or its precursor, kube-dns.

Your Kubernetes server must be at or later than version v1.6. To check the version, enter kubectl version.

## Create a simple Pod to use as a test environment

[admin/dns/dnsutils.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: dnsutils
 namespace: default
spec:
 containers:
 - name: dnsutils
 image: registry.k8s.io/e2e-test-images/jessie-dnsutils:1.3
 command:
 - sleep
 - "infinity"
 imagePullPolicy: IfNotPresent
 restartPolicy: Always
```

**Note:**

This example creates a pod in the default namespace. DNS name resolution for services depends on the namespace of the pod. For more information, review [DNS for Services and Pods](#).

Use that manifest to create a Pod:

```
kubectl apply -f https://k8s.io/examples/admin/dns/dnsutils.yaml
```

```
pod/dnsutils created
```

...and verify its status:

```
kubectl get pods dnsutils
```

| NAME     | READY | STATUS  | RESTARTS | AGE         |
|----------|-------|---------|----------|-------------|
| dnsutils | 1/1   | Running | 0        | <some-time> |

Once that Pod is running, you can exec nslookup in that environment. If you see something like the following, DNS is working correctly.

```
kubectl exec -i -t dnsutils -- nslookup kubernetes.default
```

```
Server: 10.0.0.10
Address 1: 10.0.0.10
```

```
Name: kubernetes.default
Address 1: 10.0.0.1
```

If the nslookup command fails, check the following:

## Check the local DNS configuration first

Take a look inside the resolv.conf file. (See [Customizing DNS Service](#) and [Known issues](#) below for more information)

```
kubectl exec -ti dnsutils -- cat /etc/resolv.conf
```

Verify that the search path and name server are set up like the following (note that search path may vary for different cloud providers):

```
search default.svc.cluster.local svc.cluster.local cluster.local google.internal
c.gce_project_id.internal
nameserver 10.0.0.10
options ndots:5
```

Errors such as the following indicate a problem with the CoreDNS (or kube-dns) add-on or with associated Services:

```
kubectl exec -i -t dnsutils -- nslookup kubernetes.default
```

```
Server: 10.0.0.10
Address 1: 10.0.0.10
```

```
nslookup: can't resolve 'kubernetes.default'
```

or

```
kubectl exec -i -t dnsutils -- nslookup kubernetes.default
```

```
Server: 10.0.0.10
```

```
Address 1: 10.0.0.10 kube-dns.kube-system.svc.cluster.local
```

```
nslookup: can't resolve 'kubernetes.default'
```

## Check if the DNS pod is running

Use the `kubectl get pods` command to verify that the DNS pod is running.

```
kubectl get pods --namespace=kube-system -l k8s-app=kube-dns
```

| NAME                     | READY | STATUS  | RESTARTS | AGE |
|--------------------------|-------|---------|----------|-----|
| ...                      |       |         |          |     |
| coredns-7b96bf9f76-5hsxb | 1/1   | Running | 0        | 1h  |
| coredns-7b96bf9f76-mvmmt | 1/1   | Running | 0        | 1h  |
| ...                      |       |         |          |     |

### Note:

The value for label `k8s-app` is `kube-dns` for both CoreDNS and kube-dns deployments.

If you see that no CoreDNS Pod is running or that the Pod has failed/completed, the DNS add-on may not be deployed by default in your current environment and you will have to deploy it manually.

## Check for errors in the DNS pod

Use the `kubectl logs` command to see logs for the DNS containers.

For CoreDNS:

```
kubectl logs --namespace=kube-system -l k8s-app=kube-dns
```

Here is an example of a healthy CoreDNS log:

```
..:53
2018/08/15 14:37:17 [INFO] CoreDNS-1.2.2
2018/08/15 14:37:17 [INFO] linux/amd64, go1.10.3, 2e322f6
CoreDNS-1.2.2
linux/amd64, go1.10.3, 2e322f6
2018/08/15 14:37:17 [INFO] plugin/reload: Running configuration MD5 =
24e6c59e83ce706f07bcc82c31b1ea1c
```

See if there are any suspicious or unexpected messages in the logs.

## Is DNS service up?

Verify that the DNS service is up by using the `kubectl get service` command.

```
kubectl get svc --namespace=kube-system
```

| NAME     | TYPE      | CLUSTER-IP | EXTERNAL-IP | PORT(S)       | AGE |
|----------|-----------|------------|-------------|---------------|-----|
| ...      |           |            |             |               |     |
| kube-dns | ClusterIP | 10.0.0.10  | <none>      | 53/UDP,53/TCP | 1h  |
| ...      |           |            |             |               |     |

### Note:

The service name is `kube-dns` for both CoreDNS and `kube-dns` deployments.

If you have created the Service or in the case it should be created by default but it does not appear, see [debugging Services](#) for more information.

## Are DNS endpoints exposed?

You can verify that DNS endpoints are exposed by using the `kubectl get endpoints` command.

```
kubectl get endpoints kube-dns --namespace=kube-system
```

| NAME     | ENDPOINTS                     | AGE |
|----------|-------------------------------|-----|
| kube-dns | 10.180.3.17:53,10.180.3.17:53 | 1h  |

If you do not see the endpoints, see the endpoints section in the [debugging Services](#) documentation.

For additional Kubernetes DNS examples, see the [cluster-dns examples](#) in the Kubernetes GitHub repository.

## Are DNS queries being received/processed?

You can verify if queries are being received by CoreDNS by adding the `log` plugin to the CoreDNS configuration (aka Corefile). The CoreDNS Corefile is held in a [ConfigMap](#) named `coredns`. To edit it, use the command:

```
kubectl -n kube-system edit configmap coredns
```

Then add `log` in the Corefile section per the example below:

```
apiVersion: v1
kind: ConfigMap
metadata:
 name: coredns
 namespace: kube-system
data:
 Corefile: |
 .:53 {
 log
 errors
```

```

health
kubernetes cluster.local in-addr.arpa ip6.arpa {
 pods insecure
 upstream
 fallthrough in-addr.arpa ip6.arpa
}
prometheus :9153
forward . /etc/resolv.conf
cache 30
loop
reload
loadbalance
}

```

After saving the changes, it may take up to minute or two for Kubernetes to propagate these changes to the CoreDNS pods.

Next, make some queries and view the logs per the sections above in this document. If CoreDNS pods are receiving the queries, you should see them in the logs.

Here is an example of a query in the log:

```

.:53
2018/08/15 14:37:15 [INFO] CoreDNS-1.2.0
2018/08/15 14:37:15 [INFO] linux/amd64, go1.10.3, 2e322f6
CoreDNS-1.2.0
linux/amd64, go1.10.3, 2e322f6
2018/09/07 15:29:04 [INFO] plugin/reload: Running configuration MD5 =
162475cdf272d8aa601e6fe67a6ad42f
2018/09/07 15:29:04 [INFO] Reloading complete
172.17.0.18:41675 - [07/Sep/2018:15:29:11 +0000] 59925 "A IN kubernetes.default.svc.cluster.local.
udp 54 false 512" NOERROR qr,aa,rd,ra 106 0.000066649s

```

## Does CoreDNS have sufficient permissions?

CoreDNS must be able to list [service](#) and [endpoint](#) related resources to properly resolve service names.

Sample error message:

```

2022-03-18T07:12:15.699431183Z [INFO] 10.96.144.227:52299 - 3686 "A IN
serverproxy.contoso.net.cluster.local. udp 52 false 512" SERVFAIL qr,aa,rd 145 0.000091221s

```

First, get the current ClusterRole of system:coredns:

```
kubectl describe clusterrole system:coredns -n kube-system
```

Expected output:

| PolicyRule: |                   |                |              |
|-------------|-------------------|----------------|--------------|
| Resources   | Non-Resource URLs | Resource Names | Verbs        |
| -----       | -----             | -----          | ----         |
| endpoints   | []                | []             | [list watch] |
| namespaces  | []                | []             | [list watch] |

```

pods [] [] [list watch]
services [] [] [list watch]
endpointslices.discovery.k8s.io [] [] [list watch]
```

If any permissions are missing, edit the ClusterRole to add them:

```
kubectcl edit clusterrole system:coredns -n kube-system
```

Example insertion of EndpointSlices permissions:

```
...
- apiGroups:
 - discovery.k8s.io
resources:
- endpointslices
verbs:
- list
- watch
...
```

## Are you in the right namespace for the service?

DNS queries that don't specify a namespace are limited to the pod's namespace.

If the namespace of the pod and service differ, the DNS query must include the namespace of the service.

This query is limited to the pod's namespace:

```
kubectcl exec -i -t dnsutils -- nslookup <service-name>
```

This query specifies the namespace:

```
kubectcl exec -i -t dnsutils -- nslookup <service-name>.<namespace>
```

To learn more about name resolution, see [DNS for Services and Pods](#).

## Known issues

Some Linux distributions (e.g. Ubuntu) use a local DNS resolver by default (systemd-resolved). Systemd-resolved moves and replaces /etc/resolv.conf with a stub file that can cause a fatal forwarding loop when resolving names in upstream servers. This can be fixed manually by using kubelet's --resolv-conf flag to point to the correct resolv.conf (With systemd-resolved, this is /run/systemd/resolve/resolv.conf). kubeadm automatically detects systemd-resolved, and adjusts the kubelet flags accordingly.

Kubernetes installs do not configure the nodes' resolv.conf files to use the cluster DNS by default, because that process is inherently distribution-specific. This should probably be implemented eventually.

Linux's libc (a.k.a. glibc) has a limit for the DNS nameserver records to 3 by default and Kubernetes needs to consume 1 nameserver record. This means that if a local installation already uses 3 nameservers, some of those entries will be lost. To work around this limit, the

node can run `dnsmasq`, which will provide more `nameserver` entries. You can also use kubelet's `--resolv-conf` flag.

If you are using Alpine version 3.17 or earlier as your base image, DNS may not work properly due to a design issue with Alpine. Until `musl` version 1.24 didn't include TCP fallback to the DNS stub resolver meaning any DNS call above 512 bytes would fail. Please upgrade your images to Alpine version 3.18 or above.

## What's next

- See [Autoscaling the DNS Service in a Cluster](#).
- Read [DNS for Services and Pods](#)

# Declare Network Policy

This document helps you get started using the Kubernetes [NetworkPolicy API](#) to declare network policies that govern how pods communicate with each other.

**Note:** This section links to third party projects that provide functionality required by Kubernetes. The Kubernetes project authors aren't responsible for these projects, which are listed alphabetically. To add a project to this list, read the [content guide](#) before submitting a change. [More information](#).

## Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version v1.8. To check the version, enter `kubectl version`.

Make sure you've configured a network provider with network policy support. There are a number of network providers that support NetworkPolicy, including:

- [Antrea](#)
- [Calico](#)
- [Cilium](#)
- [Kube-router](#)
- [Romana](#)
- [Weave Net](#)

## Create an `nginx` deployment and expose it via a service

To see how Kubernetes network policy works, start off by creating an `nginx` Deployment.

```
kubectl create deployment nginx --image=nginx
```

```
deployment.apps/nginx created
```

Expose the Deployment through a Service called nginx.

```
kubectl expose deployment nginx --port=80
```

```
service/nginx exposed
```

The above commands create a Deployment with an nginx Pod and expose the Deployment through a Service named nginx. The nginx Pod and Deployment are found in the default namespace.

```
kubectl get svc,pod
```

| NAME               | CLUSTER-IP  | EXTERNAL-IP | PORT(S) | AGE |
|--------------------|-------------|-------------|---------|-----|
| service/kubernetes | 10.100.0.1  | <none>      | 443/TCP | 46m |
| service/nginx      | 10.100.0.16 | <none>      | 80/TCP  | 33s |

| NAME                      | READY | STATUS  | RESTARTS | AGE |
|---------------------------|-------|---------|----------|-----|
| pod/nginx-701339712-e0qfq | 1/1   | Running | 0        | 35s |

## Test the service by accessing it from another Pod

You should be able to access the new nginx service from other Pods. To access the nginx Service from another Pod in the default namespace, start a busybox container:

```
kubectl run busybox --rm -ti --image=busybox:1.28 -- /bin/sh
```

In your shell, run the following command:

```
wget --spider --timeout=1 nginx
```

```
Connecting to nginx (10.100.0.16:80)
remote file exists
```

## Limit access to the nginx service

To limit the access to the nginx service so that only Pods with the label `access: true` can query it, create a NetworkPolicy object as follows:

[service/networking/nginx-policy.yaml](#)

```
apiVersion: networking.k8s.io/v1
kind: NetworkPolicy
metadata:
 name: access-nginx
spec:
 podSelector:
 matchLabels:
 app: nginx
 ingress:
```

```
- from:
- podSelector:
 matchLabels:
 access: "true"
```

The name of a NetworkPolicy object must be a valid [DNS subdomain name](#).

### Note:

NetworkPolicy includes a `podSelector` which selects the grouping of Pods to which the policy applies. You can see this policy selects Pods with the label `app=nginx`. The label was automatically added to the Pod in the nginx Deployment. An empty `podSelector` selects all pods in the namespace.

## Assign the policy to the service

Use `kubectl` to create a NetworkPolicy from the above `nginx-policy.yaml` file:

```
kubectl apply -f https://k8s.io/examples/service/networking/nginx-policy.yaml
```

```
networkpolicy.networking.k8s.io/access-nginx created
```

## Test access to the service when access label is not defined

When you attempt to access the nginx Service from a Pod without the correct labels, the request times out:

```
kubectl run busybox --rm -ti --image=busybox:1.28 -- /bin/sh
```

In your shell, run the command:

```
wget --spider --timeout=1 nginx
```

```
Connecting to nginx (10.100.0.16:80)
wget: download timed out
```

## Define access label and test again

You can create a Pod with the correct labels to see that the request is allowed:

```
kubectl run busybox --rm -ti --labels="access=true" --image=busybox:1.28 -- /bin/sh
```

In your shell, run the command:

```
wget --spider --timeout=1 nginx
```

```
Connecting to nginx (10.100.0.16:80)
remote file exists
```

# Developing Cloud Controller Manager

FEATURE STATE: Kubernetes v1.11 [beta]

The cloud-controller-manager is a Kubernetes [control plane](#) component that embeds cloud-specific control logic. The [cloud controller manager](#) lets you link your cluster into your cloud provider's API, and separates out the components that interact with that cloud platform from components that only interact with your cluster.

By decoupling the interoperability logic between Kubernetes and the underlying cloud infrastructure, the cloud-controller-manager component enables cloud providers to release features at a different pace compared to the main Kubernetes project.

## Background

Since cloud providers develop and release at a different pace compared to the Kubernetes project, abstracting the provider-specific code to the cloud-controller-manager binary allows cloud vendors to evolve independently from the core Kubernetes code.

The Kubernetes project provides skeleton cloud-controller-manager code with Go interfaces to allow you (or your cloud provider) to plug in your own implementations. This means that a cloud provider can implement a cloud-controller-manager by importing packages from Kubernetes core; each cloudprovider will register their own code by calling `cloudprovider.RegisterCloudProvider` to update a global variable of available cloud providers.

## Developing

### Out of tree

To build an out-of-tree cloud-controller-manager for your cloud:

1. Create a go package with an implementation that satisfies [cloudprovider.Interface](#).
2. Use [main.go in cloud-controller-manager](#) from Kubernetes core as a template for your `main.go`. As mentioned above, the only difference should be the cloud package that will be imported.
3. Import your cloud package in `main.go`, ensure your package has an `init` block to run [cloudprovider.RegisterCloudProvider](#).

Many cloud providers publish their controller manager code as open source. If you are creating a new cloud-controller-manager from scratch, you could take an existing out-of-tree cloud controller manager as your starting point.

### In tree

For in-tree cloud providers, you can run the in-tree cloud controller manager as a [DaemonSet](#) in your cluster. See [Cloud Controller Manager Administration](#) for more details.

# Enable Or Disable A Kubernetes API

This page shows how to enable or disable an API version from your cluster's [control plane](#).

Specific API versions can be turned on or off by passing `--runtime-config=api/<version>` as a command line argument to the API server. The values for this argument are a comma-separated list of API versions. Later values override earlier values.

The `runtime-config` command line argument also supports 2 special keys:

- `api/all`, representing all known APIs
- `api/legacy`, representing only legacy APIs. Legacy APIs are any APIs that have been explicitly [deprecated](#).

For example, to turn off all API versions except v1, pass `--runtime-config=api/all=false,api/v1=true` to the kube-apiserver.

## What's next

Read the [full documentation](#) for the kube-apiserver component.

# Encrypting Confidential Data at Rest

All of the APIs in Kubernetes that let you write persistent API resource data support at-rest encryption. For example, you can enable at-rest encryption for [Secrets](#). This at-rest encryption is additional to any system-level encryption for the etcd cluster or for the filesystem(s) on hosts where you are running the kube-apiserver.

This page shows how to enable and configure encryption of API data at rest.

### Note:

This task covers encryption for resource data stored using the [Kubernetes API](#). For example, you can encrypt Secret objects, including the key-value data they contain.

If you want to encrypt data in filesystems that are mounted into containers, you instead need to either:

- use a storage integration that provides encrypted [volumes](#)
- encrypt the data within your own application

## Before you begin

- You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:
  - [Killercodea](#)

- [Play with Kubernetes](#)

- This task assumes that you are running the Kubernetes API server as a [static pod](#) on each control plane node.
- Your cluster's control plane **must** use etcd v3.x (major version 3, any minor version).
- To encrypt a custom resource, your cluster must be running Kubernetes v1.26 or newer.
- To use a wildcard to match resources, your cluster must be running Kubernetes v1.27 or newer.

To check the version, enter `kubectl version`.

## Determine whether encryption at rest is already enabled

By default, the API server stores plain-text representations of resources into etcd, with no at-rest encryption.

The `kube-apiserver` process accepts an argument `--encryption-provider-config` that specifies a path to a configuration file. The contents of that file, if you specify one, control how Kubernetes API data is encrypted in etcd. If you are running the `kube-apiserver` without the `--encryption-provider-config` command line argument, you do not have encryption at rest enabled. If you are running the `kube-apiserver` with the `--encryption-provider-config` command line argument, and the file that it references specifies the identity provider as the first encryption provider in the list, then you do not have at-rest encryption enabled (**the default identity provider does not provide any confidentiality protection.**)

If you are running the `kube-apiserver` with the `--encryption-provider-config` command line argument, and the file that it references specifies a provider other than identity as the first encryption provider in the list, then you already have at-rest encryption enabled. However, that check does not tell you whether a previous migration to encrypted storage has succeeded. If you are not sure, see [ensure all relevant data are encrypted](#).

## Understanding the encryption at rest configuration

```

#
CAUTION: this is an example configuration.
Do not use this for your own cluster!
#
apiVersion: apiserver.config.k8s.io/v1
kind: EncryptionConfiguration
resources:
- resources:
 - secrets
 - configmaps
 - pandas.awesome.bears.example # a custom resource API
providers:
This configuration does not provide data confidentiality. The first
configured provider is specifying the "identity" mechanism, which
stores resources as plain text.
```

```
#
- identity: {} # plain text, in other words NO encryption
- aesgcm:
 keys:
 - name: key1
 secret: c2VjcmV0IGlzIHNIY3VyZQ==
 - name: key2
 secret: dGhpcyBpcyBwYXNzd29yZA==
- aescbc:
 keys:
 - name: key1
 secret: c2VjcmV0IGlzIHNIY3VyZQ==
 - name: key2
 secret: dGhpcyBpcyBwYXNzd29yZA==
- secretbox:
 keys:
 - name: key1
 secret: YWJjZGVmZ2hpamtsbW5vcHFyc3R1dnd4eXoxMjM0NTY=
- resources:
 - events
providers:
- identity: {} # do not encrypt Events even though '*' is specified below
- resources:
 - '*.apps' # wildcard match requires Kubernetes 1.27 or later
providers:
- aescbc:
 keys:
 - name: key2
 secret: c2VjcmV0IGlzIHNIY3VyZSwgb3IgaXMgaXQ/Cg==
- resources:
 - '*.*' # wildcard match requires Kubernetes 1.27 or later
providers:
- aescbc:
 keys:
 - name: key3
 secret: c2VjcmV0IGlzIHNIY3VyZSwgSSB0aGluaw==
```

Each resources array item is a separate config and contains a complete configuration. The `resources.resources` field is an array of Kubernetes resource names (resource or resource.group) that should be encrypted like Secrets, ConfigMaps, or other resources.

If custom resources are added to `EncryptionConfiguration` and the cluster version is 1.26 or newer, any newly created custom resources mentioned in the `EncryptionConfiguration` will be encrypted. Any custom resources that existed in etcd prior to that version and configuration will be unencrypted until they are next written to storage. This is the same behavior as built-in resources. See the [Ensure all secrets are encrypted](#) section.

The `providers` array is an ordered list of the possible encryption providers to use for the APIs that you listed. Each provider supports multiple keys - the keys are tried in order for decryption, and if the provider is the first provider, the first key is used for encryption.

Only one provider type may be specified per entry (identity or aescbc may be provided, but not both in the same item). The first provider in the list is used to encrypt resources written into the

storage. When reading resources from storage, each provider that matches the stored data attempts in order to decrypt the data. If no provider can read the stored data due to a mismatch in format or secret key, an error is returned which prevents clients from accessing that resource.

`EncryptionConfiguration` supports the use of wildcards to specify the resources that should be encrypted. Use `'*.<group>'` to encrypt all resources within a group (for eg `'*.apps'` in above example) or `'**'` to encrypt all resources. `'*.'` can be used to encrypt all resource in the core group. `'**'` will encrypt all resources, even custom resources that are added after API server start.

#### Note:

Use of wildcards that overlap within the same resource list or across multiple entries are not allowed since part of the configuration would be ineffective. The resources list's processing order and precedence are determined by the order it's listed in the configuration.

If you have a wildcard covering resources and want to opt out of at-rest encryption for a particular kind of resource, you achieve that by adding a separate resources array item with the name of the resource that you want to exempt, followed by a providers array item where you specify the identity provider. You add this item to the list so that it appears earlier than the configuration where you do specify encryption (a provider that is not identity).

For example, if `'*.'` is enabled and you want to opt out of encryption for Events and ConfigMaps, add a new **earlier** item to the resources, followed by the providers array item with identity as the provider. The more specific entry must come before the wildcard entry.

The new item would look similar to:

```
...
- resources:
 - configmaps. # specifically from the core API group,
 # because of trailing "."
 - events
providers:
 - identity: {}
and then other entries in resources
```

Ensure that the exemption is listed *before* the wildcard `'**'` item in the resources array to give it precedence.

For more detailed information about the `EncryptionConfiguration` struct, please refer to the [encryption configuration API](#).

#### Caution:

If any resource is not readable via the encryption configuration (because keys were changed), and you cannot restore a working configuration, your only recourse is to delete that entry from the underlying etcd directly.

Any calls to the Kubernetes API that attempt to read that resource will fail until it is deleted or a valid decryption key is provided.

## Available providers

Before you configure encryption-at-rest for data in your cluster's Kubernetes API, you need to select which provider(s) you will use.

The following table describes each available provider.

Providers for Kubernetes encryption at rest

| Name                                                   | Encryption                                                                                                                                                                                                                                                                                                                                                                                                                                                                 | Strength                             | Speed                                     | Key length         |
|--------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------------------------------------|-------------------------------------------|--------------------|
| identity                                               | None                                                                                                                                                                                                                                                                                                                                                                                                                                                                       | N/A                                  | N/A                                       | N/A                |
|                                                        | Resources written as-is without encryption. When set as the first provider, the resource will be decrypted as new values are written. Existing encrypted resources are <b>not</b> automatically overwritten with the plaintext data. The identity provider is the default if you do not specify otherwise.                                                                                                                                                                 |                                      |                                           |                    |
| aescbc                                                 | AES-CBC with <a href="#">PKCS#7</a> padding                                                                                                                                                                                                                                                                                                                                                                                                                                | Weak                                 | Fast                                      | 32-byte            |
|                                                        | Not recommended due to CBC's vulnerability to padding oracle attacks. Key material accessible from control plane host.                                                                                                                                                                                                                                                                                                                                                     |                                      |                                           |                    |
| aesgcm                                                 | AES-GCM with random nonce                                                                                                                                                                                                                                                                                                                                                                                                                                                  | Must be rotated every 200,000 writes | Fastest                                   | 16, 24, or 32-byte |
|                                                        | Not recommended for use except when an automated key rotation scheme is implemented. Key material accessible from control plane host.                                                                                                                                                                                                                                                                                                                                      |                                      |                                           |                    |
| kms v1<br>( <i>deprecated since Kubernetes v1.28</i> ) | Uses envelope encryption scheme with DEK per resource.                                                                                                                                                                                                                                                                                                                                                                                                                     | Strongest                            | Slow ( <i>compared to kms version 2</i> ) | 32-bytes           |

|                                                        | Uses relatively new encryption technologies that may not be considered acceptable in environments that require high levels of review. Key material accessible from control plane host.                                                                                                                                                                                                                                                                                     |                                      |                                           |                    |

The identity provider is the default if you do not specify otherwise. **The identity provider does not encrypt stored data and provides no additional confidentiality protection.**

## Key storage

### Local key storage

Encrypting secret data with a locally managed key protects against an etcd compromise, but it fails to protect against a host compromise. Since the encryption keys are stored on the host in the EncryptionConfiguration YAML file, a skilled attacker can access that file and extract the encryption keys.

### Managed (KMS) key storage

The KMS provider uses *envelope encryption*: Kubernetes encrypts resources using a data key, and then encrypts that data key using the managed encryption service. Kubernetes generates a unique data key for each resource. The API server stores an encrypted version of the data key in etcd alongside the ciphertext; when reading the resource, the API server calls the managed encryption service and provides both the ciphertext and the (encrypted) data key. Within the managed encryption service, the provider uses a *key encryption key* to decipher the data key, deciphers the data key, and finally recovers the plain text. Communication between the control plane and the KMS requires in-transit protection, such as TLS.

Using envelope encryption creates dependence on the key encryption key, which is not stored in Kubernetes. In the KMS case, an attacker who intends to get unauthorised access to the plaintext values would need to compromise etcd **and** the third-party KMS provider.

## Protection for encryption keys

You should take appropriate measures to protect the confidential information that allows decryption, whether that is a local encryption key, or an authentication token that allows the API server to call KMS.

Even when you rely on a provider to manage the use and lifecycle of the main encryption key (or keys), you are still responsible for making sure that access controls and other security measures for the managed encryption service are appropriate for your security needs.

## Encrypt your data

### Generate the encryption key

The following steps assume that you are not using KMS, and therefore the steps also assume that you need to generate an encryption key. If you already have an encryption key, skip to [Write an encryption configuration file](#).

#### Caution:

Storing the raw encryption key in the EncryptionConfig only moderately improves your security posture, compared to no encryption.

For additional secrecy, consider using the kms provider as this relies on keys held outside your Kubernetes cluster. Implementations of kms can work with hardware security modules or with encryption services managed by your cloud provider.

To learn about setting up encryption at rest using KMS, see [Using a KMS provider for data encryption](#). The KMS provider plugin that you use may also come with additional specific documentation.

Start by generating a new encryption key, and then encode it using base64:

- [Linux](#)
- [macOS](#)
- [Windows](#)

Generate a 32-byte random key and base64 encode it. You can use this command:

```
head -c 32 /dev/urandom | base64
```

You can use `/dev/hwrng` instead of `/dev/urandom` if you want to use your PC's built-in hardware entropy source. Not all Linux devices provide a hardware random generator.

Generate a 32-byte random key and base64 encode it. You can use this command:

```
head -c 32 /dev/urandom | base64
```

Generate a 32-byte random key and base64 encode it. You can use this command:

```
Do not run this in a session where you have set a random number
generator seed.
[Convert]::ToBase64String((1..32|%{[byte](Get-Random -Max 256)}))
```

#### **Note:**

Keep the encryption key confidential, including while you generate it and ideally even after you are no longer actively using it.

## **Replicate the encryption key**

Using a secure mechanism for file transfer, make a copy of that encryption key available to every other control plane host.

At a minimum, use encryption in transit - for example, secure shell (SSH). For more security, use asymmetric encryption between hosts, or change the approach you are using so that you're relying on KMS encryption.

## **Write an encryption configuration file**

#### **Caution:**

The encryption configuration file may contain keys that can decrypt content in etcd. If the configuration file contains any key material, you must properly restrict permissions on all your control plane hosts so only the user who runs the kube-apiserver can read this configuration.

Create a new encryption configuration file. The contents should be similar to:

```

apiVersion: apiserver.config.k8s.io/v1
kind: EncryptionConfiguration
resources:
 - resources:
 - secrets
 - configmaps
 - pandas.awesome.bears.example
 providers:
 - aescbc:
 keys:
 - name: key1
 # See the following text for more details about the secret value
 secret: <BASE 64 ENCODED SECRET>
 - identity: {} # this fallback allows reading unencrypted secrets;
 # for example, during initial migration
```

To create a new encryption key (that does not use KMS), see [Generate the encryption key](#).

## Use the new encryption configuration file

You will need to mount the new encryption config file to the kube-apiserver static pod. Here is an example on how to do that:

1. Save the new encryption config file to `/etc/kubernetes/enc/enc.yaml` on the control-plane node.
2. Edit the manifest for the kube-apiserver static pod: `/etc/kubernetes/manifests/kube-apiserver.yaml` so that it is similar to:

```

#
This is a fragment of a manifest for a static Pod.
Check whether this is correct for your cluster and for your API server.
#
apiVersion: v1
kind: Pod
metadata:
 annotations:
 kubeadm.kubernetes.io/kube-apiserver.advertise-address.endpoint: 10.20.30.40:443
 creationTimestamp: null
 labels:
 app.kubernetes.io/component: kube-apiserver
 tier: control-plane
 name: kube-apiserver
 namespace: kube-system
spec:
 containers:
 - command:
 - kube-apiserver
 ...
```

```

- --encryption-provider-config=/etc/kubernetes/enc/enc.yaml # add this line
volumeMounts:
...
- name: enc # add this line
 mountPath: /etc/kubernetes/enc # add this line
 readOnly: true # add this line
...
volumes:
...
- name: enc # add this line
 hostPath: # add this line
 path: /etc/kubernetes/enc # add this line
 type: DirectoryOrCreate # add this line
...

```

3. Restart your API server.

### Caution:

Your config file contains keys that can decrypt the contents in etcd, so you must properly restrict permissions on your control-plane nodes so only the user who runs the kube-apiserver can read it.

You now have encryption in place for **one** control plane host. A typical Kubernetes cluster has multiple control plane hosts, so there is more to do.

## Reconfigure other control plane hosts

If you have multiple API servers in your cluster, you should deploy the changes in turn to each API server.

### Caution:

For cluster configurations with two or more control plane nodes, the encryption configuration should be identical across each control plane node.

If there is a difference in the encryption provider configuration between control plane nodes, this difference may mean that the kube-apiserver can't decrypt data.

When you are planning to update the encryption configuration of your cluster, plan this so that the API servers in your control plane can always decrypt the stored data (even part way through rolling out the change).

Make sure that you use the **same** encryption configuration on each control plane host.

## Verify that newly written data is encrypted

Data is encrypted when written to etcd. After restarting your kube-apiserver, any newly created or updated Secret (or other resource kinds configured in EncryptionConfiguration) should be encrypted when stored.

To check this, you can use the `etcdctl` command line program to retrieve the contents of your secret data.

This example shows how to check this for encrypting the Secret API.

1. Create a new Secret called `secret1` in the default namespace:

```
kubectl create secret generic secret1 -n default --from-literal=mykey=mydata
```

2. Using the `etcdctl` command line tool, read that Secret out of etcd:

```
ETCDCTL_API=3 etcdctl get /registry/secrets/default/secret1 [...] | hexdump -C
```

where [...] must be the additional arguments for connecting to the etcd server.

For example:

```
ETCDCTL_API=3 etcdctl \
 --cacert=/etc/kubernetes/pki/etcd/ca.crt \
 --cert=/etc/kubernetes/pki/etcd/server.crt \
 --key=/etc/kubernetes/pki/etcd/server.key \
 get /registry/secrets/default/secret1 | hexdump -C
```

The output is similar to this (abbreviated):

```
00000000 2f 72 65 67 69 73 74 72 79 2f 73 65 63 72 65 74 |/registry/secret|
00000010 73 2f 64 65 66 61 75 6c 74 2f 73 65 63 72 65 74 |s/default/secret|
00000020 31 0a 6b 38 73 3a 65 6e 63 3a 61 65 73 63 62 63 |1.k8s:enc:aescbc|
00000030 3a 76 31 3a 6b 65 79 31 3a c7 6c e7 d3 09 bc 06 |:v1:key1:l.....|
00000040 25 51 91 e4 e0 6c e5 b1 4d 7a 8b 3d b9 c2 7c 6e |%Q...l..Mz.=..|n|
00000050 b4 79 df 05 28 ae 0d 8e 5f 35 13 2c c0 18 99 3e |.y..(..._5,...>|
[...]
00000110 23 3a 0d fc 28 ca 48 2d 6b 2d 46 cc 72 0b 70 4c |#..(.H-k-F.r.pL|
00000120 a5 fc 35 43 12 4e 60 ef bf 6f fe cf df 0b ad 1f |..5C.N`..o.....|
00000130 82 c4 88 53 02 da 3e 66 ff 0a |...S..>f..|
0000013a
```

3. Verify the stored Secret is prefixed with `k8s:enc:aescbc:v1:` which indicates the `aescbc` provider has encrypted the resulting data. Confirm that the key name shown in `etcd` matches the key name specified in the `EncryptionConfiguration` mentioned above. In this example, you can see that the encryption key named `key1` is used in `etcd` and in `EncryptionConfiguration`.
4. Verify the Secret is correctly decrypted when retrieved via the API:

```
kubectl get secret secret1 -n default -o yaml
```

The output should contain `mykey: bXlkYXRh`, with contents of `mydata` encoded using base64; read [decoding a Secret](#) to learn how to completely decode the Secret.

## Ensure all relevant data are encrypted

It's often not enough to make sure that new objects get encrypted: you also want that encryption to apply to the objects that are already stored.

For this example, you have configured your cluster so that Secrets are encrypted on write. Performing a replace operation for each Secret will encrypt that content at rest, where the objects are unchanged.

You can make this change across all Secrets in your cluster:

```
Run this as an administrator that can read and write all Secrets
kubectl get secrets --all-namespaces -o json | kubectl replace -f -
```

The command above reads all Secrets and then updates them with the same data, in order to apply server side encryption.

**Note:**

If an error occurs due to a conflicting write, retry the command. It is safe to run that command more than once.

For larger clusters, you may wish to subdivide the Secrets by namespace, or script an update.

## Prevent plain text retrieval

If you want to make sure that the only access to a particular API kind is done using encryption, you can remove the API server's ability to read that API's backing data as plaintext.

**Warning:**

Making this change prevents the API server from retrieving resources that are marked as encrypted at rest, but are actually stored in the clear.

When you have configured encryption at rest for an API (for example: the API kind Secret, representing secrets resources in the core API group), you **must** ensure that all those resources in this cluster really are encrypted at rest. Check this before you carry on with the next steps.

Once all Secrets in your cluster are encrypted, you can remove the identity part of the encryption configuration. For example:

```

apiVersion: apiserver.config.k8s.io/v1
kind: EncryptionConfiguration
resources:
- resources:
 - secrets
providers:
- aescbc:
 keys:
 - name: key1
 secret: <BASE 64 ENCODED SECRET>
- identity: {} # REMOVE THIS LINE
```

...and then restart each API server in turn. This change prevents the API server from accessing a plain-text Secret, even by accident.

## Rotate a decryption key

Changing an encryption key for Kubernetes without incurring downtime requires a multi-step operation, especially in the presence of a highly-available deployment where multiple kube-apiserver processes are running.

1. Generate a new key and add it as the second key entry for the current provider on all control plane nodes.
2. Restart **all** kube-apiserver processes, to ensure each server can decrypt any data that are encrypted with the new key.
3. Make a secure backup of the new encryption key. If you lose all copies of this key you would need to delete all the resources were encrypted under the lost key, and workloads may not operate as expected during the time that at-rest encryption is broken.
4. Make the new key the first entry in the keys array so that it is used for encryption-at-rest for new writes
5. Restart all kube-apiserver processes to ensure each control plane host now encrypts using the new key
6. As a privileged user, run `kubectl get secrets --all-namespaces -o json | kubectl replace -f -` to encrypt all existing Secrets with the new key
7. After you have updated all existing Secrets to use the new key and have made a secure backup of the new key, remove the old decryption key from the configuration.

## Decrypt all data

This example shows how to stop encrypting the Secret API at rest. If you are encrypting other API kinds, adjust the steps to match.

To disable encryption at rest, place the identity provider as the first entry in your encryption configuration file:

```

apiVersion: apiserver.config.k8s.io/v1
kind: EncryptionConfiguration
resources:
 - resources:
 - secrets
 # list any other resources here that you previously were
 # encrypting at rest
 providers:
 - identity: {} # add this line
 - aescbc:
 keys:
 - name: key1
 secret: <BASE 64 ENCODED SECRET> # keep this in place
 # make sure it comes after "identity"
```

Then run the following command to force decryption of all Secrets:

```
kubectl get secrets --all-namespaces -o json | kubectl replace -f -
```

Once you have replaced all existing encrypted resources with backing data that don't use encryption, you can remove the encryption settings from the kube-apiserver.

## Configure automatic reloading

You can configure automatic reloading of encryption provider configuration. That setting determines whether the [API server](#) should load the file you specify for `--encryption-provider-config` only once at startup, or automatically whenever you change that file. Enabling this option allows you to change the keys for encryption at rest without restarting the API server.

To allow automatic reloading, configure the API server to run with: `--encryption-provider-config-automatic-reload=true`. When enabled, file changes are polled every minute to observe the modifications. The `apiserver_encryption_config_controller_automatic_reload_last_timestamp_seconds` metric identifies when the new config becomes effective. This allows encryption keys to be rotated without restarting the API server.

## What's next

- Read about [decrypting data that are already stored at rest](#)
- Learn more about the [EncryptionConfiguration configuration API \(v1\)](#).

## Decrypt Confidential Data that is Already Encrypted at Rest

All of the APIs in Kubernetes that let you write persistent API resource data support at-rest encryption. For example, you can enable at-rest encryption for [Secrets](#). This at-rest encryption is additional to any system-level encryption for the etcd cluster or for the filesystem(s) on hosts where you are running the kube-apiserver.

This page shows how to switch from encryption of API data at rest, so that API data are stored unencrypted. You might want to do this to improve performance; usually, though, if it was a good idea to encrypt some data, it's also a good idea to leave them encrypted.

### Note:

This task covers encryption for resource data stored using the [Kubernetes API](#). For example, you can encrypt Secret objects, including the key-value data they contain.

If you wanted to manage encryption for data in filesystems that are mounted into containers, you instead need to either:

- use a storage integration that provides encrypted [volumes](#)
- encrypt the data within your own application

## Before you begin

- You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not

already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

- This task assumes that you are running the Kubernetes API server as a [static pod](#) on each control plane node.
- Your cluster's control plane **must** use etcd v3.x (major version 3, any minor version).
- To encrypt a custom resource, your cluster must be running Kubernetes v1.26 or newer.
- You should have some API data that are already encrypted.

To check the version, enter `kubectl version`.

## Determine whether encryption at rest is already enabled

By default, the API server uses an identity provider that stores plain-text representations of resources. **The default identity provider does not provide any confidentiality protection.**

The kube-apiserver process accepts an argument `--encryption-provider-config` that specifies a path to a configuration file. The contents of that file, if you specify one, control how Kubernetes API data is encrypted in etcd. If it is not specified, you do not have encryption at rest enabled.

The format of that configuration file is YAML, representing a configuration API kind named [EncryptionConfiguration](#). You can see an example configuration in [Encryption at rest configuration](#).

If `--encryption-provider-config` is set, check which resources (such as secrets) are configured for encryption, and what provider is used. Make sure that the preferred provider for that resource type is **not** identity; you only set identity (*no encryption*) as default when you want to disable encryption at rest. Verify that the first-listed provider for a resource is something **other** than identity, which means that any new information written to resources of that type will be encrypted as configured. If you do see identity as the first-listed provider for any resource, this means that those resources are being written out to etcd without encryption.

## Decrypt all data

This example shows how to stop encrypting the Secret API at rest. If you are encrypting other API kinds, adjust the steps to match.

### Locate the encryption configuration file

First, find the API server configuration files. On each control plane node, static Pod manifest for the kube-apiserver specifies a command line argument, `--encryption-provider-config`. You are likely to find that this file is mounted into the static Pod using a [hostPath](#) volume mount. Once you locate the volume you can find the file on the node filesystem and inspect it.

## Configure the API server to decrypt objects

To disable encryption at rest, place the identity provider as the first entry in your encryption configuration file.

For example, if your existing EncryptionConfiguration file reads:

```

apiVersion: apiserver.config.k8s.io/v1
kind: EncryptionConfiguration
resources:
- resources:
 - secrets
providers:
- aescbc:
 keys:
 # Do not use this (invalid) example key for encryption
 - name: example
 secret: 2KfZgdiq2K0g2YrYpyDYs9mF2LPZhQ==
```

then change it to:

```

apiVersion: apiserver.config.k8s.io/v1
kind: EncryptionConfiguration
resources:
- resources:
 - secrets
providers:
- identity: {} # add this line
- aescbc:
 keys:
 - name: example
 secret: 2KfZgdiq2K0g2YrYpyDYs9mF2LPZhQ==
```

and restart the kube-apiserver Pod on this node.

## Reconfigure other control plane hosts

If you have multiple API servers in your cluster, you should deploy the changes in turn to each API server.

Make sure that you use the same encryption configuration on each control plane host.

## Force decryption

Then run the following command to force decryption of all Secrets:

```
If you are decrypting a different kind of object, change "secrets" to match.
kubectl get secrets --all-namespaces -o json | kubectl replace -f -
```

Once you have replaced **all** existing encrypted resources with backing data that don't use encryption, you can remove the encryption settings from the kube-apiserver.

The command line options to remove are:

- `--encryption-provider-config`
- `--encryption-provider-config-automatic-reload`

Restart the kube-apiserver Pod again to apply the new configuration.

## Reconfigure other control plane hosts

If you have multiple API servers in your cluster, you should again deploy the changes in turn to each API server.

Make sure that you use the same encryption configuration on each control plane host.

# Guaranteed Scheduling For Critical Add-On Pods

Kubernetes core components such as the API server, scheduler, and controller-manager run on a control plane node. However, add-ons must run on a regular cluster node. Some of these add-ons are critical to a fully functional cluster, such as metrics-server, DNS, and UI. A cluster may stop working properly if a critical add-on is evicted (either manually or as a side effect of another operation like upgrade) and becomes pending (for example when the cluster is highly utilized and either there are other pending pods that schedule into the space vacated by the evicted critical add-on pod or the amount of resources available on the node changed for some other reason).

Note that marking a pod as critical is not meant to prevent evictions entirely; it only prevents the pod from becoming permanently unavailable. A static pod marked as critical can't be evicted. However, non-static pods marked as critical are always rescheduled.

## Marking pod as critical

To mark a Pod as critical, set `priorityClassName` for that Pod to `system-cluster-critical` or `system-node-critical`. `system-node-critical` is the highest available priority, even higher than `system-cluster-critical`.

# IP Masquerade Agent User Guide

This page shows how to configure and enable the `ip-masq-agent`.

## Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at

least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

## IP Masquerade Agent User Guide

The ip-masq-agent configures iptables rules to hide a pod's IP address behind the cluster node's IP address. This is typically done when sending traffic to destinations outside the cluster's pod [CIDR](#) range.

### Key Terms

- **NAT (Network Address Translation):** Is a method of remapping one IP address to another by modifying either the source and/or destination address information in the IP header. Typically performed by a device doing IP routing.
- **Masquerading:** A form of NAT that is typically used to perform a many to one address translation, where multiple source IP addresses are masked behind a single address, which is typically the device doing the IP routing. In Kubernetes this is the Node's IP address.
- **CIDR (Classless Inter-Domain Routing):** Based on the variable-length subnet masking, allows specifying arbitrary-length prefixes. CIDR introduced a new method of representation for IP addresses, now commonly known as **CIDR notation**, in which an address or routing prefix is written with a suffix indicating the number of bits of the prefix, such as 192.168.2.0/24.
- **Link Local:** A link-local address is a network address that is valid only for communications within the network segment or the broadcast domain that the host is connected to. Link-local addresses for IPv4 are defined in the address block 169.254.0.0/16 in CIDR notation.

The ip-masq-agent configures iptables rules to handle masquerading node/pod IP addresses when sending traffic to destinations outside the cluster node's IP and the Cluster IP range. This essentially hides pod IP addresses behind the cluster node's IP address. In some environments, traffic to "external" addresses must come from a known machine address. For example, in Google Cloud, any traffic to the internet must come from a VM's IP. When containers are used, as in Google Kubernetes Engine, the Pod IP will be rejected for egress. To avoid this, we must hide the Pod IP behind the VM's own IP address - generally known as "masquerade". By default, the agent is configured to treat the three private IP ranges specified by [RFC 1918](#) as non-masquerade [CIDR](#). These ranges are 10.0.0.0/8, 172.16.0.0/12, and 192.168.0.0/16. The agent will also treat link-local (169.254.0.0/16) as a non-masquerade CIDR by default. The agent is configured to reload its configuration from the location `/etc/config/ip-masq-agent` every 60 seconds, which is also configurable.

### masq/non-masq example

The agent configuration file must be written in YAML or JSON syntax, and may contain three optional keys:

- `nonMasqueradeCIDRs`: A list of strings in [CIDR](#) notation that specify the non-masquerade ranges.

- `masqLinkLocal`: A Boolean (true/false) which indicates whether to masquerade traffic to the link local prefix 169.254.0.0/16. False by default.
- `resyncInterval`: A time interval at which the agent attempts to reload config from disk. For example: '30s', where 's' means seconds, 'ms' means milliseconds.

Traffic to 10.0.0.0/8, 172.16.0.0/12 and 192.168.0.0/16 ranges will NOT be masqueraded. Any other traffic (assumed to be internet) will be masqueraded. An example of a local destination from a pod could be its Node's IP address as well as another node's address or one of the IP addresses in Cluster's IP range. Any other traffic will be masqueraded by default. The below entries show the default set of rules that are applied by the ip-masq-agent:

```
iptables -t nat -L IP-MASQ-AGENT
```

```
target prot opt source destination
RETURN all -- anywhere 169.254.0.0/16 /* ip-masq-agent: cluster-local traffic
should not be subject to MASQUERADE */ ADDRTYPE match dst-type !LOCAL
RETURN all -- anywhere 10.0.0.0/8 /* ip-masq-agent: cluster-local traffic
should not be subject to MASQUERADE */ ADDRTYPE match dst-type !LOCAL
RETURN all -- anywhere 172.16.0.0/12 /* ip-masq-agent: cluster-local traffic
should not be subject to MASQUERADE */ ADDRTYPE match dst-type !LOCAL
RETURN all -- anywhere 192.168.0.0/16 /* ip-masq-agent: cluster-local traffic
should not be subject to MASQUERADE */ ADDRTYPE match dst-type !LOCAL
MASQUERADE all -- anywhere anywhere /* ip-masq-agent: outbound traffic
should be subject to MASQUERADE (this match must come after cluster-local CIDR matches) */
ADDRTYPE match dst-type !LOCAL
```

By default, in GCE/Google Kubernetes Engine, if network policy is enabled or you are using a cluster CIDR not in the 10.0.0.0/8 range, the ip-masq-agent will run in your cluster. If you are running in another environment, you can add the ip-masq-agent [DaemonSet](#) to your cluster.

## Create an ip-masq-agent

To create an ip-masq-agent, run the following kubectl command:

```
kubectl apply -f https://raw.githubusercontent.com/kubernetes-sigs/ip-masq-agent/master/ip-masq-agent.yaml
```

You must also apply the appropriate node label to any nodes in your cluster that you want the agent to run on.

```
kubectl label nodes my-node node.kubernetes.io/masq-agent-ds-ready=true
```

More information can be found in the ip-masq-agent documentation [here](#).

In most cases, the default set of rules should be sufficient; however, if this is not the case for your cluster, you can create and apply a [ConfigMap](#) to customize the IP ranges that are affected. For example, to allow only 10.0.0.0/8 to be considered by the ip-masq-agent, you can create the following [ConfigMap](#) in a file called "config".

### Note:

It is important that the file is called config since, by default, that will be used as the key for lookup by the ip-masq-agent:

```
nonMasqueradeCIDRs:
- 10.0.0.0/8
resyncInterval: 60s
```

Run the following command to add the configmap to your cluster:

```
kubectl create configmap ip-masq-agent --from-file=config --namespace=kube-system
```

This will update a file located at `/etc/config/ip-masq-agent` which is periodically checked every `resyncInterval` and applied to the cluster node. After the `resync` interval has expired, you should see the `iptables` rules reflect your changes:

```
iptables -t nat -L IP-MASQ-AGENT
```

Chain IP-MASQ-AGENT (1 references)

```
target prot opt source destination
RETURN all -- anywhere 169.254.0.0/16 /* ip-masq-agent: cluster-local traffic
should not be subject to MASQUERADE */ ADDRTYPE match dst-type !LOCAL
RETURN all -- anywhere 10.0.0.0/8 /* ip-masq-agent: cluster-local
MASQUERADE all -- anywhere anywhere /* ip-masq-agent: outbound traffic
should be subject to MASQUERADE (this match must come after cluster-local CIDR matches) */
ADDRTYPE match dst-type !LOCAL
```

By default, the link local range (169.254.0.0/16) is also handled by the `ip-masq` agent, which sets up the appropriate `iptables` rules. To have the `ip-masq-agent` ignore link local, you can set `masqLinkLocal` to `true` in the `ConfigMap`.

```
nonMasqueradeCIDRs:
- 10.0.0.0/8
resyncInterval: 60s
masqLinkLocal: true
```

## Limit Storage Consumption

This example demonstrates how to limit the amount of storage consumed in a namespace.

The following resources are used in the demonstration: [ResourceQuota](#), [LimitRange](#), and [PersistentVolumeClaim](#).

### Before you begin

- You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

## Scenario: Limiting Storage Consumption

The cluster-admin is operating a cluster on behalf of a user population and the admin wants to control how much storage a single namespace can consume in order to control cost.

The admin would like to limit:

1. The number of persistent volume claims in a namespace
2. The amount of storage each claim can request
3. The amount of cumulative storage the namespace can have

## LimitRange to limit requests for storage

Adding a `LimitRange` to a namespace enforces storage request sizes to a minimum and maximum. Storage is requested via `PersistentVolumeClaim`. The admission controller that enforces limit ranges will reject any PVC that is above or below the values set by the admin.

In this example, a PVC requesting 10Gi of storage would be rejected because it exceeds the 2Gi max.

```
apiVersion: v1
kind: LimitRange
metadata:
 name: storagelimits
spec:
 limits:
 - type: PersistentVolumeClaim
 max:
 storage: 2Gi
 min:
 storage: 1Gi
```

Minimum storage requests are used when the underlying storage provider requires certain minimums. For example, AWS EBS volumes have a 1Gi minimum requirement.

## StorageQuota to limit PVC count and cumulative storage capacity

Admins can limit the number of PVCs in a namespace as well as the cumulative capacity of those PVCs. New PVCs that exceed either maximum value will be rejected.

In this example, a 6th PVC in the namespace would be rejected because it exceeds the maximum count of 5. Alternatively, a 5Gi maximum quota when combined with the 2Gi max limit above, cannot have 3 PVCs where each has 2Gi. That would be 6Gi requested for a namespace capped at 5Gi.

```
apiVersion: v1
kind: ResourceQuota
metadata:
 name: storagequota
spec:
```

```
hard:
 persistentvolumeclaims: "5"
 requests.storage: "5Gi"
```

## Summary

A limit range can put a ceiling on how much storage is requested while a resource quota can effectively cap the storage consumed by a namespace through claim counts and cumulative storage capacity. This allows a cluster-admin to plan their cluster's storage budget without risk of any one project going over their allotment.

# Migrate Replicated Control Plane To Use Cloud Controller Manager

The cloud-controller-manager is a Kubernetes [control plane](#) component that embeds cloud-specific control logic. The [cloud controller manager](#) lets you link your cluster into your cloud provider's API, and separates out the components that interact with that cloud platform from components that only interact with your cluster.

By decoupling the interoperability logic between Kubernetes and the underlying cloud infrastructure, the cloud-controller-manager component enables cloud providers to release features at a different pace compared to the main Kubernetes project.

## Background

As part of the [cloud provider extraction effort](#), all cloud specific controllers must be moved out of the kube-controller-manager. All existing clusters that run cloud controllers in the kube-controller-manager must migrate to instead run the controllers in a cloud provider specific cloud-controller-manager.

Leader Migration provides a mechanism in which HA clusters can safely migrate "cloud specific" controllers between the kube-controller-manager and the cloud-controller-manager via a shared resource lock between the two components while upgrading the replicated control plane. For a single-node control plane, or if unavailability of controller managers can be tolerated during the upgrade, Leader Migration is not needed and this guide can be ignored.

Leader Migration can be enabled by setting `--enable-leader-migration` on kube-controller-manager or cloud-controller-manager. Leader Migration only applies during the upgrade and can be safely disabled or left enabled after the upgrade is complete.

This guide walks you through the manual process of upgrading the control plane from kube-controller-manager with built-in cloud provider to running both kube-controller-manager and cloud-controller-manager. If you use a tool to deploy and manage the cluster, please refer to the documentation of the tool and the cloud provider for specific instructions of the migration.

## Before you begin

It is assumed that the control plane is running Kubernetes version N and to be upgraded to version N + 1. Although it is possible to migrate within the same version, ideally the migration

should be performed as part of an upgrade so that changes of configuration can be aligned to each release. The exact versions of N and N + 1 depend on each cloud provider. For example, if a cloud provider builds a cloud-controller-manager to work with Kubernetes 1.24, then N can be 1.23 and N + 1 can be 1.24.

The control plane nodes should run kube-controller-manager with Leader Election enabled, which is the default. As of version N, an in-tree cloud provider must be set with --cloud-provider flag and cloud-controller-manager should not yet be deployed.

The out-of-tree cloud provider must have built a cloud-controller-manager with Leader Migration implementation. If the cloud provider imports k8s.io/cloud-provider and k8s.io/controller-manager of version v0.21.0 or later, Leader Migration will be available. However, for version before v0.22.0, Leader Migration is alpha and requires feature gate ControllerManagerLeaderMigration to be enabled in cloud-controller-manager.

This guide assumes that kubelet of each control plane node starts kube-controller-manager and cloud-controller-manager as static pods defined by their manifests. If the components run in a different setting, please adjust the steps accordingly.

For authorization, this guide assumes that the cluster uses RBAC. If another authorization mode grants permissions to kube-controller-manager and cloud-controller-manager components, please grant the needed access in a way that matches the mode.

## Grant access to Migration Lease

The default permissions of the controller manager allow only accesses to their main Lease. In order for the migration to work, accesses to another Lease are required.

You can grant kube-controller-manager full access to the leases API by modifying the system::leader-locking-kube-controller-manager role. This task guide assumes that the name of the migration lease is cloud-provider-extraction-migration.

```
kubectl patch -n kube-system role 'system::leader-locking-kube-controller-manager' -p '{"rules": [{"apiGroups": ["coordination.k8s.io"], "resources": ["leases"], "resourceNames": ["cloud-provider-extraction-migration"], "verbs": ["create", "list", "get", "update"] }]}' --type=merge`
```

Do the same to the system::leader-locking-cloud-controller-manager role.

```
kubectl patch -n kube-system role 'system::leader-locking-cloud-controller-manager' -p '{"rules": [{"apiGroups": ["coordination.k8s.io"], "resources": ["leases"], "resourceNames": ["cloud-provider-extraction-migration"], "verbs": ["create", "list", "get", "update"] }]}' --type=merge`
```

## Initial Leader Migration configuration

Leader Migration optionally takes a configuration file representing the state of controller-to-manager assignment. At this moment, with in-tree cloud provider, kube-controller-manager runs route, service, and cloud-node-lifecycle. The following example configuration shows the assignment.

Leader Migration can be enabled without a configuration. Please see [Default Configuration](#) for details.

```
kind: LeaderMigrationConfiguration
apiVersion: controllermanager.config.k8s.io/v1
leaderName: cloud-provider-extraction-migration
controllerLeaders:
 - name: route
 component: kube-controller-manager
 - name: service
 component: kube-controller-manager
 - name: cloud-node-lifecycle
 component: kube-controller-manager
```

Alternatively, because the controllers can run under either controller managers, setting component to `*` for both sides makes the configuration file consistent between both parties of the migration.

```
wildcard version
kind: LeaderMigrationConfiguration
apiVersion: controllermanager.config.k8s.io/v1
leaderName: cloud-provider-extraction-migration
controllerLeaders:
 - name: route
 component: *
 - name: service
 component: *
 - name: cloud-node-lifecycle
 component: *
```

On each control plane node, save the content to `/etc/leadermigration.conf`, and update the manifest of kube-controller-manager so that the file is mounted inside the container at the same location. Also, update the same manifest to add the following arguments:

- `--enable-leader-migration` to enable Leader Migration on the controller manager
- `--leader-migration-config=/etc/leadermigration.conf` to set configuration file

Restart kube-controller-manager on each node. At this moment, kube-controller-manager has leader migration enabled and is ready for the migration.

## Deploy Cloud Controller Manager

In version  $N + 1$ , the desired state of controller-to-manager assignment can be represented by a new configuration file, shown as follows. Please note component field of each controllerLeaders changing from kube-controller-manager to cloud-controller-manager. Alternatively, use the wildcard version mentioned above, which has the same effect.

```
kind: LeaderMigrationConfiguration
apiVersion: controllermanager.config.k8s.io/v1
leaderName: cloud-provider-extraction-migration
controllerLeaders:
 - name: route
 component: cloud-controller-manager
 - name: service
 component: cloud-controller-manager
```

```
- name: cloud-node-lifecycle
 component: cloud-controller-manager
```

When creating control plane nodes of version  $N + 1$ , the content should be deployed to `/etc/leadermigration.conf`. The manifest of `cloud-controller-manager` should be updated to mount the configuration file in the same manner as `kube-controller-manager` of version  $N$ . Similarly, add `--enable-leader-migration` and `--leader-migration-config=/etc/leadermigration.conf` to the arguments of `cloud-controller-manager`.

Create a new control plane node of version  $N + 1$  with the updated `cloud-controller-manager` manifest, and with the `--cloud-provider` flag set to `external` for `kube-controller-manager`. `kube-controller-manager` of version  $N + 1$  **MUST NOT** have Leader Migration enabled because, with an external cloud provider, it does not run the migrated controllers anymore, and thus it is not involved in the migration.

Please refer to [Cloud Controller Manager Administration](#) for more detail on how to deploy `cloud-controller-manager`.

## Upgrade Control Plane

The control plane now contains nodes of both version  $N$  and  $N + 1$ . The nodes of version  $N$  run `kube-controller-manager` only, and these of version  $N + 1$  run both `kube-controller-manager` and `cloud-controller-manager`. The migrated controllers, as specified in the configuration, are running under either `kube-controller-manager` of version  $N$  or `cloud-controller-manager` of version  $N + 1$  depending on which controller manager holds the migration lease. No controller will ever be running under both controller managers at any time.

In a rolling manner, create a new control plane node of version  $N + 1$  and bring down one of version  $N$  until the control plane contains only nodes of version  $N + 1$ . If a rollback from version  $N + 1$  to  $N$  is required, add nodes of version  $N$  with Leader Migration enabled for `kube-controller-manager` back to the control plane, replacing one of version  $N + 1$  each time until there are only nodes of version  $N$ .

## (Optional) Disable Leader Migration

Now that the control plane has been upgraded to run both `kube-controller-manager` and `cloud-controller-manager` of version  $N + 1$ , Leader Migration has finished its job and can be safely disabled to save one Lease resource. It is safe to re-enable Leader Migration for the rollback in the future.

In a rolling manner, update manifest of `cloud-controller-manager` to unset both `--enable-leader-migration` and `--leader-migration-config=` flag, also remove the mount of `/etc/leadermigration.conf`, and finally remove `/etc/leadermigration.conf`. To re-enable Leader Migration, recreate the configuration file and add its mount and the flags that enable Leader Migration back to `cloud-controller-manager`.

## Default Configuration

Starting Kubernetes 1.22, Leader Migration provides a default configuration suitable for the default controller-to-manager assignment. The default configuration can be enabled by setting `--enable-leader-migration` but without `--leader-migration-config=`.

For kube-controller-manager and cloud-controller-manager, if there are no flags that enable any in-tree cloud provider or change ownership of controllers, the default configuration can be used to avoid manual creation of the configuration file.

## Special case: migrating the Node IPAM controller

If your cloud provider provides an implementation of Node IPAM controller, you should switch to the implementation in cloud-controller-manager. Disable Node IPAM controller in kube-controller-manager of version N + 1 by adding `--controllers=*,-nodeipam` to its flags. Then add nodeipam to the list of migrated controllers.

```
wildcard version, with nodeipam
kind: LeaderMigrationConfiguration
apiVersion: controllermanager.config.k8s.io/v1
leaderName: cloud-provider-extraction-migration
controllerLeaders:
- name: route
 component: *
- name: service
 component: *
- name: cloud-node-lifecycle
 component: *
- name: nodeipam
- component: *
```

## What's next

- Read the [Controller Manager Leader Migration](#) enhancement proposal.

# Namespaces Walkthrough

Kubernetes [namespaces](#) help different projects, teams, or customers to share a Kubernetes cluster.

It does this by providing the following:

1. A scope for [Names](#).
2. A mechanism to attach authorization and policy to a subsection of the cluster.

Use of multiple namespaces is optional.

This example demonstrates how to use Kubernetes namespaces to subdivide your cluster.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)

- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

## Prerequisites

This example assumes the following:

1. You have an [existing Kubernetes cluster](#).
2. You have a basic understanding of Kubernetes [Pods](#), [Services](#), and [Deployments](#).

## Understand the default namespace

By default, a Kubernetes cluster will instantiate a default namespace when provisioning the cluster to hold the default set of Pods, Services, and Deployments used by the cluster.

Assuming you have a fresh cluster, you can inspect the available namespaces by doing the following:

```
kubectl get namespaces
```

| NAME    | STATUS | AGE |
|---------|--------|-----|
| default | Active | 13m |

## Create new namespaces

For this exercise, we will create two additional Kubernetes namespaces to hold our content.

Let's imagine a scenario where an organization is using a shared Kubernetes cluster for development and production use cases.

The development team would like to maintain a space in the cluster where they can get a view on the list of Pods, Services, and Deployments they use to build and run their application. In this space, Kubernetes resources come and go, and the restrictions on who can or cannot modify resources are relaxed to enable agile development.

The operations team would like to maintain a space in the cluster where they can enforce strict procedures on who can or cannot manipulate the set of Pods, Services, and Deployments that run the production site.

One pattern this organization could follow is to partition the Kubernetes cluster into two namespaces: development and production.

Let's create two new namespaces to hold our work.

Use the file [namespace-dev.yaml](#) which describes a development namespace:

[admin/namespace-dev.yaml](#)

```
apiVersion: v1
kind: Namespace
metadata:
```

```
name: development
labels:
 name: development
```

Create the development namespace using kubectl.

```
kubectl create -f https://k8s.io/examples/admin/namespace-dev.yaml
```

Save the following contents into file [namespace-prod.yaml](#) which describes a production namespace:

[admin/namespace-prod.yaml](#)

```
apiVersion: v1
kind: Namespace
metadata:
 name: production
 labels:
 name: production
```

And then let's create the production namespace using kubectl.

```
kubectl create -f https://k8s.io/examples/admin/namespace-prod.yaml
```

To be sure things are right, let's list all of the namespaces in our cluster.

```
kubectl get namespaces --show-labels
```

| NAME        | STATUS | AGE | LABELS           |
|-------------|--------|-----|------------------|
| default     | Active | 32m | <none>           |
| development | Active | 29s | name=development |
| production  | Active | 23s | name=production  |

## Create pods in each namespace

A Kubernetes namespace provides the scope for Pods, Services, and Deployments in the cluster.

Users interacting with one namespace do not see the content in another namespace.

To demonstrate this, let's spin up a simple Deployment and Pods in the development namespace.

We first check what is the current context:

```
kubectl config view
```

```
apiVersion: v1
clusters:
- cluster:
 certificate-authority-data: REDACTED
 server: https://130.211.122.180
 name: lithe-cocoa-92103_kubernetes
contexts:
- context:
```

```
cluster: lithe-cocoa-92103_kubernetes
user: lithe-cocoa-92103_kubernetes
name: lithe-cocoa-92103_kubernetes
current-context: lithe-cocoa-92103_kubernetes
kind: Config
preferences: {}
users:
- name: lithe-cocoa-92103_kubernetes
 user:
 client-certificate-data: REDACTED
 client-key-data: REDACTED
 token: 65rZW78y8HbwXXtSXuUw9DbP4FLjHi4b
- name: lithe-cocoa-92103_kubernetes-basic-auth
 user:
 password: h5M0FtUUIfBSdI7
 username: admin
```

```
kubectl config current-context
```

```
lithe-cocoa-92103_kubernetes
```

The next step is to define a context for the kubectl client to work in each namespace. The value of "cluster" and "user" fields are copied from the current context.

```
kubectl config set-context dev --namespace=development \
--cluster=lithe-cocoa-92103_kubernetes \
--user=lithe-cocoa-92103_kubernetes

kubectl config set-context prod --namespace=production \
--cluster=lithe-cocoa-92103_kubernetes \
--user=lithe-cocoa-92103_kubernetes
```

By default, the above commands add two contexts that are saved into file `.kube/config`. You can now view the contexts and alternate against the two new request contexts depending on which namespace you wish to work against.

To view the new contexts:

```
kubectl config view
```

```
apiVersion: v1
clusters:
- cluster:
 certificate-authority-data: REDACTED
 server: https://130.211.122.180
 name: lithe-cocoa-92103_kubernetes
contexts:
- context:
 cluster: lithe-cocoa-92103_kubernetes
 user: lithe-cocoa-92103_kubernetes
 name: lithe-cocoa-92103_kubernetes
- context:
 cluster: lithe-cocoa-92103_kubernetes
 namespace: development
```

```
 user: lithe-cocoa-92103_kubernetes
name: dev
- context:
 cluster: lithe-cocoa-92103_kubernetes
 namespace: production
 user: lithe-cocoa-92103_kubernetes
 name: prod
current-context: lithe-cocoa-92103_kubernetes
kind: Config
preferences: {}
users:
- name: lithe-cocoa-92103_kubernetes
 user:
 client-certificate-data: REDACTED
 client-key-data: REDACTED
 token: 65rZW78y8HbwXXtSXuUw9DbP4FLjHi4b
- name: lithe-cocoa-92103_kubernetes-basic-auth
 user:
 password: h5M0FtUUIfBSdI7
 username: admin
```

Let's switch to operate in the development namespace.

```
kubectl config use-context dev
```

You can verify your current context by doing the following:

```
kubectl config current-context
```

```
dev
```

At this point, all requests we make to the Kubernetes cluster from the command line are scoped to the development namespace.

Let's create some contents.

[admin/snowflake-deployment.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
 labels:
 app: snowflake
 name: snowflake
spec:
 replicas: 2
 selector:
 matchLabels:
 app: snowflake
 template:
 metadata:
 labels:
 app: snowflake
 spec:
```

```
containers:
- image: registry.k8s.io/serve_hostname
 imagePullPolicy: Always
 name: snowflake
```

Apply the manifest to create a Deployment

```
kubectl apply -f https://k8s.io/examples/admin/snowflake-deployment.yaml
```

We have created a deployment whose replica size is 2 that is running the pod called snowflake with a basic container that serves the hostname.

```
kubectl get deployment
```

| NAME      | READY | UP-TO-DATE | AVAILABLE | AGE |
|-----------|-------|------------|-----------|-----|
| snowflake | 2/2   | 2          | 2         | 2m  |

```
kubectl get pods -l app=snowflake
```

| NAME                       | READY | STATUS  | RESTARTS | AGE |
|----------------------------|-------|---------|----------|-----|
| snowflake-3968820950-9dgr8 | 1/1   | Running | 0        | 2m  |
| snowflake-3968820950-vgc4n | 1/1   | Running | 0        | 2m  |

And this is great, developers are able to do what they want, and they do not have to worry about affecting content in the production namespace.

Let's switch to the production namespace and show how resources in one namespace are hidden from the other.

```
kubectl config use-context prod
```

The production namespace should be empty, and the following commands should return nothing.

```
kubectl get deployment
kubectl get pods
```

Production likes to run cattle, so let's create some cattle pods.

```
kubectl create deployment cattle --image=registry.k8s.io/serve_hostname --replicas=5
```

```
kubectl get deployment
```

| NAME   | READY | UP-TO-DATE | AVAILABLE | AGE |
|--------|-------|------------|-----------|-----|
| cattle | 5/5   | 5          | 5         | 10s |

```
kubectl get pods -l app=cattle
```

| NAME                    | READY | STATUS  | RESTARTS | AGE |
|-------------------------|-------|---------|----------|-----|
| cattle-2263376956-41xy6 | 1/1   | Running | 0        | 34s |
| cattle-2263376956-kw466 | 1/1   | Running | 0        | 34s |
| cattle-2263376956-n4v97 | 1/1   | Running | 0        | 34s |
| cattle-2263376956-p5p3i | 1/1   | Running | 0        | 34s |
| cattle-2263376956-sxpth | 1/1   | Running | 0        | 34s |

At this point, it should be clear that the resources users create in one namespace are hidden from the other namespace.

As the policy support in Kubernetes evolves, we will extend this scenario to show how you can provide different authorization rules for each namespace.

## Operating etcd clusters for Kubernetes

etcd is a consistent and highly-available key value store used as Kubernetes' backing store for all cluster data.

If your Kubernetes cluster uses etcd as its backing store, make sure you have a [back up](#) plan for the data.

You can find in-depth information about etcd in the official [documentation](#).

### Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to follow this guide on a cluster with at least two nodes that are not acting as control plane nodes. If you do not already have a cluster, you can create one by using [minikube](#).

### Prerequisites

- Run etcd as a cluster of odd members.
- etcd is a leader-based distributed system. Ensure that the leader periodically send heartbeats on time to all followers to keep the cluster stable.
- Ensure that no resource starvation occurs.

Performance and stability of the cluster is sensitive to network and disk I/O. Any resource starvation can lead to heartbeat timeout, causing instability of the cluster. An unstable etcd indicates that no leader is elected. Under such circumstances, a cluster cannot make any changes to its current state, which implies no new pods can be scheduled.

- Keeping etcd clusters stable is critical to the stability of Kubernetes clusters. Therefore, run etcd clusters on dedicated machines or isolated environments for [guaranteed resource requirements](#).
- The minimum recommended etcd versions to run in production are 3.4.22+ and 3.5.6+.

### Resource requirements

Operating etcd with limited resources is suitable only for testing purposes. For deploying in production, advanced hardware configuration is required. Before deploying etcd in production, see [resource requirement reference](#).

# Starting etcd clusters

This section covers starting a single-node and multi-node etcd cluster.

## Single-node etcd cluster

Use a single-node etcd cluster only for testing purposes.

1. Run the following:

```
etcd --listen-client-urls=http://$PRIVATE_IP:2379 \
--advertise-client-urls=http://$PRIVATE_IP:2379
```

2. Start the Kubernetes API server with the flag `--etcd-servers=$PRIVATE_IP:2379`.

Make sure `PRIVATE_IP` is set to your etcd client IP.

## Multi-node etcd cluster

For durability and high availability, run etcd as a multi-node cluster in production and back it up periodically. A five-member cluster is recommended in production. For more information, see [FAQ documentation](#).

Configure an etcd cluster either by static member information or by dynamic discovery. For more information on clustering, see [etcd clustering documentation](#).

For an example, consider a five-member etcd cluster running with the following client URLs: `http://$IP1:2379`, `http://$IP2:2379`, `http://$IP3:2379`, `http://$IP4:2379`, and `http://$IP5:2379`. To start a Kubernetes API server:

1. Run the following:

```
etcd --listen-client-urls=http://$IP1:2379,http://$IP2:2379,http://$IP3:2379,http://$IP4:2379,http://$IP5:2379 --advertise-client-urls=http://$IP1:2379,http://$IP2:2379,http://$IP3:2379,http://$IP4:2379,http://$IP5:2379
```

2. Start the Kubernetes API servers with the flag `--etcd-servers=$IP1:2379,$IP2:2379,$IP3:2379,$IP4:2379,$IP5:2379`.

Make sure the `IP<n>` variables are set to your client IP addresses.

## Multi-node etcd cluster with load balancer

To run a load balancing etcd cluster:

1. Set up an etcd cluster.
2. Configure a load balancer in front of the etcd cluster. For example, let the address of the load balancer be `$LB`.
3. Start Kubernetes API Servers with the flag `--etcd-servers=$LB:2379`.

## Securing etcd clusters

Access to etcd is equivalent to root permission in the cluster so ideally only the API server should have access to it. Considering the sensitivity of the data, it is recommended to grant permission to only those nodes that require access to etcd clusters.

To secure etcd, either set up firewall rules or use the security features provided by etcd. etcd security features depend on x509 Public Key Infrastructure (PKI). To begin, establish secure communication channels by generating a key and certificate pair. For example, use key pairs `peer.key` and `peer.cert` for securing communication between etcd members, and `client.key` and `client.cert` for securing communication between etcd and its clients. See the [example scripts](#) provided by the etcd project to generate key pairs and CA files for client authentication.

### Securing communication

To configure etcd with secure peer communication, specify flags `--peer-key-file=peer.key` and `--peer-cert-file=peer.cert`, and use HTTPS as the URL schema.

Similarly, to configure etcd with secure client communication, specify flags `--key-file=k8sclient.key` and `--cert-file=k8sclient.cert`, and use HTTPS as the URL schema. Here is an example on a client command that uses secure communication:

```
ETCDCTL_API=3 etcdctl --endpoints 10.2.0.9:2379 \
--cert=/etc/kubernetes/pki/etcd/server.crt \
--key=/etc/kubernetes/pki/etcd/server.key \
--cacert=/etc/kubernetes/pki/etcd/ca.crt \
member list
```

### Limiting access of etcd clusters

After configuring secure communication, restrict the access of the etcd cluster to only the Kubernetes API servers using TLS authentication.

For example, consider key pairs `k8sclient.key` and `k8sclient.cert` that are trusted by the CA `etcd.ca`. When etcd is configured with `--client-cert-auth` along with TLS, it verifies the certificates from clients by using system CAs or the CA passed in by `--trusted-ca-file` flag. Specifying flags `--client-cert-auth=true` and `--trusted-ca-file=etcd.ca` will restrict the access to clients with the certificate `k8sclient.cert`.

Once etcd is configured correctly, only clients with valid certificates can access it. To give Kubernetes API servers the access, configure them with the flags `--etcd-certfile=k8sclient.cert`, `--etcd-keyfile=k8sclient.key` and `--etcd-cafile=ca.cert`.

#### Note:

etcd authentication is not planned for Kubernetes.

## Replacing a failed etcd member

etcd cluster achieves high availability by tolerating minor member failures. However, to improve the overall health of the cluster, replace failed members immediately. When multiple

members fail, replace them one by one. Replacing a failed member involves two steps: removing the failed member and adding a new member.

Though etcd keeps unique member IDs internally, it is recommended to use a unique name for each member to avoid human errors. For example, consider a three-member etcd cluster. Let the URLs be, member1=http://10.0.0.1, member2=http://10.0.0.2, and member3=http://10.0.0.3. When member1 fails, replace it with member4=http://10.0.0.4.

1. Get the member ID of the failed member1:

```
etcdctl --endpoints=http://10.0.0.2,http://10.0.0.3 member list
```

The following message is displayed:

```
8211f1d0f64f3269, started, member1, http://10.0.0.1:2380, http://10.0.0.1:2379
91bc3c398fb3c146, started, member2, http://10.0.0.2:2380, http://10.0.0.2:2379
fd422379fda50e48, started, member3, http://10.0.0.3:2380, http://10.0.0.3:2379
```

2. Do either of the following:

1. If each Kubernetes API server is configured to communicate with all etcd members, remove the failed member from the --etcd-servers flag, then restart each Kubernetes API server.
2. If each Kubernetes API server communicates with a single etcd member, then stop the Kubernetes API server that communicates with the failed etcd.

3. Stop the etcd server on the broken node. It is possible that other clients besides the Kubernetes API server are causing traffic to etcd and it is desirable to stop all traffic to prevent writes to the data directory.

4. Remove the failed member:

```
etcdctl member remove 8211f1d0f64f3269
```

The following message is displayed:

```
Removed member 8211f1d0f64f3269 from cluster
```

5. Add the new member:

```
etcdctl member add member4 --peer-urls=http://10.0.0.4:2380
```

The following message is displayed:

```
Member 2be1eb8f84b7f63e added to cluster ef37ad9dc622a7c4
```

6. Start the newly added member on a machine with the IP 10.0.0.4:

```
export ETCD_NAME="member4"
export ETCD_INITIAL_CLUSTER="member2=http://10.0.0.2:2380,member3=http://
10.0.0.3:2380,member4=http://10.0.0.4:2380"
export ETCD_INITIAL_CLUSTER_STATE=existing
etcd [flags]
```

Do either of the following:

7.
  1. If each Kubernetes API server is configured to communicate with all etcd members, add the newly added member to the `--etcd-servers` flag, then restart each Kubernetes API server.
  2. If each Kubernetes API server communicates with a single etcd member, start the Kubernetes API server that was stopped in step 2. Then configure Kubernetes API server clients to again route requests to the Kubernetes API server that was stopped. This can often be done by configuring a load balancer.

For more information on cluster reconfiguration, see [etcd reconfiguration documentation](#).

## Backing up an etcd cluster

All Kubernetes objects are stored in etcd. Periodically backing up the etcd cluster data is important to recover Kubernetes clusters under disaster scenarios, such as losing all control plane nodes. The snapshot file contains all the Kubernetes state and critical information. In order to keep the sensitive Kubernetes data safe, encrypt the snapshot files.

Backing up an etcd cluster can be accomplished in two ways: etcd built-in snapshot and volume snapshot.

### Built-in snapshot

etcd supports built-in snapshot. A snapshot may either be created from a live member with the `etcdctl snapshot save` command or by copying the `member/snap/db` file from an etcd [data directory](#) that is not currently used by an etcd process. Creating the snapshot will not affect the performance of the member.

Below is an example for creating a snapshot of the keyspace served by \$ENDPOINT to the file `snapshot.db`:

```
ETCDCTL_API=3 etcdctl --endpoints $ENDPOINT snapshot save snapshot.db
```

Verify the snapshot:

```
ETCDCTL_API=3 etcdctl --write-out=table snapshot status snapshot.db
```

```
+-----+-----+-----+-----+
| HASH | REVISION | TOTAL KEYS | TOTAL SIZE |
+-----+-----+-----+-----+
| fe01cf57 | 10 | 7 | 2.1 MB |
+-----+-----+-----+-----+
```

### Volume snapshot

If etcd is running on a storage volume that supports backup, such as Amazon Elastic Block Store, back up etcd data by creating a snapshot of the storage volume.

### Snapshot using etcdctl options

We can also create the snapshot using various options given by `etcdctl`. For example:

```
ETCDCTL_API=3 etcdctl -h
```

will list various options available from etcdctl. For example, you can create a snapshot by specifying the endpoint, certificates and key as shown below:

```
ETCDCTL_API=3 etcdctl --endpoints=https://127.0.0.1:2379 \
--cacert=<trusted-ca-file> --cert=<cert-file> --key=<key-file> \
snapshot save <backup-file-location>
```

where trusted-ca-file, cert-file and key-file can be obtained from the description of the etcd Pod.

## Scaling out etcd clusters

Scaling out etcd clusters increases availability by trading off performance. Scaling does not increase cluster performance nor capability. A general rule is not to scale out or in etcd clusters. Do not configure any auto scaling groups for etcd clusters. It is strongly recommended to always run a static five-member etcd cluster for production Kubernetes clusters at any officially supported scale.

A reasonable scaling is to upgrade a three-member cluster to a five-member one, when more reliability is desired. See [etcd reconfiguration documentation](#) for information on how to add members into an existing cluster.

## Restoring an etcd cluster

etcd supports restoring from snapshots that are taken from an etcd process of the [major.minor](#) version. Restoring a version from a different patch version of etcd is also supported. A restore operation is employed to recover the data of a failed cluster.

Before starting the restore operation, a snapshot file must be present. It can either be a snapshot file from a previous backup operation, or from a remaining [data directory](#).

When restoring the cluster, use the --data-dir option to specify to which folder the cluster should be restored:

```
ETCDCTL_API=3 etcdctl --data-dir <data-dir-location> snapshot restore snapshot.db
```

where <data-dir-location> is a directory that will be created during the restore process.

Yet another example would be to first export the ETCDCTL\_API environment variable:

```
export ETCDCTL_API=3
etcdctl --data-dir <data-dir-location> snapshot restore snapshot.db
```

If <data-dir-location> is the same folder as before, delete it and stop the etcd process before restoring the cluster. Otherwise, change etcd configuration and restart the etcd process after restoration to have it use the new data directory.

For more information and examples on restoring a cluster from a snapshot file, see [etcd disaster recovery documentation](#).

If the access URLs of the restored cluster are changed from the previous cluster, the Kubernetes API server must be reconfigured accordingly. In this case, restart Kubernetes API servers with

the flag `--etcd-servers=$NEW_ETCD_CLUSTER` instead of the flag `--etcd-servers=$OLD_ETCD_CLUSTER`. Replace `$NEW_ETCD_CLUSTER` and `$OLD_ETCD_CLUSTER` with the respective IP addresses. If a load balancer is used in front of an etcd cluster, you might need to update the load balancer instead.

If the majority of etcd members have permanently failed, the etcd cluster is considered failed. In this scenario, Kubernetes cannot make any changes to its current state. Although the scheduled pods might continue to run, no new pods can be scheduled. In such cases, recover the etcd cluster and potentially reconfigure Kubernetes API servers to fix the issue.

**Note:**

If any API servers are running in your cluster, you should not attempt to restore instances of etcd. Instead, follow these steps to restore etcd:

- stop *all* API server instances
- restore state in all etcd instances
- restart all API server instances

We also recommend restarting any components (e.g. kube-scheduler, kube-controller-manager, kubelet) to ensure that they don't rely on some stale data. Note that in practice, the restore takes a bit of time. During the restoration, critical components will lose leader lock and restart themselves.

## Upgrading etcd clusters

For more details on etcd upgrade, please refer to the [etcd upgrades](#) documentation.

**Note:**

Before you start an upgrade, please back up your etcd cluster first.

## Maintaining etcd clusters

For more details on etcd maintenance, please refer to the [etcd maintenance](#) documentation.

This item links to a third party project or product that is not part of Kubernetes itself. [More information](#)

**Note:**

Defragmentation is an expensive operation, so it should be executed as infrequently as possible. On the other hand, it's also necessary to make sure any etcd member will not exceed the storage quota. The Kubernetes project recommends that when you perform defragmentation, you use a tool such as [etcd-defrag](#).

You can also run the defragmentation tool as a Kubernetes CronJob, to make sure that defragmentation happens regularly. See [etcd-defrag-cronjob.yaml](#) for details.

# Reserve Compute Resources for System Daemons

Kubernetes nodes can be scheduled to Capacity. Pods can consume all the available capacity on a node by default. This is an issue because nodes typically run quite a few system daemons that power the OS and Kubernetes itself. Unless resources are set aside for these system daemons, pods and system daemons compete for resources and lead to resource starvation issues on the node.

The kubelet exposes a feature named 'Node Allocatable' that helps to reserve compute resources for system daemons. Kubernetes recommends cluster administrators to configure 'Node Allocatable' based on their workload density on each node.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version 1.8. To check the version, enter kubectl version. Your Kubernetes server must be at or later than version 1.17 to use the kubelet command line option --reserved-cpus to set an [explicitly reserved CPU list](#).

## Node Allocatable

node capacity

'Allocatable' on a Kubernetes node is defined as the amount of compute resources that are available for pods. The scheduler does not over-subscribe 'Allocatable'. 'CPU', 'memory' and 'ephemeral-storage' are supported as of now.

Node Allocatable is exposed as part of v1.Node object in the API and as part of kubectl describe node in the CLI.

Resources can be reserved for two categories of system daemons in the kubelet.

## Enabling QoS and Pod level cgroups

To properly enforce node allocatable constraints on the node, you must enable the new cgroup hierarchy via the --cgroups-per-qos flag. This flag is enabled by default. When enabled, the kubelet will parent all end-user pods under a cgroup hierarchy managed by the kubelet.

## Configuring a cgroup driver

The kubelet supports manipulation of the cgroup hierarchy on the host using a cgroup driver. The driver is configured via the --cgroup-driver flag.

The supported values are the following:

- `cgroupfs` is the default driver that performs direct manipulation of the cgroup filesystem on the host in order to manage cgroup sandboxes.
- `systemd` is an alternative driver that manages cgroup sandboxes using transient slices for resources that are supported by that init system.

Depending on the configuration of the associated container runtime, operators may have to choose a particular cgroup driver to ensure proper system behavior. For example, if operators use the `systemd` cgroup driver provided by the `containerd` runtime, the `kubelet` must be configured to use the `systemd` cgroup driver.

## Kube Reserved

- **Kubelet Flag:** `--kube-reserved=[cpu=100m][,][memory=100Mi][,][ephemeral-storage=1Gi][,][pid=1000]`
- **Kubelet Flag:** `--kube-reserved-cgroup=`

`kube-reserved` is meant to capture resource reservation for kubernetes system daemons like the `kubelet`, container runtime, node problem detector, etc. It is not meant to reserve resources for system daemons that are run as pods. `kube-reserved` is typically a function of pod density on the nodes.

In addition to `cpu`, `memory`, and `ephemeral-storage`, `pid` may be specified to reserve the specified number of process IDs for kubernetes system daemons.

To optionally enforce `kube-reserved` on kubernetes system daemons, specify the parent control group for kube daemons as the value for `--kube-reserved-cgroup` kubelet flag.

It is recommended that the kubernetes system daemons are placed under a top level control group (`runtime.slice` on `systemd` machines for example). Each system daemon should ideally run within its own child control group. Refer to [the design proposal](#) for more details on recommended control group hierarchy.

Note that Kubelet **does not** create `--kube-reserved-cgroup` if it doesn't exist. The kubelet will fail to start if an invalid cgroup is specified. With `systemd` cgroup driver, you should follow a specific pattern for the name of the cgroup you define: the name should be the value you set for `--kube-reserved-cgroup`, with `.slice` appended.

## System Reserved

- **Kubelet Flag:** `--system-reserved=[cpu=100m][,][memory=100Mi][,][ephemeral-storage=1Gi][,][pid=1000]`
- **Kubelet Flag:** `--system-reserved-cgroup=`

`system-reserved` is meant to capture resource reservation for OS system daemons like `sshd`, `udev`, etc. `system-reserved` should reserve memory for the kernel too since kernel memory is not accounted to pods in Kubernetes at this time. Reserving resources for user login sessions is also recommended (`user.slice` in `systemd` world).

In addition to `cpu`, `memory`, and `ephemeral-storage`, `pid` may be specified to reserve the specified number of process IDs for OS system daemons.

To optionally enforce system-reserved on system daemons, specify the parent control group for OS system daemons as the value for --system-reserved-cgroup kubelet flag.

It is recommended that the OS system daemons are placed under a top level control group (system.slice on systemd machines for example).

Note that kubelet **does not** create --system-reserved-cgroup if it doesn't exist. kubelet will fail if an invalid cgroup is specified. With systemd cgroup driver, you should follow a specific pattern for the name of the cgroup you define: the name should be the value you set for --system-reserved-cgroup, with .slice appended.

## Explicitly Reserved CPU List

FEATURE STATE: Kubernetes v1.17 [stable]

**Kubelet Flag:** --reserved-cpus=0-3 **KubeletConfiguration Flag:** reservedSystemCPUs: 0-3

reserved-cpus is meant to define an explicit CPU set for OS system daemons and kubernetes system daemons. reserved-cpus is for systems that do not intend to define separate top level cgroups for OS system daemons and kubernetes system daemons with regard to cpuset resource. If the Kubelet **does not** have --system-reserved-cgroup and --kube-reserved-cgroup, the explicit cpuset provided by reserved-cpus will take precedence over the CPUs defined by --kube-reserved and --system-reserved options.

This option is specifically designed for Telco/NFV use cases where uncontrolled interrupts/timers may impact the workload performance. you can use this option to define the explicit cpuset for the system/kubernetes daemons as well as the interrupts/timers, so the rest CPUs on the system can be used exclusively for workloads, with less impact from uncontrolled interrupts/timers. To move the system daemon, kubernetes daemons and interrupts/timers to the explicit cpuset defined by this option, other mechanism outside Kubernetes should be used. For example: in Centos, you can do this using the tuned toolset.

## Eviction Thresholds

**Kubelet Flag:** --eviction-hard=[memory.available<500Mi]

Memory pressure at the node level leads to System OOMs which affects the entire node and all pods running on it. Nodes can go offline temporarily until memory has been reclaimed. To avoid (or reduce the probability of) system OOMs kubelet provides [out of resource](#) management. Evictions are supported for memory and ephemeral-storage only. By reserving some memory via --eviction-hard flag, the kubelet attempts to evict pods whenever memory availability on the node drops below the reserved value. Hypothetically, if system daemons did not exist on a node, pods cannot use more than capacity - eviction-hard. For this reason, resources reserved for evictions are not available for pods.

## Enforcing Node Allocatable

**Kubelet Flag:** --enforce-node-allocatable=pods[,][system-reserved][,][kube-reserved]

The scheduler treats 'Allocatable' as the available capacity for pods.

kubelet enforce 'Allocatable' across pods by default. Enforcement is performed by evicting pods whenever the overall usage across all pods exceeds 'Allocatable'. More details on eviction policy

can be found on the [node pressure eviction](#) page. This enforcement is controlled by specifying pods value to the kubelet flag `--enforce-node-allocatable`.

Optionally, kubelet can be made to enforce kube-reserved and system-reserved by specifying kube-reserved & system-reserved values in the same flag. Note that to enforce kube-reserved or system-reserved, `--kube-reserved-cgroup` or `--system-reserved-cgroup` needs to be specified respectively.

## General Guidelines

System daemons are expected to be treated similar to [Guaranteed pods](#). System daemons can burst within their bounding control groups and this behavior needs to be managed as part of kubernetes deployments. For example, kubelet should have its own control group and share kube-reserved resources with the container runtime. However, Kubelet cannot burst and use up all available Node resources if kube-reserved is enforced.

Be extra careful while enforcing system-reserved reservation since it can lead to critical system services being CPU starved, OOM killed, or unable to fork on the node. The recommendation is to enforce system-reserved only if a user has profiled their nodes exhaustively to come up with precise estimates and is confident in their ability to recover if any process in that group is oom-killed.

- To begin with enforce 'Allocatable' on pods.
- Once adequate monitoring and alerting is in place to track kube system daemons, attempt to enforce kube-reserved based on usage heuristics.
- If absolutely necessary, enforce system-reserved over time.

The resource requirements of kube system daemons may grow over time as more and more features are added. Over time, kubernetes project will attempt to bring down utilization of node system daemons, but that is not a priority as of now. So expect a drop in Allocatable capacity in future releases.

## Example Scenario

Here is an example to illustrate Node Allocatable computation:

- Node has 32Gi of memory, 16 CPUs and 100Gi of Storage
- `--kube-reserved` is set to `cpu=1,memory=2Gi,ephemeral-storage=1Gi`
- `--system-reserved` is set to `cpu=500m,memory=1Gi,ephemeral-storage=1Gi`
- `--eviction-hard` is set to `memory.available<500Mi,nodefs.available<10%`

Under this scenario, 'Allocatable' will be 14.5 CPUs, 28.5Gi of memory and 88Gi of local storage. Scheduler ensures that the total memory requests across all pods on this node does not exceed 28.5Gi and storage doesn't exceed 88Gi. Kubelet evicts pods whenever the overall memory usage across pods exceeds 28.5Gi, or if overall disk usage exceeds 88Gi. If all processes on the node consume as much CPU as they can, pods together cannot consume more than 14.5 CPUs.

If kube-reserved and/or system-reserved is not enforced and system daemons exceed their reservation, kubelet evicts pods whenever the overall node memory usage is higher than 31.5Gi or storage is greater than 90Gi.

# Running Kubernetes Node Components as a Non-root User

FEATURE STATE: Kubernetes v1.22 [alpha]

This document describes how to run Kubernetes Node components such as kubelet, CRI, OCI, and CNI without root privileges, by using a [user namespace](#).

This technique is also known as *rootless mode*.

## Note:

This document describes how to run Kubernetes Node components (and hence pods) as a non-root user.

If you are just looking for how to run a pod as a non-root user, see [SecurityContext](#).

## Before you begin

Your Kubernetes server must be at or later than version 1.22. To check the version, enter `kubectl version`.

- [Enable Cgroup v2](#)
- [Enable systemd with user session](#)
- [Configure several sysctl values, depending on host Linux distribution](#)
- [Ensure that your unprivileged user is listed in /etc/subuid and /etc/subgid](#)
- Enable the KubeletInUserNamespace [feature gate](#)

## Running Kubernetes inside Rootless Docker/Podman

### kind

[kind](#) supports running Kubernetes inside Rootless Docker or Rootless Podman.

See [Running kind with Rootless Docker](#).

### minikube

[minikube](#) also supports running Kubernetes inside Rootless Docker or Rootless Podman.

See the Minikube documentation:

- [Rootless Docker](#)
- [Rootless Podman](#)

## Running Kubernetes inside Unprivileged Containers

**Note:** This section links to third party projects that provide functionality required by Kubernetes. The Kubernetes project authors aren't responsible for these projects, which are

listed alphabetically. To add a project to this list, read the [content guide](#) before submitting a change. [More information.](#)

## **sysbox**

[Sysbox](#) is an open-source container runtime (similar to "runc") that supports running system-level workloads such as Docker and Kubernetes inside unprivileged containers isolated with the Linux user namespace.

See [Sysbox Quick Start Guide: Kubernetes-in-Docker](#) for more info.

Sysbox supports running Kubernetes inside unprivileged containers without requiring Cgroup v2 and without the KubeletInUserNamespace feature gate. It does this by exposing specially crafted /proc and /sys filesystems inside the container plus several other advanced OS virtualization techniques.

## **Running Rootless Kubernetes directly on a host**

**Note:** This section links to third party projects that provide functionality required by Kubernetes. The Kubernetes project authors aren't responsible for these projects, which are listed alphabetically. To add a project to this list, read the [content guide](#) before submitting a change. [More information.](#)

### **K3s**

[K3s](#) experimentally supports rootless mode.

See [Running K3s with Rootless mode](#) for the usage.

### **Usernetes**

[Usernetes](#) is a reference distribution of Kubernetes that can be installed under \$HOME directory without the root privilege.

Usernetes supports both containerd and CRI-O as CRI runtimes. Usernetes supports multi-node clusters using Flannel (VXLAN).

See [the Usernetes repo](#) for the usage.

## **Manually deploy a node that runs the kubelet in a user namespace**

This section provides hints for running Kubernetes in a user namespace manually.

### **Note:**

This section is intended to be read by developers of Kubernetes distributions, not by end users.

## Creating a user namespace

The first step is to create a [user namespace](#).

If you are trying to run Kubernetes in a user-namespaced container such as Rootless Docker/Podman or LXC/LXD, you are all set, and you can go to the next subsection.

Otherwise you have to create a user namespace by yourself, by calling `unshare(2)` with `CLONE_NEWUSER`.

A user namespace can be also unshared by using command line tools such as:

- [unshare\(1\)](#)
- [RootlessKit](#)
- [become-root](#)

After unsharing the user namespace, you will also have to unshare other namespaces such as mount namespace.

You do *not* need to call `chroot()` nor `pivot_root()` after unsharing the mount namespace, however, you have to mount writable filesystems on several directories *in* the namespace.

At least, the following directories need to be writable *in* the namespace (not *outside* the namespace):

- `/etc`
- `/run`
- `/var/logs`
- `/var/lib/kubelet`
- `/var/lib/cni`
- `/var/lib/containerd` (for containerd)
- `/var/lib/containers` (for CRI-O)

## Creating a delegated cgroup tree

In addition to the user namespace, you also need to have a writable cgroup tree with cgroup v2.

### Note:

Kubernetes support for running Node components in user namespaces requires cgroup v2. Cgroup v1 is not supported.

If you are trying to run Kubernetes in Rootless Docker/Podman or LXC/LXD on a systemd-based host, you are all set.

Otherwise you have to create a systemd unit with `Delegate=yes` property to delegate a cgroup tree with writable permission.

On your node, systemd must already be configured to allow delegation; for more details, see [cgroup v2](#) in the Rootless Containers documentation.

## Configuring network

**Note:** This section links to third party projects that provide functionality required by Kubernetes. The Kubernetes project authors aren't responsible for these projects, which are listed alphabetically. To add a project to this list, read the [content guide](#) before submitting a change. [More information](#).

The network namespace of the Node components has to have a non-loopback interface, which can be for example configured with [slirp4netns](#), [VPNKit](#), or [lxc-user-nic\(1\)](#).

The network namespaces of the Pods can be configured with regular CNI plugins. For multi-node networking, Flannel (VXLAN, 8472/UDP) is known to work.

Ports such as the kubelet port (10250/TCP) and NodePort service ports have to be exposed from the Node network namespace to the host with an external port forwarder, such as RootlessKit, slirp4netns, or [socat\(1\)](#).

You can use the port forwarder from K3s. See [Running K3s in Rootless Mode](#) for more details. The implementation can be found in [the pkg/rootlessports package](#) of k3s.

## Configuring CRI

The kubelet relies on a container runtime. You should deploy a container runtime such as containerd or CRI-O and ensure that it is running within the user namespace before the kubelet starts.

- [containerd](#)
- [CRI-O](#)

Running CRI plugin of containerd in a user namespace is supported since containerd 1.4.

Running containerd within a user namespace requires the following configurations.

```
version = 2

[plugins."io.containerd.grpc.v1.cri"]
Disable AppArmor
 disable_apparmor = true
Ignore an error during setting oom_score_adj
 restrict_oom_score_adj = true
Disable hugetlb cgroup v2 controller (because systemd does not support delegating hugetlb
controller)
 disable_hugetlb_controller = true

[plugins."io.containerd.grpc.v1.cri".containerd]
Using non-fuse overlayfs is also possible for kernel >= 5.11, but requires SELinux to be
disabled
 snapshotter = "fuse-overlayfs"

[plugins."io.containerd.grpc.v1.cri".containerd.runtimes.runc.options]
We use cgroupfs that is delegated by systemd, so we do not use SystemdCgroup driver
(unless you run another systemd in the namespace)
 SystemdCgroup = false
```

The default path of the configuration file is `/etc/containerd/config.toml`. The path can be specified with `containerd -c /path/to/containerd/config.toml`.

Running CRI-O in a user namespace is supported since CRI-O 1.22.

CRI-O requires an environment variable `_CRIO_ROOTLESS=1` to be set.

The following configurations are also recommended:

```
[crio]
storage_driver = "overlay"
Using non-fuse overlayfs is also possible for kernel >= 5.11, but requires SELinux to be
disabled
storage_option = ["overlay.mount_program=/usr/local/bin/fuse-overlayfs"]

[crio.runtime]
We use cgroupfs that is delegated by systemd, so we do not use "systemd" driver
(unless you run another systemd in the namespace)
cgroup_manager = "cgroupfs"
```

The default path of the configuration file is `/etc/crio/crio.conf`. The path can be specified with `crio --config /path/to/crio/crio.conf`.

## Configuring kubelet

Running kubelet in a user namespace requires the following configuration:

```
apiVersion: kubelet.config.k8s.io/v1beta1
kind: KubeletConfiguration
featureGates:
 KubeletInUserNamespace: true
We use cgroupfs that is delegated by systemd, so we do not use "systemd" driver
(unless you run another systemd in the namespace)
cgroupDriver: "cgroupfs"
```

When the `KubeletInUserNamespace` feature gate is enabled, the kubelet ignores errors that may happen during setting the following `sysctl` values on the node.

- `vm.overcommit_memory`
- `vm.panic_on_oom`
- `kernel.panic`
- `kernel.panic_on_oops`
- `kernel.keys.root_maxkeys`
- `kernel.keys.root_maxbytes`.

Within a user namespace, the kubelet also ignores any error raised from trying to open `/dev/kmsg`. This feature gate also allows kube-proxy to ignore an error during setting `RLIMIT_NOFILE`.

The `KubeletInUserNamespace` feature gate was introduced in Kubernetes v1.22 with "alpha" status.

Running kubelet in a user namespace without using this feature gate is also possible by mounting a specially crafted proc filesystem (as done by [Sysbox](#)), but not officially supported.

## Configuring kube-proxy

Running kube-proxy in a user namespace requires the following configuration:

```
apiVersion: kubeproxy.config.k8s.io/v1alpha1
kind: KubeProxyConfiguration
mode: "iptables" # or "userspace"
conntrack:
Skip setting sysctl value "net.netfilter.nf_conntrack_max"
 maxPerCore: 0
Skip setting "net.netfilter.nf_conntrack_tcp_timeout_established"
 tcpEstablishedTimeout: 0s
Skip setting "net.netfilter.nf_conntrack_tcp_timeout_close"
 tcpCloseWaitTimeout: 0s
```

## Caveats

- Most of "non-local" volume drivers such as nfs and iscsi do not work. Local volumes like local, hostPath, emptyDir, configMap, secret, and downwardAPI are known to work.
- Some CNI plugins may not work. Flannel (VXLAN) is known to work.

For more on this, see the [Caveats and Future work](#) page on the rootlesscontainers website.

## Safely Drain a Node

This page shows how to safely drain a [node](#), optionally respecting the PodDisruptionBudget you have defined.

## Before you begin

This task assumes that you have met the following prerequisites:

1. You do not require your applications to be highly available during the node drain, or
2. You have read about the [PodDisruptionBudget](#) concept, and have [configured PodDisruptionBudgets](#) for applications that need them.

## (Optional) Configure a disruption budget

To ensure that your workloads remain available during maintenance, you can configure a [PodDisruptionBudget](#).

If availability is important for any applications that run or could run on the node(s) that you are draining, [configure a PodDisruptionBudgets](#) first and then continue following this guide.

It is recommended to set AlwaysAllow [Unhealthy Pod Eviction Policy](#) to your PodDisruptionBudgets to support eviction of misbehaving applications during a node drain. The default behavior is to wait for the application pods to become [healthy](#) before the drain can proceed.

## Use kubectl drain to remove a node from service

You can use kubectl drain to safely evict all of your pods from a node before you perform maintenance on the node (e.g. kernel upgrade, hardware maintenance, etc.). Safe evictions allow the pod's containers to [gracefully terminate](#) and will respect the PodDisruptionBudgets you have specified.

### Note:

By default kubectl drain ignores certain system pods on the node that cannot be killed; see the [kubectl drain](#) documentation for more details.

When kubectl drain returns successfully, that indicates that all of the pods (except the ones excluded as described in the previous paragraph) have been safely evicted (respecting the desired graceful termination period, and respecting the PodDisruptionBudget you have defined). It is then safe to bring down the node by powering down its physical machine or, if running on a cloud platform, deleting its virtual machine.

### Note:

If any new Pods tolerate the node.kubernetes.io/unschedulable taint, then those Pods might be scheduled to the node you have drained. Avoid tolerating that taint other than for DaemonSets.

If you or another API user directly set the [nodeName](#) field for a Pod (bypassing the scheduler), then the Pod is bound to the specified node and will run there, even though you have drained that node and marked it unschedulable.

First, identify the name of the node you wish to drain. You can list all of the nodes in your cluster with

```
kubectl get nodes
```

Next, tell Kubernetes to drain the node:

```
kubectl drain --ignore-daemonsets <node name>
```

If there are pods managed by a DaemonSet, you will need to specify `--ignore-daemonsets` with kubectl to successfully drain the node. The kubectl drain subcommand on its own does not actually drain a node of its DaemonSet pods: the DaemonSet controller (part of the control

plane) immediately replaces missing Pods with new equivalent Pods. The DaemonSet controller also creates Pods that ignore unschedulable taints, which allows the new Pods to launch onto a node that you are draining.

Once it returns (without giving an error), you can power down the node (or equivalently, if on a cloud platform, delete the virtual machine backing the node). If you leave the node in the cluster during the maintenance operation, you need to run

```
kubectl uncordon <node name>
```

afterwards to tell Kubernetes that it can resume scheduling new pods onto the node.

## Draining multiple nodes in parallel

The `kubectl drain` command should only be issued to a single node at a time. However, you can run multiple `kubectl drain` commands for different nodes in parallel, in different terminals or in the background. Multiple drain commands running concurrently will still respect the `PodDisruptionBudget` you specify.

For example, if you have a `StatefulSet` with three replicas and have set a `PodDisruptionBudget` for that set specifying `minAvailable: 2`, `kubectl drain` only evicts a pod from the `StatefulSet` if all three replicas pods are [healthy](#); if then you issue multiple drain commands in parallel, Kubernetes respects the `PodDisruptionBudget` and ensures that only 1 (calculated as `replicas - minAvailable`) Pod is unavailable at any given time. Any drains that would cause the number of [healthy](#) replicas to fall below the specified budget are blocked.

## The Eviction API

If you prefer not to use [kubectl drain](#) (such as to avoid calling to an external command, or to get finer control over the pod eviction process), you can also programmatically cause evictions using the eviction API.

For more information, see [API-initiated eviction](#).

## What's next

- Follow steps to protect your application by [configuring a Pod Disruption Budget](#).

# Securing a Cluster

This document covers topics related to protecting a cluster from accidental or malicious access and provides recommendations on overall security.

## Before you begin

- You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not

already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

## Controlling access to the Kubernetes API

As Kubernetes is entirely API-driven, controlling and limiting who can access the cluster and what actions they are allowed to perform is the first line of defense.

### Use Transport Layer Security (TLS) for all API traffic

Kubernetes expects that all API communication in the cluster is encrypted by default with TLS, and the majority of installation methods will allow the necessary certificates to be created and distributed to the cluster components. Note that some components and installation methods may enable local ports over HTTP and administrators should familiarize themselves with the settings of each component to identify potentially unsecured traffic.

### API Authentication

Choose an authentication mechanism for the API servers to use that matches the common access patterns when you install a cluster. For instance, small, single-user clusters may wish to use a simple certificate or static Bearer token approach. Larger clusters may wish to integrate an existing OIDC or LDAP server that allow users to be subdivided into groups.

All API clients must be authenticated, even those that are part of the infrastructure like nodes, proxies, the scheduler, and volume plugins. These clients are typically [service accounts](#) or use x509 client certificates, and they are created automatically at cluster startup or are setup as part of the cluster installation.

Consult the [authentication reference document](#) for more information.

### API Authorization

Once authenticated, every API call is also expected to pass an authorization check. Kubernetes ships an integrated [Role-Based Access Control \(RBAC\)](#) component that matches an incoming user or group to a set of permissions bundled into roles. These permissions combine verbs (get, create, delete) with resources (pods, services, nodes) and can be namespace-scoped or cluster-scoped. A set of out-of-the-box roles are provided that offer reasonable default separation of responsibility depending on what actions a client might want to perform. It is recommended that you use the [Node](#) and [RBAC](#) authorizers together, in combination with the [NodeRestriction](#) admission plugin.

As with authentication, simple and broad roles may be appropriate for smaller clusters, but as more users interact with the cluster, it may become necessary to separate teams into separate [namespaces](#) with more limited roles.

With authorization, it is important to understand how updates on one object may cause actions in other places. For instance, a user may not be able to create pods directly, but allowing them to create a deployment, which creates pods on their behalf, will let them create those pods

indirectly. Likewise, deleting a node from the API will result in the pods scheduled to that node being terminated and recreated on other nodes. The out-of-the box roles represent a balance between flexibility and common use cases, but more limited roles should be carefully reviewed to prevent accidental escalation. You can make roles specific to your use case if the out-of-box ones don't meet your needs.

Consult the [authorization reference section](#) for more information.

## Controlling access to the Kubelet

Kubelets expose HTTPS endpoints which grant powerful control over the node and containers. By default Kubelets allow unauthenticated access to this API.

Production clusters should enable Kubelet authentication and authorization.

Consult the [Kubelet authentication/authorization reference](#) for more information.

## Controlling the capabilities of a workload or user at runtime

Authorization in Kubernetes is intentionally high level, focused on coarse actions on resources. More powerful controls exist as **policies** to limit by use case how those objects act on the cluster, themselves, and other resources.

### Limiting resource usage on a cluster

[Resource quota](#) limits the number or capacity of resources granted to a namespace. This is most often used to limit the amount of CPU, memory, or persistent disk a namespace can allocate, but can also control how many pods, services, or volumes exist in each namespace.

[Limit ranges](#) restrict the maximum or minimum size of some of the resources above, to prevent users from requesting unreasonably high or low values for commonly reserved resources like memory, or to provide default limits when none are specified.

### Controlling what privileges containers run with

A pod definition contains a [security context](#) that allows it to request access to run as a specific Linux user on a node (like root), access to run privileged or access the host network, and other controls that would otherwise allow it to run unfettered on a hosting node.

You can configure [Pod security admission](#) to enforce use of a particular [Pod Security Standard](#) in a [namespace](#), or to detect breaches.

Generally, most application workloads need limited access to host resources so they can successfully run as a root process (uid 0) without access to host information. However, considering the privileges associated with the root user, you should write application containers to run as a non-root user. Similarly, administrators who wish to prevent client applications from escaping their containers should apply the **Baseline** or **Restricted** Pod Security Standard.

## Preventing containers from loading unwanted kernel modules

The Linux kernel automatically loads kernel modules from disk if needed in certain circumstances, such as when a piece of hardware is attached or a filesystem is mounted. Of particular relevance to Kubernetes, even unprivileged processes can cause certain network-protocol-related kernel modules to be loaded, just by creating a socket of the appropriate type. This may allow an attacker to exploit a security hole in a kernel module that the administrator assumed was not in use.

To prevent specific modules from being automatically loaded, you can uninstall them from the node, or add rules to block them. On most Linux distributions, you can do that by creating a file such as `/etc/modprobe.d/kubernetes-blacklist.conf` with contents like:

```
DCCP is unlikely to be needed, has had multiple serious
vulnerabilities, and is not well-maintained.
blacklist dccp

SCTP is not used in most Kubernetes clusters, and has also had
vulnerabilities in the past.
blacklist sctp
```

To block module loading more generically, you can use a Linux Security Module (such as SELinux) to completely deny the `module_request` permission to containers, preventing the kernel from loading modules for containers under any circumstances. (Pods would still be able to use modules that had been loaded manually, or modules that were loaded by the kernel on behalf of some more-privileged process.)

## Restricting network access

The [network policies](#) for a namespace allows application authors to restrict which pods in other namespaces may access pods and ports within their namespaces. Many of the supported [Kubernetes networking providers](#) now respect network policy.

Quota and limit ranges can also be used to control whether users may request node ports or load-balanced services, which on many clusters can control whether those users applications are visible outside of the cluster.

Additional protections may be available that control network rules on a per-plugin or per-environment basis, such as per-node firewalls, physically separating cluster nodes to prevent cross talk, or advanced networking policy.

## Restricting cloud metadata API access

Cloud platforms (AWS, Azure, GCE, etc.) often expose metadata services locally to instances. By default these APIs are accessible by pods running on an instance and can contain cloud credentials for that node, or provisioning data such as kubelet credentials. These credentials can be used to escalate within the cluster or to other cloud services under the same account.

When running Kubernetes on a cloud platform, limit permissions given to instance credentials, use [network policies](#) to restrict pod access to the metadata API, and avoid using provisioning data to deliver secrets.

## Controlling which nodes pods may access

By default, there are no restrictions on which nodes may run a pod. Kubernetes offers a [rich set of policies for controlling placement of pods onto nodes](#) and the [taint-based pod placement and eviction](#) that are available to end users. For many clusters use of these policies to separate workloads can be a convention that authors adopt or enforce via tooling.

As an administrator, a beta admission plugin PodNodeSelector can be used to force pods within a namespace to default or require a specific node selector, and if end users cannot alter namespaces, this can strongly limit the placement of all of the pods in a specific workload.

## Protecting cluster components from compromise

This section describes some common patterns for protecting clusters from compromise.

### Restrict access to etcd

Write access to the etcd backend for the API is equivalent to gaining root on the entire cluster, and read access can be used to escalate fairly quickly. Administrators should always use strong credentials from the API servers to their etcd server, such as mutual auth via TLS client certificates, and it is often recommended to isolate the etcd servers behind a firewall that only the API servers may access.

#### Caution:

Allowing other components within the cluster to access the master etcd instance with read or write access to the full keypace is equivalent to granting cluster-admin access. Using separate etcd instances for non-master components or using etcd ACLs to restrict read and write access to a subset of the keypace is strongly recommended.

### Enable audit logging

The [audit logger](#) is a beta feature that records actions taken by the API for later analysis in the event of a compromise. It is recommended to enable audit logging and archive the audit file on a secure server.

### Restrict access to alpha or beta features

Alpha and beta Kubernetes features are in active development and may have limitations or bugs that result in security vulnerabilities. Always assess the value an alpha or beta feature may provide against the possible risk to your security posture. When in doubt, disable features you do not use.

### Rotate infrastructure credentials frequently

The shorter the lifetime of a secret or credential the harder it is for an attacker to make use of that credential. Set short lifetimes on certificates and automate their rotation. Use an authentication provider that can control how long issued tokens are available and use short lifetimes where possible. If you use service-account tokens in external integrations, plan to rotate those tokens frequently. For example, once the bootstrap phase is complete, a bootstrap token used for setting up nodes should be revoked or its authorization removed.

## Review third party integrations before enabling them

Many third party integrations to Kubernetes may alter the security profile of your cluster. When enabling an integration, always review the permissions that an extension requests before granting it access. For example, many security integrations may request access to view all secrets on your cluster which is effectively making that component a cluster admin. When in doubt, restrict the integration to functioning in a single namespace if possible.

Components that create pods may also be unexpectedly powerful if they can do so inside namespaces like the kube-system namespace, because those pods can gain access to service account secrets or run with elevated permissions if those service accounts are granted access to permissive [PodSecurityPolicies](#).

If you use [Pod Security admission](#) and allow any component to create Pods within a namespace that permits privileged Pods, those Pods may be able to escape their containers and use this widened access to elevate their privileges.

You should not allow untrusted components to create Pods in any system namespace (those with names that start with kube-) nor in any namespace where that access grant allows the possibility of privilege escalation.

## Encrypt secrets at rest

In general, the etcd database will contain any information accessible via the Kubernetes API and may grant an attacker significant visibility into the state of your cluster. Always encrypt your backups using a well reviewed backup and encryption solution, and consider using full disk encryption where possible.

Kubernetes supports optional [encryption at rest](#) for information in the Kubernetes API. This lets you ensure that when Kubernetes stores data for objects (for example, Secret or ConfigMap objects), the API server writes an encrypted representation of the object. That encryption means that even someone who has access to etcd backup data is unable to view the content of those objects. In Kubernetes 1.30 you can also encrypt custom resources; encryption-at-rest for extension APIs defined in CustomResourceDefinitions was added to Kubernetes as part of the v1.26 release.

## Receiving alerts for security updates and reporting vulnerabilities

Join the [kubernetes-announce](#) group for emails about security announcements. See the [security reporting](#) page for more on how to report vulnerabilities.

## What's next

- [Security Checklist](#) for additional information on Kubernetes security guidance.

# Set Kubelet Parameters Via A Configuration File

## Before you begin

Some steps in this page use the jq tool. If you don't have jq, you can install it via your operating system's software sources, or fetch it from <https://jqlang.github.io/jq/>.

Some steps also involve installing curl, which can be installed via your operating system's software sources.

A subset of the kubelet's configuration parameters may be set via an on-disk config file, as a substitute for command-line flags.

Providing parameters via a config file is the recommended approach because it simplifies node deployment and configuration management.

## Create the config file

The subset of the kubelet's configuration that can be configured via a file is defined by the [KubeletConfiguration](#) struct.

The configuration file must be a JSON or YAML representation of the parameters in this struct. Make sure the kubelet has read permissions on the file.

Here is an example of what this file might look like:

```
apiVersion: kubelet.config.k8s.io/v1beta1
kind: KubeletConfiguration
address: "192.168.0.8"
port: 20250
serializeImagePulls: false
evictionHard:
 memory.available: "100Mi"
 nodefs.available: "10%"
 nodefs.inodesFree: "5%"
 imagefs.available: "15%"
```

In this example, the kubelet is configured with the following settings:

1. address: The kubelet will serve on IP address 192.168.0.8.
2. port: The kubelet will serve on port 20250.
3. serializeImagePulls: Image pulls will be done in parallel.
4. evictionHard: The kubelet will evict Pods under one of the following conditions:
  - When the node's available memory drops below 100MiB.
  - When the node's main filesystem's available space is less than 10%.
  - When the image filesystem's available space is less than 15%.

- When more than 95% of the node's main filesystem's inodes are in use.

**Note:**

In the example, by changing the default value of only one parameter for `evictionHard`, the default values of other parameters will not be inherited and will be set to zero. In order to provide custom values, you should provide all the threshold values respectively.

The `imagefs` is an optional filesystem that container runtimes use to store container images and container writable layers.

## Start a kubelet process configured via the config file

**Note:**

If you use `kubeadm` to initialize your cluster, use the `kubelet-config` while creating your cluster with `kubeadm init`. See [configuring kubelet using kubeadm](#) for details.

Start the kubelet with the `--config` flag set to the path of the kubelet's config file. The kubelet will then load its config from this file.

Note that command line flags which target the same value as a config file will override that value. This helps ensure backwards compatibility with the command-line API.

Note that relative file paths in the kubelet config file are resolved relative to the location of the kubelet config file, whereas relative paths in command line flags are resolved relative to the kubelet's current working directory.

Note that some default values differ between command-line flags and the kubelet config file. If `--config` is provided and the values are not specified via the command line, the defaults for the `KubeletConfiguration` version apply. In the above example, this version is `kubelet.config.k8s.io/v1beta1`.

## Drop-in directory for kubelet configuration files

FEATURE STATE: Kubernetes v1.30 [beta]

You can specify a drop-in configuration directory for the kubelet. By default, the kubelet does not look for drop-in configuration files anywhere - you must specify a path. For example: `--config-dir=/etc/kubernetes/kubelet.conf.d`

For Kubernetes v1.28 to v1.29, you can only specify `--config-dir` if you also set the environment variable `KUBELET_CONFIG_DROPIN_DIR_ALPHA` for the kubelet process (the value of that variable does not matter).

**Note:**

The suffix of a valid kubelet drop-in configuration file **must** be `.conf`. For instance: `99-kubelet-address.conf`

The kubelet processes files in its config drop-in directory by sorting the **entire file name** alphanumerically. For instance, 00-kubelet.conf is processed first, and then overridden with a file named 01-kubelet.conf.

These files may contain partial configurations but should not be invalid and must include type metadata, specifically `apiVersion` and `kind`. Validation is only performed on the final resulting configuration structure stored internally in the kubelet. This offers flexibility in managing and merging kubelet configurations from different sources while preventing undesirable configurations. However, it is important to note that behavior varies based on the data type of the configuration fields.

Different data types in the kubelet configuration structure merge differently. See the [reference document](#) for more information.

## Kubelet configuration merging order

On startup, the kubelet merges configuration from:

- Feature gates specified over the command line (lowest precedence).
- The kubelet configuration.
- Drop-in configuration files, according to sort order.
- Command line arguments excluding feature gates (highest precedence).

### Note:

The config drop-in dir mechanism for the kubelet is similar but different from how the kubeadm tool allows you to patch configuration. The kubeadm tool uses a specific [patching strategy](#) for its configuration, whereas the only patch strategy for kubelet configuration drop-in files is replace. The kubelet determines the order of merges based on sorting the **suffixes** alphanumerically, and replaces every field present in a higher priority file.

## Viewing the kubelet configuration

Since the configuration could now be spread over multiple files with this feature, if someone wants to inspect the final actuated configuration, they can follow these steps to inspect the kubelet configuration:

1. Start a proxy server using [kubectrl proxy](#) in your terminal.

```
kubectrl proxy
```

Which gives output like:

```
Starting to serve on 127.0.0.1:8001
```

2. Open another terminal window and use `curl` to fetch the kubelet configuration. Replace `<node-name>` with the actual name of your node:

```
curl -X GET http://127.0.0.1:8001/api/v1/nodes/<node-name>/proxy/configz | jq .
```

```

## What's next

- Learn more about kubelet configuration by checking the [KubeletConfiguration](#) reference.
- Learn more about kubelet configuration merging in the [reference document](#).

# Share a Cluster with Namespaces

This page shows how to view, work in, and delete [namespaces](#). The page also shows how to use Kubernetes namespaces to subdivide your cluster.

## Before you begin

- Have an [existing Kubernetes cluster](#).
- You have a basic understanding of Kubernetes [Pods](#), [Services](#), and [Deployments](#).

## Viewing namespaces

List the current namespaces in a cluster using:

```
kubectl get namespaces
```

| NAME            | STATUS | AGE |
|-----------------|--------|-----|
| default         | Active | 11d |
| kube-node-lease | Active | 11d |
| kube-public     | Active | 11d |
| kube-system     | Active | 11d |

Kubernetes starts with four initial namespaces:

- default The default namespace for objects with no other namespace
- kube-node-lease This namespace holds [Lease](#) objects associated with each node. Node leases allow the kubelet to send [heartbeats](#) so that the control plane can detect node failure.
- kube-public This namespace is created automatically and is readable by all users (including those not authenticated). This namespace is mostly reserved for cluster usage, in case that some resources should be visible and readable publicly throughout the whole cluster. The public aspect of this namespace is only a convention, not a requirement.
- kube-system The namespace for objects created by the Kubernetes system

You can also get the summary of a specific namespace using:

```
kubectl get namespaces <name>
```

Or you can get detailed information with:

```
kubectl describe namespaces <name>
```

```
Name: default
Labels: <none>
Annotations: <none>
Status: Active
```

No resource quota.

#### Resource Limits

| Type      | Resource | Min | Max | Default |
|-----------|----------|-----|-----|---------|
| Container | cpu      | -   | -   | 100m    |

Note that these details show both resource quota (if present) as well as resource limit ranges.

Resource quota tracks aggregate usage of resources in the Namespace and allows cluster operators to define *Hard* resource usage limits that a Namespace may consume.

A limit range defines min/max constraints on the amount of resources a single entity can consume in a Namespace.

See [Admission control: Limit Range](#)

A namespace can be in one of two phases:

- Active the namespace is in use
- Terminating the namespace is being deleted, and can not be used for new objects

For more details, see [Namespace](#) in the API reference.

## Creating a new namespace

### Note:

Avoid creating namespace with prefix kube-, since it is reserved for Kubernetes system namespaces.

Create a new YAML file called my-namespace.yaml with the contents:

```
apiVersion: v1
kind: Namespace
metadata:
 name: <insert-namespace-name-here>
```

Then run:

```
kubectl create -f ./my-namespace.yaml
```

Alternatively, you can create namespace using below command:

```
kubectl create namespace <insert-namespace-name-here>
```

The name of your namespace must be a valid [DNS label](#).

There's an optional field `finalizers`, which allows observables to purge resources whenever the namespace is deleted. Keep in mind that if you specify a nonexistent finalizer, the namespace will be created but will get stuck in the Terminating state if the user tries to delete it.

More information on finalizers can be found in the namespace [design doc](#).

## Deleting a namespace

Delete a namespace with

```
kubectl delete namespaces <insert-some-namespace-name>
```

### Warning:

This deletes *everything* under the namespace!

This delete is asynchronous, so for a time you will see the namespace in the Terminating state.

## Subdividing your cluster using Kubernetes namespaces

By default, a Kubernetes cluster will instantiate a default namespace when provisioning the cluster to hold the default set of Pods, Services, and Deployments used by the cluster.

Assuming you have a fresh cluster, you can introspect the available namespaces by doing the following:

```
kubectl get namespaces
```

| NAME    | STATUS | AGE |
|---------|--------|-----|
| default | Active | 13m |

### Create new namespaces

For this exercise, we will create two additional Kubernetes namespaces to hold our content.

In a scenario where an organization is using a shared Kubernetes cluster for development and production use cases:

- The development team would like to maintain a space in the cluster where they can get a view on the list of Pods, Services, and Deployments they use to build and run their application. In this space, Kubernetes resources come and go, and the restrictions on who can or cannot modify resources are relaxed to enable agile development.
- The operations team would like to maintain a space in the cluster where they can enforce strict procedures on who can or cannot manipulate the set of Pods, Services, and Deployments that run the production site.

One pattern this organization could follow is to partition the Kubernetes cluster into two namespaces: development and production. Let's create two new namespaces to hold our work.

Create the development namespace using kubectl:

```
kubectl create -f https://k8s.io/examples/admin/namespace-dev.json
```

And then let's create the production namespace using kubectl:

```
kubectl create -f https://k8s.io/examples/admin/namespace-prod.json
```

To be sure things are right, list all of the namespaces in our cluster.

```
kubectl get namespaces --show-labels
```

| NAME        | STATUS | AGE | LABELS           |
|-------------|--------|-----|------------------|
| default     | Active | 32m | <none>           |
| development | Active | 29s | name=development |
| production  | Active | 23s | name=production  |

## Create pods in each namespace

A Kubernetes namespace provides the scope for Pods, Services, and Deployments in the cluster. Users interacting with one namespace do not see the content in another namespace. To demonstrate this, let's spin up a simple Deployment and Pods in the development namespace.

```
kubectl create deployment snowflake \
--image=registry.k8s.io/serve_hostname \
-n=development --replicas=2
```

We have created a deployment whose replica size is 2 that is running the pod called snowflake with a basic container that serves the hostname.

```
kubectl get deployment -n=development
```

| NAME      | READY | UP-TO-DATE | AVAILABLE | AGE |
|-----------|-------|------------|-----------|-----|
| snowflake | 2/2   | 2          | 2         | 2m  |

```
kubectl get pods -l app=snowflake -n=development
```

| NAME                       | READY | STATUS  | RESTARTS | AGE |
|----------------------------|-------|---------|----------|-----|
| snowflake-3968820950-9dgr8 | 1/1   | Running | 0        | 2m  |
| snowflake-3968820950-vgc4n | 1/1   | Running | 0        | 2m  |

And this is great, developers are able to do what they want, and they do not have to worry about affecting content in the production namespace.

Let's switch to the production namespace and show how resources in one namespace are hidden from the other. The production namespace should be empty, and the following commands should return nothing.

```
kubectl get deployment -n=production
kubectl get pods -n=production
```

Production likes to run cattle, so let's create some cattle pods.

```
kubectl create deployment cattle --image=registry.k8s.io/serve_hostname -n=production
kubectl scale deployment cattle --replicas=5 -n=production

kubectl get deployment -n=production
```

| NAME   | READY | UP-TO-DATE | AVAILABLE | AGE |
|--------|-------|------------|-----------|-----|
| cattle | 5/5   | 5          | 5         | 10s |

```
kubectl get pods -l app=cattle -n=production
```

| NAME                    | READY | STATUS  | RESTARTS | AGE |
|-------------------------|-------|---------|----------|-----|
| cattle-2263376956-41xy6 | 1/1   | Running | 0        | 34s |
| cattle-2263376956-kw466 | 1/1   | Running | 0        | 34s |
| cattle-2263376956-n4v97 | 1/1   | Running | 0        | 34s |
| cattle-2263376956-p5p3i | 1/1   | Running | 0        | 34s |
| cattle-2263376956-sxpth | 1/1   | Running | 0        | 34s |

At this point, it should be clear that the resources users create in one namespace are hidden from the other namespace.

As the policy support in Kubernetes evolves, we will extend this scenario to show how you can provide different authorization rules for each namespace.

## Understanding the motivation for using namespaces

A single cluster should be able to satisfy the needs of multiple users or groups of users (henceforth in this document a *user community*).

Kubernetes *namespaces* help different projects, teams, or customers to share a Kubernetes cluster.

It does this by providing the following:

1. A scope for [names](#).
2. A mechanism to attach authorization and policy to a subsection of the cluster.

Use of multiple namespaces is optional.

Each user community wants to be able to work in isolation from other communities. Each user community has its own:

1. resources (pods, services, replication controllers, etc.)
2. policies (who can or cannot perform actions in their community)
3. constraints (this community is allowed this much quota, etc.)

A cluster operator may create a Namespace for each unique user community.

The Namespace provides a unique scope for:

1. named resources (to avoid basic naming collisions)
2. delegated management authority to trusted users
3. ability to limit community resource consumption

Use cases include:

1. As a cluster operator, I want to support multiple user communities on a single cluster.
2. As a cluster operator, I want to delegate authority to partitions of the cluster to trusted users in those communities.
3. As a cluster operator, I want to limit the amount of resources each community can consume in order to limit the impact to other communities using the cluster.
4. As a cluster user, I want to interact with resources that are pertinent to my user community in isolation of what other user communities are doing on the cluster.

## Understanding namespaces and DNS

When you create a [Service](#), it creates a corresponding [DNS entry](#). This entry is of the form `<service-name>.<namespace-name>.svc.cluster.local`, which means that if a container uses `<service-name>` it will resolve to the service which is local to a namespace. This is useful for using the same configuration across multiple namespaces such as Development, Staging and Production. If you want to reach across namespaces, you need to use the fully qualified domain name (FQDN).

## What's next

- Learn more about [setting the namespace preference](#).
- Learn more about [setting the namespace for a request](#)
- See [namespaces design](#).

## Upgrade A Cluster

This page provides an overview of the steps you should follow to upgrade a Kubernetes cluster.

The way that you upgrade a cluster depends on how you initially deployed it and on any subsequent changes.

At a high level, the steps you perform are:

- Upgrade the [control plane](#)
- Upgrade the nodes in your cluster
- Upgrade clients such as [kubect](#)
- Adjust manifests and other resources based on the API changes that accompany the new Kubernetes version

## Before you begin

You must have an existing cluster. This page is about upgrading from Kubernetes 1.29 to Kubernetes 1.30. If your cluster is not currently running Kubernetes 1.29 then please check the documentation for the version of Kubernetes that you plan to upgrade to.

# Upgrade approaches

## kubeadm

If your cluster was deployed using the kubeadm tool, refer to [Upgrading kubeadm clusters](#) for detailed information on how to upgrade the cluster.

Once you have upgraded the cluster, remember to [install the latest version of kubectl](#).

## Manual deployments

### Caution:

These steps do not account for third-party extensions such as network and storage plugins.

You should manually update the control plane following this sequence:

- etcd (all instances)
- kube-apiserver (all control plane hosts)
- kube-controller-manager
- kube-scheduler
- cloud controller manager, if you use one

At this point you should [install the latest version of kubectl](#).

For each node in your cluster, [drain](#) that node and then either replace it with a new node that uses the 1.30 kubelet, or upgrade the kubelet on that node and bring the node back into service.

### Caution:

Draining nodes before upgrading kubelet ensures that pods are re-admitted and containers are re-created, which may be necessary to resolve some security issues or other important bugs.

## Other deployments

Refer to the documentation for your cluster deployment tool to learn the recommended set up steps for maintenance.

# Post-upgrade tasks

## Switch your cluster's storage API version

The objects that are serialized into etcd for a cluster's internal representation of the Kubernetes resources active in the cluster are written using a particular version of the API.

When the supported API changes, these objects may need to be rewritten in the newer API. Failure to do this will eventually result in resources that are no longer decodable or usable by the Kubernetes API server.

For each affected object, fetch it using the latest supported API and then write it back also using the latest supported API.

## Update manifests

Upgrading to a new Kubernetes version can provide new APIs.

You can use `kubectl convert` command to convert manifests between different API versions. For example:

```
kubectl convert -f pod.yaml --output-version v1
```

The `kubectl` tool replaces the contents of `pod.yaml` with a manifest that sets `kind` to `Pod` (unchanged), but with a revised `apiVersion`.

## Device Plugins

If your cluster is running device plugins and the node needs to be upgraded to a Kubernetes release with a newer device plugin API version, device plugins must be upgraded to support both version before the node is upgraded in order to guarantee that device allocations continue to complete successfully during the upgrade.

Refer to [API compatibility](#) and [Kubelet Device Manager API Versions](#) for more details.

# Use Cascading Deletion in a Cluster

This page shows you how to specify the type of [cascading deletion](#) to use in your cluster during [garbage collection](#).

## Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

You also need to [create a sample Deployment](#) to experiment with the different types of cascading deletion. You will need to recreate the Deployment for each type.

## Check owner references on your pods

Check that the `ownerReferences` field is present on your pods:

```
kubectl get pods -l app=nginx --output=yaml
```

The output has an `ownerReferences` field similar to this:

```
apiVersion: v1
...
ownerReferences:
- apiVersion: apps/v1
```

```
blockOwnerDeletion: true
controller: true
kind: ReplicaSet
name: nginx-deployment-6b474476c4
uid: 4fdcd81c-bd5d-41f7-97af-3a3b759af9a7
...
```

## Use foreground cascading deletion

By default, Kubernetes uses [background cascading deletion](#) to delete dependents of an object. You can switch to foreground cascading deletion using either `kubectl` or the Kubernetes API, depending on the Kubernetes version your cluster runs. To check the version, enter `kubectl version`.

You can delete objects using foreground cascading deletion using `kubectl` or the Kubernetes API.

### Using `kubectl`

Run the following command:

```
kubectl delete deployment nginx-deployment --cascade=foreground
```

### Using the Kubernetes API

1. Start a local proxy session:

```
kubectl proxy --port=8080
```

2. Use `curl` to trigger deletion:

```
curl -X DELETE localhost:8080/apis/apps/v1/namespaces/default/deployments/nginx-deployment \
-d '{"kind":"DeleteOptions","apiVersion":"v1","propagationPolicy":"Foreground"}' \
-H "Content-Type: application/json"
```

The output contains a foregroundDeletion [finalizer](#) like this:

```
"kind": "Deployment",
"apiVersion": "apps/v1",
"metadata": {
 "name": "nginx-deployment",
 "namespace": "default",
 "uid": "d1ce1b02-cae8-4288-8a53-30e84d8fa505",
 "resourceVersion": "1363097",
 "creationTimestamp": "2021-07-08T20:24:37Z",
 "deletionTimestamp": "2021-07-08T20:27:39Z",
 "finalizers": [
 "foregroundDeletion"
]
}
...
```

# Use background cascading deletion

1. [Create a sample Deployment](#).
2. Use either kubectl or the Kubernetes API to delete the Deployment, depending on the Kubernetes version your cluster runs. To check the version, enter kubectl version.

You can delete objects using background cascading deletion using kubectl or the Kubernetes API.

Kubernetes uses background cascading deletion by default, and does so even if you run the following commands without the `--cascade` flag or the `propagationPolicy` argument.

## Using kubectl

Run the following command:

```
kubectl delete deployment nginx-deployment --cascade=background
```

## Using the Kubernetes API

1. Start a local proxy session:

```
kubectl proxy --port=8080
```

2. Use curl to trigger deletion:

```
curl -X DELETE localhost:8080/apis/apps/v1/namespaces/default/deployments/nginx-deployment \
-d '{"kind":"DeleteOptions","apiVersion":"v1","propagationPolicy":"Background"}' \
-H "Content-Type: application/json"
```

The output is similar to this:

```
"kind": "Status",
"apiVersion": "v1",
...
"status": "Success",
"details": {
 "name": "nginx-deployment",
 "group": "apps",
 "kind": "deployments",
 "uid": "cc9ee9b9-2d49-4445-b1c1-d261c9396456"
}
```

# Delete owner objects and orphan dependents

By default, when you tell Kubernetes to delete an object, the [controller](#) also deletes dependent objects. You can make Kubernetes *orphan* these dependents using kubectl or the Kubernetes API, depending on the Kubernetes version your cluster runs. To check the version, enter kubectl version.

## Using kubectl

Run the following command:

```
kubectl delete deployment nginx-deployment --cascade=orphan
```

## Using the Kubernetes API

1. Start a local proxy session:

```
kubectl proxy --port=8080
```

2. Use curl to trigger deletion:

```
curl -X DELETE localhost:8080/apis/apps/v1/namespaces/default/deployments/nginx-
deployment \
-d '{"kind":"DeleteOptions","apiVersion":"v1","propagationPolicy":"Orphan"}' \
-H "Content-Type: application/json"
```

The output contains orphan in the finalizers field, similar to this:

```
"kind": "Deployment",
"apiVersion": "apps/v1",
"namespace": "default",
"uid": "6f577034-42a0-479d-be21-78018c466f1f",
"creationTimestamp": "2021-07-09T16:46:37Z",
"deletionTimestamp": "2021-07-09T16:47:08Z",
"deletionGracePeriodSeconds": 0,
"finalizers": [
 "orphan"
],
...
```

You can check that the Pods managed by the Deployment are still running:

```
kubectl get pods -l app=nginx
```

## What's next

- Learn about [owners and dependents](#) in Kubernetes.
- Learn about Kubernetes [finalizers](#).
- Learn about [garbage collection](#).

# Using a KMS provider for data encryption

This page shows how to configure a Key Management Service (KMS) provider and plugin to enable secret data encryption. In Kubernetes 1.30 there are two versions of KMS at-rest encryption. You should use KMS v2 if feasible because KMS v1 is deprecated (since Kubernetes v1.28) and disabled by default (since Kubernetes v1.29). KMS v2 offers significantly better performance characteristics than KMS v1.

## Caution:

This documentation is for the generally available implementation of KMS v2 (and for the deprecated version 1 implementation). If you are using any control plane components older than Kubernetes v1.29, please check the equivalent page in the documentation for the version of Kubernetes that your cluster is running. Earlier releases of Kubernetes had different behavior that may be relevant for information security.

## Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

The version of Kubernetes that you need depends on which KMS API version you have selected. Kubernetes recommends using KMS v2.

- If you selected KMS API v2, you should use Kubernetes v1.30 (if you are running a different version of Kubernetes that also supports the v2 KMS API, switch to the documentation for that version of Kubernetes).
- If you selected KMS API v1 to support clusters prior to version v1.27 or if you have a legacy KMS plugin that only supports KMS v1, any supported Kubernetes version will work. This API is deprecated as of Kubernetes v1.28. Kubernetes does not recommend the use of this API.

To check the version, enter `kubectl version`.

### KMS v1

FEATURE STATE: Kubernetes v1.28 [deprecated]

- Kubernetes version 1.10.0 or later is required
- For version 1.29 and later, the v1 implementation of KMS is disabled by default. To enable the feature, set `--feature-gates=KMSv1=true` to configure a KMS v1 provider.
- Your cluster must use etcd v3 or later

### KMS v2

FEATURE STATE: Kubernetes v1.29 [stable]

- Your cluster must use etcd v3 or later

# KMS encryption and per-object encryption keys

The KMS encryption provider uses an envelope encryption scheme to encrypt data in etcd. The data is encrypted using a data encryption key (DEK). The DEKs are encrypted with a key encryption key (KEK) that is stored and managed in a remote KMS.

If you use the (deprecated) v1 implementation of KMS, a new DEK is generated for each encryption.

With KMS v2, a new DEK is generated **per encryption**: the API server uses a *key derivation function* to generate single use data encryption keys from a secret seed combined with some random data. The seed is rotated whenever the KEK is rotated (see the *Understanding key\_id and Key Rotation* section below for more details).

The KMS provider uses gRPC to communicate with a specific KMS plugin over a UNIX domain socket. The KMS plugin, which is implemented as a gRPC server and deployed on the same host(s) as the Kubernetes control plane, is responsible for all communication with the remote KMS.

## Configuring the KMS provider

To configure a KMS provider on the API server, include a provider of type `kms` in the `providers` array in the encryption configuration file and set the following properties:

### KMS v1

- `apiVersion`: API Version for KMS provider. Leave this value empty or set it to `v1`.
- `name`: Display name of the KMS plugin. Cannot be changed once set.
- `endpoint`: Listen address of the gRPC server (KMS plugin). The endpoint is a UNIX domain socket.
- `cacheSize`: Number of data encryption keys (DEKs) to be cached in the clear. When cached, DEKs can be used without another call to the KMS; whereas DEKs that are not cached require a call to the KMS to unwrap.
- `timeout`: How long should kube-apiserver wait for kms-plugin to respond before returning an error (default is 3 seconds).

### KMS v2

- `apiVersion`: API Version for KMS provider. Set this to `v2`.
- `name`: Display name of the KMS plugin. Cannot be changed once set.
- `endpoint`: Listen address of the gRPC server (KMS plugin). The endpoint is a UNIX domain socket.
- `timeout`: How long should kube-apiserver wait for kms-plugin to respond before returning an error (default is 3 seconds).

KMS v2 does not support the `cacheSize` property. All data encryption keys (DEKs) will be cached in the clear once the server has unwrapped them via a call to the KMS. Once cached, DEKs can be used to perform decryption indefinitely without making a call to the KMS.

See [Understanding the encryption at rest configuration](#).

# Implementing a KMS plugin

To implement a KMS plugin, you can develop a new plugin gRPC server or enable a KMS plugin already provided by your cloud provider. You then integrate the plugin with the remote KMS and deploy it on the Kubernetes control plane.

## Enabling the KMS supported by your cloud provider

Refer to your cloud provider for instructions on enabling the cloud provider-specific KMS plugin.

## Developing a KMS plugin gRPC server

You can develop a KMS plugin gRPC server using a stub file available for Go. For other languages, you use a proto file to create a stub file that you can use to develop the gRPC server code.

### KMS v1

- Using Go: Use the functions and data structures in the stub file: [api.pb.go](#) to develop the gRPC server code
- Using languages other than Go: Use the protoc compiler with the proto file: [api.proto](#) to generate a stub file for the specific language

### KMS v2

- Using Go: A high level [library](#) is provided to make the process easier. Low level implementations can use the functions and data structures in the stub file: [api.pb.go](#) to develop the gRPC server code
- Using languages other than Go: Use the protoc compiler with the proto file: [api.proto](#) to generate a stub file for the specific language

Then use the functions and data structures in the stub file to develop the server code.

## Notes

### KMS v1

- kms plugin version: v1beta1

In response to procedure call Version, a compatible KMS plugin should return v1beta1 as VersionResponse.version.

- message version: v1beta1

All messages from KMS provider have the version field set to v1beta1.

- protocol: UNIX domain socket (unix)

The plugin is implemented as a gRPC server that listens at UNIX domain socket. The plugin deployment should create a file on the file system to run the gRPC unix domain socket connection. The API server (gRPC client) is configured with the KMS provider (gRPC server) unix domain socket endpoint in order to communicate with it. An abstract Linux socket may be used by starting the endpoint with `/@`, i.e. `unix:///@foo`. Care must be taken when using this type of socket as they do not have concept of ACL (unlike traditional file based sockets). However, they are subject to Linux networking namespace, so will only be accessible to containers within the same pod unless host networking is used.

## KMS v2

- KMS plugin version: v2

In response to the `Status` remote procedure call, a compatible KMS plugin should return its KMS compatibility version as `StatusResponse.version`. That status response should also include "ok" as `StatusResponse.healthz` and a `key_id` (remote KMS KEK ID) as `StatusResponse.key_id`. The Kubernetes project recommends you make your plugin compatible with the stable v2 KMS API. Kubernetes 1.30 also supports the v2beta1 API for KMS; future Kubernetes releases are likely to continue supporting that beta version.

The API server polls the `Status` procedure call approximately every minute when everything is healthy, and every 10 seconds when the plugin is not healthy. Plugins must take care to optimize this call as it will be under constant load.

- Encryption

The `EncryptRequest` procedure call provides the plaintext and a UID for logging purposes. The response must include the ciphertext, the `key_id` for the KEK used, and, optionally, any metadata that the KMS plugin needs to aid in future `DecryptRequest` calls (via the `annotations` field). The plugin must guarantee that any distinct plaintext results in a distinct response (ciphertext, `key_id`, `annotations`).

If the plugin returns a non-empty `annotations` map, all map keys must be fully qualified domain names such as `example.com`. An example use case of annotation is `{"kms.example.io/remote-kms-auditid": "<audit ID used by the remote KMS>"}`

The API server does not perform the `EncryptRequest` procedure call at a high rate. Plugin implementations should still aim to keep each request's latency at under 100 milliseconds.

- Decryption

The `DecryptRequest` procedure call provides the (ciphertext, `key_id`, `annotations`) from `EncryptRequest` and a UID for logging purposes. As expected, it is the inverse of the `EncryptRequest` call. Plugins must verify that the `key_id` is one that they understand - they must not attempt to decrypt data unless they are sure that it was encrypted by them at an earlier time.

The API server may perform thousands of `DecryptRequest` procedure calls on startup to fill its watch cache. Thus plugin implementations must perform these calls as quickly as possible, and should aim to keep each request's latency at under 10 milliseconds.

- Understanding `key_id` and Key Rotation

The `key_id` is the public, non-secret name of the remote KMS KEK that is currently in use. It may be logged during regular operation of the API server, and thus must not contain any private data. Plugin implementations are encouraged to use a hash to avoid leaking any data. The KMS v2 metrics take care to hash this value before exposing it via the `/metrics` endpoint.

The API server considers the `key_id` returned from the `Status` procedure call to be authoritative. Thus, a change to this value signals to the API server that the remote KEK has changed, and data encrypted with the old KEK should be marked stale when a no-op write is performed (as described below). If an `EncryptRequest` procedure call returns a `key_id` that is different from `Status`, the response is thrown away and the plugin is considered unhealthy. Thus implementations must guarantee that the `key_id` returned from `Status` will be the same as the one returned by `EncryptRequest`. Furthermore, plugins must ensure that the `key_id` is stable and does not flip-flop between values (i.e. during a remote KEK rotation).

Plugins must not re-use `key_ids`, even in situations where a previously used remote KEK has been reinstated. For example, if a plugin was using `key_id=A`, switched to `key_id=B`, and then went back to `key_id=A` - instead of reporting `key_id=A` the plugin should report some derivative value such as `key_id=A_001` or use a new value such as `key_id=C`.

Since the API server polls `Status` about every minute, `key_id` rotation is not immediate. Furthermore, the API server will coast on the last valid state for about three minutes. Thus if a user wants to take a passive approach to storage migration (i.e. by waiting), they must schedule a migration to occur at  $3 + N + M$  minutes after the remote KEK has been rotated ( $N$  is how long it takes the plugin to observe the `key_id` change and  $M$  is the desired buffer to allow config changes to be processed - a minimum  $M$  of five minutes is recommend). Note that no API server restart is required to perform KEK rotation.

### **Caution:**

Because you don't control the number of writes performed with the DEK, the Kubernetes project recommends rotating the KEK at least every 90 days.

- protocol: UNIX domain socket (unix)

The plugin is implemented as a gRPC server that listens at UNIX domain socket. The plugin deployment should create a file on the file system to run the gRPC unix domain socket connection. The API server (gRPC client) is configured with the KMS provider (gRPC server) unix domain socket endpoint in order to communicate with it. An abstract Linux socket may be used by starting the endpoint with `/@`, i.e. `unix:///@foo`. Care must be taken when using this type of socket as they do not have concept of ACL (unlike traditional file based sockets). However, they are subject to Linux networking namespace, so will only be accessible to containers within the same pod unless host networking is used.

## **Integrating a KMS plugin with the remote KMS**

The KMS plugin can communicate with the remote KMS using any protocol supported by the KMS. All configuration data, including authentication credentials the KMS plugin uses to communicate with the remote KMS, are stored and managed by the KMS plugin independently. The KMS plugin can encode the ciphertext with additional metadata that may be required

before sending it to the KMS for decryption (KMS v2 makes this process easier by providing a dedicated annotations field).

## Deploying the KMS plugin

Ensure that the KMS plugin runs on the same host(s) as the Kubernetes API server(s).

## Encrypting your data with the KMS provider

To encrypt the data:

1. Create a new EncryptionConfiguration file using the appropriate properties for the kms provider to encrypt resources like Secrets and ConfigMaps. If you want to encrypt an extension API that is defined in a CustomResourceDefinition, your cluster must be running Kubernetes v1.26 or newer.
2. Set the `--encryption-provider-config` flag on the kube-apiserver to point to the location of the configuration file.
3. `--encryption-provider-config-automatic-reload` boolean argument determines if the file set by `--encryption-provider-config` should be [automatically reloaded](#) if the disk contents change.
4. Restart your API server.

### KMS v1

```
apiVersion: apiserver.config.k8s.io/v1
kind: EncryptionConfiguration
resources:
- resources:
 - secrets
 - configmaps
 - pandas.awesome.bears.example
providers:
- kms:
 name: myKmsPluginFoo
 endpoint: unix:///tmp/socketfile-foo.sock
 cachesize: 100
 timeout: 3s
- kms:
 name: myKmsPluginBar
 endpoint: unix:///tmp/socketfile-bar.sock
 cachesize: 100
 timeout: 3s
```

### KMS v2

```
apiVersion: apiserver.config.k8s.io/v1
kind: EncryptionConfiguration
resources:
- resources:
```

```
- secrets
- configmaps
- pandas.awesome.bears.example
providers:
- kms:
 apiVersion: v2
 name: myKmsPluginFoo
 endpoint: unix:///tmp/socketfile-foo.sock
 timeout: 3s
- kms:
 apiVersion: v2
 name: myKmsPluginBar
 endpoint: unix:///tmp/socketfile-bar.sock
 timeout: 3s
```

Setting `--encryption-provider-config-automatic-reload` to `true` collapses all health checks to a single health check endpoint. Individual health checks are only available when KMS v1 providers are in use and the encryption config is not auto-reloaded.

The following table summarizes the health check endpoints for each KMS version:

| KMS configurations | Without Automatic Reload | With Automatic Reload |
|--------------------|--------------------------|-----------------------|
| KMS v1 only        | Individual Healthchecks  | Single Healthcheck    |
| KMS v2 only        | Single Healthcheck       | Single Healthcheck    |
| Both KMS v1 and v2 | Individual Healthchecks  | Single Healthcheck    |
| No KMS             | None                     | Single Healthcheck    |

Single Healthcheck means that the only health check endpoint is `/healthz/kms-providers`.

Individual Healthchecks means that each KMS plugin has an associated health check endpoint based on its location in the encryption config: `/healthz/kms-provider-0`, `/healthz/kms-provider-1` etc.

These healthcheck endpoint paths are hard coded and generated/controlled by the server. The indices for individual healthchecks corresponds to the order in which the KMS encryption config is processed.

Until the steps defined in [Ensuring all secrets are encrypted](#) are performed, the providers list should end with the identity: `{}` provider to allow unencrypted data to be read. Once all resources are encrypted, the identity provider should be removed to prevent the API server from honoring unencrypted data.

For details about the EncryptionConfiguration format, please check the [API server encryption API reference](#).

## Verifying that the data is encrypted

When encryption at rest is correctly configured, resources are encrypted on write. After restarting your kube-apiserver, any newly created or updated Secret or other resource types

configured in EncryptionConfiguration should be encrypted when stored. To verify, you can use the etcdctl command line program to retrieve the contents of your secret data.

1. Create a new secret called secret1 in the default namespace:

```
kubectl create secret generic secret1 -n default --from-literal=mykey=mydata
```

2. Using the etcdctl command line, read that secret out of etcd:

```
ETCDCTL_API=3 etcdctl get /kubernetes.io/secrets/default/secret1 [...] | hexdump -C
```

where [...] contains the additional arguments for connecting to the etcd server.

3. Verify the stored secret is prefixed with k8s:enc:kms:v1: for KMS v1 or prefixed with k8s:enc:kms:v2: for KMS v2, which indicates that the kms provider has encrypted the resulting data.
4. Verify that the secret is correctly decrypted when retrieved via the API:

```
kubectl describe secret secret1 -n default
```

The Secret should contain mykey: mydata

## Ensuring all secrets are encrypted

When encryption at rest is correctly configured, resources are encrypted on write. Thus we can perform an in-place no-op update to ensure that data is encrypted.

The following command reads all secrets and then updates them to apply server side encryption. If an error occurs due to a conflicting write, retry the command. For larger clusters, you may wish to subdivide the secrets by namespace or script an update.

```
kubectl get secrets --all-namespaces -o json | kubectl replace -f -
```

## Switching from a local encryption provider to the KMS provider

To switch from a local encryption provider to the kms provider and re-encrypt all of the secrets:

1. Add the kms provider as the first entry in the configuration file as shown in the following example.

```
apiVersion: apiserver.config.k8s.io/v1
kind: EncryptionConfiguration
resources:
- resources:
 - secrets
providers:
- kms:
 apiVersion: v2
 name : myKmsPlugin
 endpoint: unix:///tmp/socketfile.sock
- aescbc:
```

```
keys:
- name: key1
 secret: <BASE 64 ENCODED SECRET>
```

2. Restart all kube-apiserver processes.
3. Run the following command to force all secrets to be re-encrypted using the kms provider.

```
kubectl get secrets --all-namespaces -o json | kubectl replace -f -
```

## What's next

If you no longer want to use encryption for data persisted in the Kubernetes API, read [decrypt data that are already stored at rest](#).

# Using CoreDNS for Service Discovery

This page describes the CoreDNS upgrade process and how to install CoreDNS instead of kube-dns.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version v1.9. To check the version, enter `kubectl version`.

## About CoreDNS

[CoreDNS](#) is a flexible, extensible DNS server that can serve as the Kubernetes cluster DNS. Like Kubernetes, the CoreDNS project is hosted by the [CNCF](#).

You can use CoreDNS instead of kube-dns in your cluster by replacing kube-dns in an existing deployment, or by using tools like kubeadm that will deploy and upgrade the cluster for you.

## Installing CoreDNS

For manual deployment or replacement of kube-dns, see the documentation at the [CoreDNS website](#).

# Migrating to CoreDNS

## Upgrading an existing cluster with kubeadm

In Kubernetes version 1.21, kubeadm removed its support for kube-dns as a DNS application. For kubeadm v1.30, the only supported cluster DNS application is CoreDNS.

You can move to CoreDNS when you use kubeadm to upgrade a cluster that is using kube-dns. In this case, kubeadm generates the CoreDNS configuration ("Corefile") based upon the kube-dns ConfigMap, preserving configurations for stub domains, and upstream name server.

## Upgrading CoreDNS

You can check the version of CoreDNS that kubeadm installs for each version of Kubernetes in the page [CoreDNS version in Kubernetes](#).

CoreDNS can be upgraded manually in case you want to only upgrade CoreDNS or use your own custom image. There is a helpful [guideline and walkthrough](#) available to ensure a smooth upgrade. Make sure the existing CoreDNS configuration ("Corefile") is retained when upgrading your cluster.

If you are upgrading your cluster using the kubeadm tool, kubeadm can take care of retaining the existing CoreDNS configuration automatically.

## Tuning CoreDNS

When resource utilisation is a concern, it may be useful to tune the configuration of CoreDNS. For more details, check out the [documentation on scaling CoreDNS](#).

## What's next

You can configure [CoreDNS](#) to support many more use cases than kube-dns does by modifying the CoreDNS configuration ("Corefile"). For more information, see the [documentation](#) for the Kubernetes CoreDNS plugin, or read the [Custom DNS Entries for Kubernetes](#) in the CoreDNS blog.

# Using NodeLocal DNSCache in Kubernetes Clusters

FEATURE STATE: Kubernetes v1.18 [stable]

This page provides an overview of NodeLocal DNSCache feature in Kubernetes.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at

least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

## Introduction

NodeLocal DNSCache improves Cluster DNS performance by running a DNS caching agent on cluster nodes as a DaemonSet. In today's architecture, Pods in 'ClusterFirst' DNS mode reach out to a kube-dns serviceIP for DNS queries. This is translated to a kube-dns/CoreDNS endpoint via iptables rules added by kube-proxy. With this new architecture, Pods will reach out to the DNS caching agent running on the same node, thereby avoiding iptables DNAT rules and connection tracking. The local caching agent will query kube-dns service for cache misses of cluster hostnames ("cluster.local" suffix by default).

## Motivation

- With the current DNS architecture, it is possible that Pods with the highest DNS QPS have to reach out to a different node, if there is no local kube-dns/CoreDNS instance. Having a local cache will help improve the latency in such scenarios.
- Skipping iptables DNAT and connection tracking will help reduce [conntrack races](#) and avoid UDP DNS entries filling up conntrack table.
- Connections from the local caching agent to kube-dns service can be upgraded to TCP. TCP conntrack entries will be removed on connection close in contrast with UDP entries that have to timeout ([default](#) `nf_conntrack_udp_timeout` is 30 seconds)
- Upgrading DNS queries from UDP to TCP would reduce tail latency attributed to dropped UDP packets and DNS timeouts usually up to 30s (3 retries + 10s timeout). Since the nodelocal cache listens for UDP DNS queries, applications don't need to be changed.
- Metrics & visibility into DNS requests at a node level.
- Negative caching can be re-enabled, thereby reducing the number of queries for the kube-dns service.

## Architecture Diagram

This is the path followed by DNS Queries after NodeLocal DNSCache is enabled:

NodeLocal DNSCache flow

**Nodelocal DNSCache flow**

This image shows how NodeLocal DNSCache handles DNS queries.

# Configuration

## Note:

The local listen IP address for NodeLocal DNSCache can be any address that can be guaranteed to not collide with any existing IP in your cluster. It's recommended to use an address with a local scope, for example, from the 'link-local' range '169.254.0.0/16' for IPv4 or from the 'Unique Local Address' range in IPv6 'fd00::/8'.

This feature can be enabled using the following steps:

- Prepare a manifest similar to the sample [nodelocaldns.yaml](#) and save it as `nodelocaldns.yaml`.
- If using IPv6, the CoreDNS configuration file needs to enclose all the IPv6 addresses into square brackets if used in 'IP:Port' format. If you are using the sample manifest from the previous point, this will require you to modify [the configuration line L70](#) like this:  
"health [\_\_PILLAR\_\_LOCAL\_\_DNS\_\_]:8080"
- Substitute the variables in the manifest with the right values:

```
kubedns=`kubectl get svc kube-dns -n kube-system -o jsonpath={.spec.clusterIP}`
domain=<cluster-domain>
localdns=<node-local-address>
```

<cluster-domain> is "cluster.local" by default. <node-local-address> is the local listen IP address chosen for NodeLocal DNSCache.

- If kube-proxy is running in IPTABLES mode:

```
sed -i "s/__PILLAR__LOCAL__DNS__/$localdns/g; s/
__PILLAR__DNS__DOMAIN__/$domain/g; s/__PILLAR__DNS__SERVER__/$kubedns/g" nodelocaldns.yaml
```

\_\_PILLAR\_\_CLUSTER\_\_DNS\_\_ and \_\_PILLAR\_\_UPSTREAM\_\_SERVERS\_\_ will be populated by the node-local-dns pods. In this mode, the node-local-dns pods listen on both the kube-dns service IP as well as <node-local-address>, so pods can look up DNS records using either IP address.

- If kube-proxy is running in IPVS mode:

```
sed -i "s/__PILLAR__LOCAL__DNS__/$localdns/g; s/
__PILLAR__DNS__DOMAIN__/$domain/g; s/,__PILLAR__DNS__SERVER__//g; s/
__PILLAR__CLUSTER__DNS__/$kubedns/g" nodelocaldns.yaml
```

In this mode, the node-local-dns pods listen only on <node-local-address>. The node-local-dns interface cannot bind the kube-dns cluster IP since the interface used for IPVS loadbalancing already uses this address.

\_\_PILLAR\_\_UPSTREAM\_\_SERVERS\_\_ will be populated by the node-local-dns pods.

- Run `kubectl create -f nodelocaldns.yaml`

- If using kube-proxy in IPVS mode, `--cluster-dns` flag to kubelet needs to be modified to use `<node-local-address>` that NodeLocal DNSCache is listening on. Otherwise, there is no need to modify the value of the `--cluster-dns` flag, since NodeLocal DNSCache listens on both the kube-dns service IP as well as `<node-local-address>`.

Once enabled, the `node-local-dns` Pods will run in the `kube-system` namespace on each of the cluster nodes. This Pod runs [CoreDNS](#) in cache mode, so all CoreDNS metrics exposed by the different plugins will be available on a per-node basis.

You can disable this feature by removing the DaemonSet, using `kubectl delete -f <manifest>`. You should also revert any changes you made to the kubelet configuration.

## StubDomains and Upstream server Configuration

StubDomains and upstream servers specified in the `kube-dns` ConfigMap in the `kube-system` namespace are automatically picked up by `node-local-dns` pods. The ConfigMap contents need to follow the format shown in [the example](#). The `node-local-dns` ConfigMap can also be modified directly with the stubDomain configuration in the Corefile format. Some cloud providers might not allow modifying `node-local-dns` ConfigMap directly. In those cases, the `kube-dns` ConfigMap can be updated.

## Setting memory limits

The `node-local-dns` Pods use memory for storing cache entries and processing queries. Since they do not watch Kubernetes objects, the cluster size or the number of Services / EndpointSlices do not directly affect memory usage. Memory usage is influenced by the DNS query pattern. From [CoreDNS docs](#),

The default cache size is 10000 entries, which uses about 30 MB when completely filled.

This would be the memory usage for each server block (if the cache gets completely filled). Memory usage can be reduced by specifying smaller cache sizes.

The number of concurrent queries is linked to the memory demand, because each extra goroutine used for handling a query requires an amount of memory. You can set an upper limit using the `max_concurrent` option in the forward plugin.

If a `node-local-dns` Pod attempts to use more memory than is available (because of total system resources, or because of a configured [resource limit](#)), the operating system may shut down that pod's container. If this happens, the container that is terminated ("OOMKilled") does not clean up the custom packet filtering rules that it previously added during startup. The `node-local-dns` container should get restarted (since managed as part of a DaemonSet), but this will lead to a brief DNS downtime each time that the container fails: the packet filtering rules direct DNS queries to a local Pod that is unhealthy.

You can determine a suitable memory limit by running `node-local-dns` pods without a limit and measuring the peak usage. You can also set up and use a [VerticalPodAutoscaler](#) in *recommender mode*, and then check its recommendations.

# Using sysctls in a Kubernetes Cluster

FEATURE STATE: Kubernetes v1.21 [stable]

This document describes how to configure and use kernel parameters within a Kubernetes cluster using the [sysctl](#) interface.

## Note:

Starting from Kubernetes version 1.23, the kubelet supports the use of either / or . as separators for sysctl names. Starting from Kubernetes version 1.25, setting Sysctls for a Pod supports setting sysctls with slashes. For example, you can represent the same sysctl name as kernel.shm\_rmid\_forced using a period as the separator, or as kernel/shm\_rmid\_forced using a slash as a separator. For more sysctl parameter conversion method details, please refer to the page [sysctl.d\(5\)](#) from the Linux man-pages project.

## Before you begin

### Note:

sysctl is a Linux-specific command-line tool used to configure various kernel parameters and it is not available on non-Linux operating systems.

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

For some steps, you also need to be able to reconfigure the command line options for the kubelets running on your cluster.

## Listing all Sysctl Parameters

In Linux, the sysctl interface allows an administrator to modify kernel parameters at runtime. Parameters are available via the /proc/sys/ virtual process file system. The parameters cover various subsystems such as:

- kernel (common prefix: kernel.)
- networking (common prefix: net.)
- virtual memory (common prefix: vm.)
- MDADM (common prefix: dev.)
- More subsystems are described in [Kernel docs](#).

To get a list of all parameters, you can run

```
sudo sysctl -a
```

# Safe and Unsafe Sysctls

Kubernetes classes sysctls as either *safe* or *unsafe*. In addition to proper namespacing, a *safe* sysctl must be properly *isolated* between pods on the same node. This means that setting a *safe* sysctl for one pod

- must not have any influence on any other pod on the node
- must not allow to harm the node's health
- must not allow to gain CPU or memory resources outside of the resource limits of a pod.

By far, most of the *namespaced* sysctls are not necessarily considered *safe*. The following sysctls are supported in the *safe* set:

- `kernel.shm_rmid_forced`;
- `net.ipv4.ip_local_port_range`;
- `net.ipv4.tcp_syncookies`;
- `net.ipv4.ping_group_range` (since Kubernetes 1.18);
- `net.ipv4.ip_unprivileged_port_start` (since Kubernetes 1.22);
- `net.ipv4.ip_local_reserved_ports` (since Kubernetes 1.27, needs kernel 3.16+);
- `net.ipv4.tcp_keepalive_time` (since Kubernetes 1.29, needs kernel 4.5+);
- `net.ipv4.tcp_fin_timeout` (since Kubernetes 1.29, needs kernel 4.6+);
- `net.ipv4.tcp_keepalive_intvl` (since Kubernetes 1.29, needs kernel 4.5+);
- `net.ipv4.tcp_keepalive_probes` (since Kubernetes 1.29, needs kernel 4.5+).

## Note:

There are some exceptions to the set of safe sysctls:

- The `net.*` sysctls are not allowed with host networking enabled.
- The `net.ipv4.tcp_syncookies` sysctl is not namespaced on Linux kernel version 4.4 or lower.

This list will be extended in future Kubernetes versions when the kubelet supports better isolation mechanisms.

## Enabling Unsafe Sysctls

All *safe* sysctls are enabled by default.

All *unsafe* sysctls are disabled by default and must be allowed manually by the cluster admin on a per-node basis. Pods with disabled unsafe sysctls will be scheduled, but will fail to launch.

With the warning above in mind, the cluster admin can allow certain *unsafe* sysctls for very special situations such as high-performance or real-time application tuning. *Unsafe* sysctls are enabled on a node-by-node basis with a flag of the kubelet; for example:

```
kubelet --allowed-unsafe-sysctls \
'kernel.msg*,net.core.somaxconn' ...
```

For [Minikube](#), this can be done via the extra-config flag:

```
minikube start --extra-config="kubelet.allowed-unsafe-
sysctls=kernel.msg*,net.core.somaxconn"...
```

Only *namespaced* sysctls can be enabled this way.

## Setting Sysctls for a Pod

A number of sysctls are *namespaced* in today's Linux kernels. This means that they can be set independently for each pod on a node. Only namespaced sysctls are configurable via the pod securityContext within Kubernetes.

The following sysctls are known to be namespaced. This list could change in future versions of the Linux kernel.

- kernel.shm\*,
- kernel.msg\*,
- kernel.sem,
- fs.mqueue.\*,
- Those net.\* that can be set in container networking namespace. However, there are exceptions (e.g., net.netfilter.nf\_conntrack\_max and net.netfilter.nf\_conntrack\_expect\_max can be set in container networking namespace but are unnamespaced before Linux 5.12.2).

Sysctls with no namespace are called *node-level* sysctls. If you need to set them, you must manually configure them on each node's operating system, or by using a DaemonSet with privileged containers.

Use the pod securityContext to configure namespaced sysctls. The securityContext applies to all containers in the same pod.

This example uses the pod securityContext to set a safe sysctl kernel.shm\_rmid\_forced and two unsafe sysctls net.core.somaxconn and kernel.msgmax. There is no distinction between *safe* and *unsafe* sysctls in the specification.

### Warning:

Only modify sysctl parameters after you understand their effects, to avoid destabilizing your operating system.

```
apiVersion: v1
kind: Pod
metadata:
 name: sysctl-example
spec:
 securityContext:
 sysctls:
 - name: kernel.shm_rmid_forced
 value: "0"
 - name: net.core.somaxconn
 value: "1024"
 - name: kernel.msgmax
 value: "65536"
 ...
```

## Warning:

Due to their nature of being *unsafe*, the use of *unsafe* sysctls is at-your-own-risk and can lead to severe problems like wrong behavior of containers, resource shortage or complete breakage of a node.

It is good practice to consider nodes with special sysctl settings as *tainted* within a cluster, and only schedule pods onto them which need those sysctl settings. It is suggested to use the Kubernetes [taints and toleration feature](#) to implement this.

A pod with the *unsafe* sysctls will fail to launch on any node which has not enabled those two *unsafe* sysctls explicitly. As with *node-level* sysctls it is recommended to use [taints and toleration feature](#) or [taints on nodes](#) to schedule those pods onto the right nodes.

# Utilizing the NUMA-aware Memory Manager

FEATURE STATE: Kubernetes v1.22 [beta]

The Kubernetes *Memory Manager* enables the feature of guaranteed memory (and hugepages) allocation for pods in the Guaranteed [QoS class](#).

The Memory Manager employs hint generation protocol to yield the most suitable NUMA affinity for a pod. The Memory Manager feeds the central manager (*Topology Manager*) with these affinity hints. Based on both the hints and Topology Manager policy, the pod is rejected or admitted to the node.

Moreover, the Memory Manager ensures that the memory which a pod requests is allocated from a minimum number of NUMA nodes.

The Memory Manager is only pertinent to Linux based hosts.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version v1.21. To check the version, enter kubectl version.

To align memory resources with other requested resources in a Pod spec:

- the CPU Manager should be enabled and proper CPU Manager policy should be configured on a Node. See [control CPU Management Policies](#);
- the Topology Manager should be enabled and proper Topology Manager policy should be configured on a Node. See [control Topology Management Policies](#).

Starting from v1.22, the Memory Manager is enabled by default through `MemoryManager` [feature gate](#).

Preceding v1.22, the kubelet must be started with the following flag:

```
--feature-gates=MemoryManager=true
```

in order to enable the Memory Manager feature.

## How Memory Manager Operates?

The Memory Manager currently offers the guaranteed memory (and hugepages) allocation for Pods in Guaranteed QoS class. To immediately put the Memory Manager into operation follow the guidelines in the section [Memory Manager configuration](#), and subsequently, prepare and deploy a Guaranteed pod as illustrated in the section [Placing a Pod in the Guaranteed QoS class](#).

The Memory Manager is a Hint Provider, and it provides topology hints for the Topology Manager which then aligns the requested resources according to these topology hints. It also enforces cgroups (i.e. `cpuset.mems`) for pods. The complete flow diagram concerning pod admission and deployment process is illustrated in [Memory Manager KEP: Design Overview](#) and below:

Memory Manager in the pod admission and deployment process

During this process, the Memory Manager updates its internal counters stored in [Node Map and Memory Maps](#) to manage guaranteed memory allocation.

The Memory Manager updates the Node Map during the startup and runtime as follows.

### Startup

This occurs once a node administrator employs `--reserved-memory` (section [Reserved memory flag](#)). In this case, the Node Map becomes updated to reflect this reservation as illustrated in [Memory Manager KEP: Memory Maps at start-up \(with examples\)](#).

The administrator must provide `--reserved-memory` flag when Static policy is configured.

### Runtime

Reference [Memory Manager KEP: Memory Maps at runtime \(with examples\)](#) illustrates how a successful pod deployment affects the Node Map, and it also relates to how potential Out-of-Memory (OOM) situations are handled further by Kubernetes or operating system.

Important topic in the context of Memory Manager operation is the management of NUMA groups. Each time pod's memory request is in excess of single NUMA node capacity, the Memory Manager attempts to create a group that comprises several NUMA nodes and features extend memory capacity. The problem has been solved as elaborated in [Memory Manager KEP: How to enable the guaranteed memory allocation over many NUMA nodes?](#). Also, reference [Memory Manager KEP: Simulation - how the Memory Manager works? \(by examples\)](#) illustrates how the management of groups occurs.

# Memory Manager configuration

Other Managers should be first pre-configured. Next, the Memory Manager feature should be enabled and be run with Static policy (section [Static policy](#)). Optionally, some amount of memory can be reserved for system or kubelet processes to increase node stability (section [Reserved memory flag](#)).

## Policies

Memory Manager supports two policies. You can select a policy via a kubelet flag `--memory-manager-policy`:

- None (default)
- Static

### None policy

This is the default policy and does not affect the memory allocation in any way. It acts the same as if the Memory Manager is not present at all.

The None policy returns default topology hint. This special hint denotes that Hint Provider (Memory Manager in this case) has no preference for NUMA affinity with any resource.

### Static policy

In the case of the Guaranteed pod, the Static Memory Manager policy returns topology hints relating to the set of NUMA nodes where the memory can be guaranteed, and reserves the memory through updating the internal [NodeMap](#) object.

In the case of the BestEffort or Burstable pod, the Static Memory Manager policy sends back the default topology hint as there is no request for the guaranteed memory, and does not reserve the memory in the internal [NodeMap](#) object.

## Reserved memory flag

The [Node Allocatable](#) mechanism is commonly used by node administrators to reserve K8S node system resources for the kubelet or operating system processes in order to enhance the node stability. A dedicated set of flags can be used for this purpose to set the total amount of reserved memory for a node. This pre-configured value is subsequently utilized to calculate the real amount of node's "allocatable" memory available to pods.

The Kubernetes scheduler incorporates "allocatable" to optimise pod scheduling process. The foregoing flags include `--kube-reserved`, `--system-reserved` and `--eviction-threshold`. The sum of their values will account for the total amount of reserved memory.

A new `--reserved-memory` flag was added to Memory Manager to allow for this total reserved memory to be split (by a node administrator) and accordingly reserved across many NUMA nodes.

The flag specifies a comma-separated list of memory reservations of different memory types per NUMA node. Memory reservations across multiple NUMA nodes can be specified using semicolon as separator. This parameter is only useful in the context of the Memory Manager

feature. The Memory Manager will not use this reserved memory for the allocation of container workloads.

For example, if you have a NUMA node "NUMA0" with 10Gi of memory available, and the `--reserved-memory` was specified to reserve 1Gi of memory at "NUMA0", the Memory Manager assumes that only 9Gi is available for containers.

You can omit this parameter, however, you should be aware that the quantity of reserved memory from all NUMA nodes should be equal to the quantity of memory specified by the [Node Allocatable feature](#). If at least one node allocatable parameter is non-zero, you will need to specify `--reserved-memory` for at least one NUMA node. In fact, eviction-hard threshold value is equal to 100Mi by default, so if Static policy is used, `--reserved-memory` is obligatory.

Also, avoid the following configurations:

1. duplicates, i.e. the same NUMA node or memory type, but with a different value;
2. setting zero limit for any of memory types;
3. NUMA node IDs that do not exist in the machine hardware;
4. memory type names different than memory or hugepages-`<size>` (hugepages of particular `<size>` should also exist).

Syntax:

```
--reserved-memory N:memory-type1=value1,memory-type2=value2,...
```

- N (integer) - NUMA node index, e.g. 0
- memory-type (string) - represents memory type:
  - memory - conventional memory
  - hugepages-2Mi or hugepages-1Gi - hugepages
- value (string) - the quantity of reserved memory, e.g. 1Gi

Example usage:

```
--reserved-memory 0:memory=1Gi,hugepages-1Gi=2Gi
```

or

```
--reserved-memory 0:memory=1Gi --reserved-memory 1:memory=2Gi
```

or

```
--reserved-memory '0:memory=1Gi;1:memory=2Gi'
```

When you specify values for `--reserved-memory` flag, you must comply with the setting that you prior provided via Node Allocatable Feature flags. That is, the following rule must be obeyed for each memory type:

$$\text{sum}(\text{reserved-memory}(i)) = \text{kube-reserved} + \text{system-reserved} + \text{eviction-threshold},$$

where *i* is an index of a NUMA node.

If you do not follow the formula above, the Memory Manager will show an error on startup.

In other words, the example above illustrates that for the conventional memory (type=memory), we reserve 3Gi in total, i.e.:

$\text{sum}(\text{reserved-memory}(i)) = \text{reserved-memory}(0) + \text{reserved-memory}(1) = 1\text{Gi} + 2\text{Gi} = 3\text{Gi}$

An example of kubelet command-line arguments relevant to the node Allocatable configuration:

- `--kube-reserved=cpu=500m,memory=50Mi`
- `--system-reserved=cpu=123m,memory=333Mi`
- `--eviction-hard=memory.available<500Mi`

#### Note:

The default hard eviction threshold is 100MiB, and **not** zero. Remember to increase the quantity of memory that you reserve by setting `--reserved-memory` by that hard eviction threshold. Otherwise, the kubelet will not start Memory Manager and display an error.

Here is an example of a correct configuration:

```
--feature-gates=MemoryManager=true
--kube-reserved=cpu=4,memory=4Gi
--system-reserved=cpu=1,memory=1Gi
--memory-manager-policy=Static
--reserved-memory '0:memory=3Gi;1:memory=2148Mi'
```

Let us validate the configuration above:

1. `kube-reserved + system-reserved + eviction-hard(default) = reserved-memory(0) + reserved-memory(1)`
2. `4GiB + 1GiB + 100MiB = 3GiB + 2148MiB`
3. `5120MiB + 100MiB = 3072MiB + 2148MiB`
4. `5220MiB = 5220MiB` (which is correct)

## Placing a Pod in the Guaranteed QoS class

If the selected policy is anything other than None, the Memory Manager identifies pods that are in the Guaranteed QoS class. The Memory Manager provides specific topology hints to the Topology Manager for each Guaranteed pod. For pods in a QoS class other than Guaranteed, the Memory Manager provides default topology hints to the Topology Manager.

The following excerpts from pod manifests assign a pod to the Guaranteed QoS class.

Pod with integer CPU(s) runs in the Guaranteed QoS class, when requests are equal to limits:

```
spec:
 containers:
 - name: nginx
 image: nginx
 resources:
 limits:
 memory: "200Mi"
 cpu: "2"
 example.com/device: "1"
 requests:
 memory: "200Mi"
```

```
cpu: "2"
example.com/device: "1"
```

Also, a pod sharing CPU(s) runs in the Guaranteed QoS class, when requests are equal to limits.

```
spec:
 containers:
 - name: nginx
 image: nginx
 resources:
 limits:
 memory: "200Mi"
 cpu: "300m"
 example.com/device: "1"
 requests:
 memory: "200Mi"
 cpu: "300m"
 example.com/device: "1"
```

Notice that both CPU and memory requests must be specified for a Pod to lend it to Guaranteed QoS class.

## Troubleshooting

The following means can be used to troubleshoot the reason why a pod could not be deployed or became rejected at a node:

- pod status - indicates topology affinity errors
- system logs - include valuable information for debugging, e.g., about generated hints
- state file - the dump of internal state of the Memory Manager (includes [Node Map and Memory Maps](#))
- starting from v1.22, the [device plugin resource API](#) can be used to retrieve information about the memory reserved for containers

### Pod status (TopologyAffinityError)

This error typically occurs in the following situations:

- a node has not enough resources available to satisfy the pod's request
- the pod's request is rejected due to particular Topology Manager policy constraints

The error appears in the status of a pod:

```
kubectl get pods
```

| NAME       | READY | STATUS                | RESTARTS | AGE  |
|------------|-------|-----------------------|----------|------|
| guaranteed | 0/1   | TopologyAffinityError | 0        | 113s |

Use `kubectl describe pod <id>` or `kubectl get events` to obtain detailed error message:

```
Warning TopologyAffinityError 10m kubelet, dell8 Resources cannot be allocated with
Topology locality
```

## System logs

Search system logs with respect to a particular pod.

The set of hints that Memory Manager generated for the pod can be found in the logs. Also, the set of hints generated by CPU Manager should be present in the logs.

Topology Manager merges these hints to calculate a single best hint. The best hint should be also present in the logs.

The best hint indicates where to allocate all the resources. Topology Manager tests this hint against its current policy, and based on the verdict, it either admits the pod to the node or rejects it.

Also, search the logs for occurrences associated with the Memory Manager, e.g. to find out information about cgroups and cpuset.mems updates.

## Examine the memory manager state on a node

Let us first deploy a sample Guaranteed pod whose specification is as follows:

```
apiVersion: v1
kind: Pod
metadata:
 name: guaranteed
spec:
 containers:
 - name: guaranteed
 image: consumer
 imagePullPolicy: Never
 resources:
 limits:
 cpu: "2"
 memory: 150Gi
 requests:
 cpu: "2"
 memory: 150Gi
 command: ["sleep", "infinity"]
```

Next, let us log into the node where it was deployed and examine the state file in `/var/lib/kubelet/memory_manager_state`:

```
{
 "policyName": "Static",
 "machineState": {
 "0": {
 "numberOfAssignments": 1,
 "memoryMap": {
 "hugepages-1Gi": {
 "total": 0,
 "systemReserved": 0,
 "allocatable": 0,
 "reserved": 0,
```

```
 "free":0
 },
 "memory":{
 "total":134987354112,
 "systemReserved":3221225472,
 "allocatable":131766128640,
 "reserved":131766128640,
 "free":0
 }
},
"nodes":[
 0,
 1
]
},
"1":{
 "numberOfAssignments":1,
 "memoryMap":{
 "hugepages-1Gi":{
 "total":0,
 "systemReserved":0,
 "allocatable":0,
 "reserved":0,
 "free":0
 },
 "memory":{
 "total":135286722560,
 "systemReserved":2252341248,
 "allocatable":133034381312,
 "reserved":29295144960,
 "free":103739236352
 }
 },
 "nodes":[
 0,
 1
]
}
},
"entries":{
 "fa9bdd38-6df9-4cf9-aa67-8c4814da37a8":{
 "guaranteed":[
 {
 "numaAffinity":[
 0,
 1
],
 "type":"memory",
 "size":161061273600
 }
]
 }
}
},
```

```
"checksum":4142013182
}
```

It can be deduced from the state file that the pod was pinned to both NUMA nodes, i.e.:

```
"numaAffinity":[
 0,
 1
],
```

Pinned term means that pod's memory consumption is constrained (through cgroups configuration) to these NUMA nodes.

This automatically implies that Memory Manager instantiated a new group that comprises these two NUMA nodes, i.e. 0 and 1 indexed NUMA nodes.

Notice that the management of groups is handled in a relatively complex manner, and further elaboration is provided in Memory Manager KEP in [this](#) and [this](#) sections.

In order to analyse memory resources available in a group, the corresponding entries from NUMA nodes belonging to the group must be added up.

For example, the total amount of free "conventional" memory in the group can be computed by adding up the free memory available at every NUMA node in the group, i.e., in the "memory" section of NUMA node 0 ("free":0) and NUMA node 1 ("free":103739236352). So, the total amount of free "conventional" memory in this group is equal to 0 + 103739236352 bytes.

The line "systemReserved":3221225472 indicates that the administrator of this node reserved 3221225472 bytes (i.e. 3Gi) to serve kubelet and system processes at NUMA node 0, by using --reserved-memory flag.

## Device plugin resource API

The kubelet provides a PodResourceLister gRPC service to enable discovery of resources and associated metadata. By using its [List gRPC endpoint](#), information about reserved memory for each container can be retrieved, which is contained in protobuf ContainerMemory message. This information can be retrieved solely for pods in Guaranteed QoS class.

# Verify Signed Kubernetes Artifacts

FEATURE STATE: Kubernetes v1.26 [beta]

## Before you begin

You will need to have the following tools installed:

- cosign ([install guide](#))
- curl (often provided by your operating system)
- jq ([download jq](#))

## Verifying binary signatures

The Kubernetes release process signs all binary artifacts (tarballs, SPDX files, standalone binaries) by using cosign's keyless signing. To verify a particular binary, retrieve it together with its signature and certificate:

```
URL=https://dl.k8s.io/release/v1.30.0/bin/linux/amd64
BINARY=kubectl

FILES=(
 "$BINARY"
 "$BINARY.sig"
 "$BINARY.cert"
)

for FILE in "${FILES[@]"; do
 curl -sSfL --retry 3 --retry-delay 3 "$URL/$FILE" -o "$FILE"
done
```

Then verify the blob by using `cosign verify-blob`:

```
cosign verify-blob "$BINARY" \
 --signature "$BINARY".sig \
 --certificate "$BINARY".cert \
 --certificate-identity krel-staging@k8s-releng-prod.iam.gserviceaccount.com \
 --certificate-oidc-issuer https://accounts.google.com
```

### Note:

Cosign 2.0 requires the `--certificate-identity` and `--certificate-oidc-issuer` options.

To learn more about keyless signing, please refer to [Keyless Signatures](#).

Previous versions of Cosign required that you set `COSIGN_EXPERIMENTAL=1`.

For additional information, please refer to the [sigstore Blog](#)

## Verifying image signatures

For a complete list of images that are signed please refer to [Releases](#).

Pick one image from this list and verify its signature using the `cosign verify` command:

```
cosign verify registry.k8s.io/kube-apiserver-amd64:v1.30.0 \
--certificate-identity krel-trust@k8s-releng-prod.iam.gserviceaccount.com \
--certificate-oidc-issuer https://accounts.google.com \
| jq .
```

## Verifying images for all control plane components

To verify all signed control plane images for the latest stable version (v1.30.0), please run the following commands:

```
curl -Ls "https://sbom.k8s.io/$(curl -Ls https://dl.k8s.io/release/stable.txt)/release" \
| grep "SPDXID: SPDXRef-Package-registry.k8s.io" \
| grep -v sha256 | cut -d- -f3- | sed 's/-/\//' | sed 's/-v1/:v1/' \
| sort > images.txt
input=images.txt
while IFS= read -r image
do
 cosign verify "$image" \
 --certificate-identity krel-trust@k8s-releng-prod.iam.gserviceaccount.com \
 --certificate-oidc-issuer https://accounts.google.com \
 | jq .
done < "$input"
```

Once you have verified an image, you can specify the image by its digest in your Pod manifests as per this example:

```
registry-url/image-
name@sha256:45b23dee08af5e43a7fea6c4cf9c25ccf269ee113168c19722f87876677c5cb2
```

For more information, please refer to the [Image Pull Policy](#) section.

## Verifying Image Signatures with Admission Controller

For non-control plane images (for example [conformance image](#)), signatures can also be verified at deploy time using [sigstore policy-controller](#) admission controller.

Here are some helpful resources to get started with policy-controller:

- [Installation](#)
- [Configuration Options](#)

## Verify the Software Bill Of Materials

You can verify the Kubernetes Software Bill of Materials (SBOM) by using the sigstore certificate and signature, or the corresponding SHA files:

```
Retrieve the latest available Kubernetes release version
VERSION=$(curl -Ls https://dl.k8s.io/release/stable.txt)

Verify the SHA512 sum
curl -Ls "https://sbom.k8s.io/$VERSION/release" -o "$VERSION.spdx"
echo "$(curl -Ls "https://sbom.k8s.io/$VERSION/release.sha512") $VERSION.spdx" | sha512sum
```

```
--check

Verify the SHA256 sum
echo "$(curl -Ls "https://sbom.k8s.io/$VERSION/release.sha256") $VERSION.spdx" | sha256sum
--check

Retrieve sigstore signature and certificate
curl -Ls "https://sbom.k8s.io/$VERSION/release.sig" -o "$VERSION.spdx.sig"
curl -Ls "https://sbom.k8s.io/$VERSION/release.cert" -o "$VERSION.spdx.cert"

Verify the sigstore signature
cosign verify-blob \
 --certificate "$VERSION.spdx.cert" \
 --signature "$VERSION.spdx.sig" \
 --certificate-identity krel-staging@k8s-releng-prod.iam.gserviceaccount.com \
 --certificate-oidc-issuer https://accounts.google.com \
 "$VERSION.spdx"
```

# Assign Memory Resources to Containers and Pods

This page shows how to assign a memory *request* and a memory *limit* to a Container. A Container is guaranteed to have as much memory as it requests, but is not allowed to use more memory than its limit.

## Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

Each node in your cluster must have at least 300 MiB of memory.

A few of the steps on this page require you to run the [metrics-server](#) service in your cluster. If you have the metrics-server running, you can skip those steps.

If you are running Minikube, run the following command to enable the metrics-server:

```
minikube addons enable metrics-server
```

To see whether the metrics-server is running, or another provider of the resource metrics API (metrics.k8s.io), run the following command:

```
kubectl get apiservices
```

If the resource metrics API is available, the output includes a reference to metrics.k8s.io.

NAME

v1beta1.metrics.k8s.io

## Create a namespace

Create a namespace so that the resources you create in this exercise are isolated from the rest of your cluster.

```
kubectl create namespace mem-example
```

## Specify a memory request and a memory limit

To specify a memory request for a Container, include the resources:requests field in the Container's resource manifest. To specify a memory limit, include resources:limits.

In this exercise, you create a Pod that has one Container. The Container has a memory request of 100 MiB and a memory limit of 200 MiB. Here's the configuration file for the Pod:

[pods/resource/memory-request-limit.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: memory-demo
 namespace: mem-example
spec:
 containers:
 - name: memory-demo-ctr
 image: polinux/stress
 resources:
 requests:
 memory: "100Mi"
 limits:
 memory: "200Mi"
 command: ["stress"]
 args: ["--vm", "1", "--vm-bytes", "150M", "--vm-hang", "1"]
```

The args section in the configuration file provides arguments for the Container when it starts. The "--vm-bytes", "150M" arguments tell the Container to attempt to allocate 150 MiB of memory.

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/resource/memory-request-limit.yaml --namespace=mem-example
```

Verify that the Pod Container is running:

```
kubectl get pod memory-demo --namespace=mem-example
```

View detailed information about the Pod:

```
kubectl get pod memory-demo --output=yaml --namespace=mem-example
```

The output shows that the one Container in the Pod has a memory request of 100 MiB and a memory limit of 200 MiB.

```
...
resources:
 requests:
 memory: 100Mi
 limits:
 memory: 200Mi
...
```

Run `kubectl top` to fetch the metrics for the pod:

```
kubectl top pod memory-demo --namespace=mem-example
```

The output shows that the Pod is using about 162,900,000 bytes of memory, which is about 150 MiB. This is greater than the Pod's 100 MiB request, but within the Pod's 200 MiB limit.

| NAME        | CPU(cores)  | MEMORY(bytes) |
|-------------|-------------|---------------|
| memory-demo | <something> | 162856960     |

Delete your Pod:

```
kubectl delete pod memory-demo --namespace=mem-example
```

## Exceed a Container's memory limit

A Container can exceed its memory request if the Node has memory available. But a Container is not allowed to use more than its memory limit. If a Container allocates more memory than its limit, the Container becomes a candidate for termination. If the Container continues to consume memory beyond its limit, the Container is terminated. If a terminated Container can be restarted, the kubelet restarts it, as with any other type of runtime failure.

In this exercise, you create a Pod that attempts to allocate more memory than its limit. Here is the configuration file for a Pod that has one Container with a memory request of 50 MiB and a memory limit of 100 MiB:

[pods/resource/memory-request-limit-2.yaml](https://k8s.io/examples/pods/resource/memory-request-limit-2.yaml)

```
apiVersion: v1
kind: Pod
metadata:
 name: memory-demo-2
```

```

namespace: mem-example
spec:
 containers:
 - name: memory-demo-2-ctr
 image: polinux/stress
 resources:
 requests:
 memory: "50Mi"
 limits:
 memory: "100Mi"
 command: ["stress"]
 args: ["--vm", "1", "--vm-bytes", "250M", "--vm-hang", "1"]

```

In the args section of the configuration file, you can see that the Container will attempt to allocate 250 MiB of memory, which is well above the 100 MiB limit.

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/resource/memory-request-limit-2.yaml --namespace=mem-example
```

View detailed information about the Pod:

```
kubectl get pod memory-demo-2 --namespace=mem-example
```

At this point, the Container might be running or killed. Repeat the preceding command until the Container is killed:

```

NAME READY STATUS RESTARTS AGE
memory-demo-2 0/1 OOMKilled 1 24s

```

Get a more detailed view of the Container status:

```
kubectl get pod memory-demo-2 --output=yaml --namespace=mem-example
```

The output shows that the Container was killed because it is out of memory (OOM):

```

lastState:
 terminated:
 containerID: 65183c1877aaec2e8427bc95609cc52677a454b56fcb24340dbd22917c23b10f
 exitCode: 137
 finishedAt: 2017-06-20T20:52:19Z
 reason: OOMKilled
 startedAt: null

```

The Container in this exercise can be restarted, so the kubelet restarts it. Repeat this command several times to see that the Container is repeatedly killed and restarted:

```
kubectl get pod memory-demo-2 --namespace=mem-example
```

The output shows that the Container is killed, restarted, killed again, restarted again, and so on:

```

kubectl get pod memory-demo-2 --namespace=mem-example
NAME READY STATUS RESTARTS AGE
memory-demo-2 0/1 OOMKilled 1 37s

```

```
kubectrl get pod memory-demo-2 --namespace=mem-example
NAME READY STATUS RESTARTS AGE
memory-demo-2 1/1 Running 2 40s
```

View detailed information about the Pod history:

```
kubectrl describe pod memory-demo-2 --namespace=mem-example
```

The output shows that the Container starts and fails repeatedly:

```
... Normal Created Created container with id
66a3a20aa7980e61be4922780bf9d24d1a1d8b7395c09861225b0eba1b1f8511
... Warning BackOff Back-off restarting failed container
```

View detailed information about your cluster's Nodes:

```
kubectrl describe nodes
```

The output includes a record of the Container being killed because of an out-of-memory condition:

```
Warning OOMKilling Memory cgroup out of memory: Kill process 4481 (stress) score 1994 or
sacrifice child
```

Delete your Pod:

```
kubectrl delete pod memory-demo-2 --namespace=mem-example
```

## Specify a memory request that is too big for your Nodes

Memory requests and limits are associated with Containers, but it is useful to think of a Pod as having a memory request and limit. The memory request for the Pod is the sum of the memory requests for all the Containers in the Pod. Likewise, the memory limit for the Pod is the sum of the limits of all the Containers in the Pod.

Pod scheduling is based on requests. A Pod is scheduled to run on a Node only if the Node has enough available memory to satisfy the Pod's memory request.

In this exercise, you create a Pod that has a memory request so big that it exceeds the capacity of any Node in your cluster. Here is the configuration file for a Pod that has one Container with a request for 1000 GiB of memory, which likely exceeds the capacity of any Node in your cluster.

[pods/resource/memory-request-limit-3.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: memory-demo-3
 namespace: mem-example
spec:
 containers:
 - name: memory-demo-3-ctr
```

```
image: polinux/stress
resources:
 requests:
 memory: "1000Gi"
 limits:
 memory: "1000Gi"
command: ["stress"]
args: ["--vm", "1", "--vm-bytes", "150M", "--vm-hang", "1"]
```

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/resource/memory-request-limit-3.yaml --namespace=mem-example
```

View the Pod status:

```
kubectl get pod memory-demo-3 --namespace=mem-example
```

The output shows that the Pod status is PENDING. That is, the Pod is not scheduled to run on any Node, and it will remain in the PENDING state indefinitely:

```
kubectl get pod memory-demo-3 --namespace=mem-example
NAME READY STATUS RESTARTS AGE
memory-demo-3 0/1 Pending 0 25s
```

View detailed information about the Pod, including events:

```
kubectl describe pod memory-demo-3 --namespace=mem-example
```

The output shows that the Container cannot be scheduled because of insufficient memory on the Nodes:

```
Events:
... Reason Message

... FailedScheduling No nodes are available that match all of the following predicates::
Insufficient memory (3).
```

## Memory units

The memory resource is measured in bytes. You can express memory as a plain integer or a fixed-point integer with one of these suffixes: E, P, T, G, M, K, Ei, Pi, Ti, Gi, Mi, Ki. For example, the following represent approximately the same value:

```
128974848, 129e6, 129M, 123Mi
```

Delete your Pod:

```
kubectl delete pod memory-demo-3 --namespace=mem-example
```

## If you do not specify a memory limit

If you do not specify a memory limit for a Container, one of the following situations applies:

- The Container has no upper bound on the amount of memory it uses. The Container could use all of the memory available on the Node where it is running which in turn could invoke the OOM Killer. Further, in case of an OOM Kill, a container with no resource limits will have a greater chance of being killed.
- The Container is running in a namespace that has a default memory limit, and the Container is automatically assigned the default limit. Cluster administrators can use a [LimitRange](#) to specify a default value for the memory limit.

## Motivation for memory requests and limits

By configuring memory requests and limits for the Containers that run in your cluster, you can make efficient use of the memory resources available on your cluster's Nodes. By keeping a Pod's memory request low, you give the Pod a good chance of being scheduled. By having a memory limit that is greater than the memory request, you accomplish two things:

- The Pod can have bursts of activity where it makes use of memory that happens to be available.
- The amount of memory a Pod can use during a burst is limited to some reasonable amount.

## Clean up

Delete your namespace. This deletes all the Pods that you created for this task:

```
kubectrl delete namespace mem-example
```

## What's next

# Assign CPU Resources to Containers and Pods

This page shows how to assign a CPU *request* and a CPU *limit* to a container. Containers cannot use more CPU than the configured limit. Provided the system has CPU time free, a container is guaranteed to be allocated as much CPU as it requests.

## Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

Your cluster must have at least 1 CPU available for use to run the task examples.

A few of the steps on this page require you to run the [metrics-server](#) service in your cluster. If you have the metrics-server running, you can skip those steps.

If you are running [Minikube](#), run the following command to enable metrics-server:

```
minikube addons enable metrics-server
```

To see whether metrics-server (or another provider of the resource metrics API, `metrics.k8s.io`) is running, type the following command:

```
kubectl get apiservices
```

If the resource metrics API is available, the output will include a reference to `metrics.k8s.io`.

```
NAME
v1beta1.metrics.k8s.io
```

## Create a namespace

Create a [Namespace](#) so that the resources you create in this exercise are isolated from the rest of your cluster.

```
kubectl create namespace cpu-example
```

# Specify a CPU request and a CPU limit

To specify a CPU request for a container, include the `resources:requests` field in the Container resource manifest. To specify a CPU limit, include `resources:limits`.

In this exercise, you create a Pod that has one container. The container has a request of 0.5 CPU and a limit of 1 CPU. Here is the configuration file for the Pod:

[pods/resource/cpu-request-limit.yaml](https://k8s.io/examples/pods/resource/cpu-request-limit.yaml)

```
apiVersion: v1
kind: Pod
metadata:
 name: cpu-demo
 namespace: cpu-example
spec:
 containers:
 - name: cpu-demo-ctr
 image: vish/stress
 resources:
 limits:
 cpu: "1"
 requests:
 cpu: "0.5"
 args:
 - -cpus
 - "2"
```

The `args` section of the configuration file provides arguments for the container when it starts. The `-cpus "2"` argument tells the Container to attempt to use 2 CPUs.

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/resource/cpu-request-limit.yaml --namespace=cpu-example
```

Verify that the Pod is running:

```
kubectl get pod cpu-demo --namespace=cpu-example
```

View detailed information about the Pod:

```
kubectl get pod cpu-demo --output=yaml --namespace=cpu-example
```

The output shows that the one container in the Pod has a CPU request of 500 milliCPU and a CPU limit of 1 CPU.

```
resources:
 limits:
 cpu: "1"
 requests:
 cpu: 500m
```

Use `kubectl top` to fetch the metrics for the Pod:

```
kubecttl top pod cpu-demo --namespace=cpu-example
```

This example output shows that the Pod is using 974 milliCPU, which is slightly less than the limit of 1 CPU specified in the Pod configuration.

| NAME     | CPU(cores) | MEMORY(bytes) |
|----------|------------|---------------|
| cpu-demo | 974m       | <something>   |

Recall that by setting `-cpu "2"`, you configured the Container to attempt to use 2 CPUs, but the Container is only being allowed to use about 1 CPU. The container's CPU use is being throttled, because the container is attempting to use more CPU resources than its limit.

#### Note:

Another possible explanation for the CPU use being below 1.0 is that the Node might not have enough CPU resources available. Recall that the prerequisites for this exercise require your cluster to have at least 1 CPU available for use. If your Container runs on a Node that has only 1 CPU, the Container cannot use more than 1 CPU regardless of the CPU limit specified for the Container.

## CPU units

The CPU resource is measured in *CPU* units. One CPU, in Kubernetes, is equivalent to:

- 1 AWS vCPU
- 1 GCP Core
- 1 Azure vCore
- 1 Hyperthread on a bare-metal Intel processor with Hyperthreading

Fractional values are allowed. A Container that requests 0.5 CPU is guaranteed half as much CPU as a Container that requests 1 CPU. You can use the suffix `m` to mean milli. For example 100m CPU, 100 milliCPU, and 0.1 CPU are all the same. Precision finer than 1m is not allowed.

CPU is always requested as an absolute quantity, never as a relative quantity; 0.1 is the same amount of CPU on a single-core, dual-core, or 48-core machine.

Delete your Pod:

```
kubecttl delete pod cpu-demo --namespace=cpu-example
```

## Specify a CPU request that is too big for your Nodes

CPU requests and limits are associated with Containers, but it is useful to think of a Pod as having a CPU request and limit. The CPU request for a Pod is the sum of the CPU requests for all the Containers in the Pod. Likewise, the CPU limit for a Pod is the sum of the CPU limits for all the Containers in the Pod.

Pod scheduling is based on requests. A Pod is scheduled to run on a Node only if the Node has enough CPU resources available to satisfy the Pod CPU request.

In this exercise, you create a Pod that has a CPU request so big that it exceeds the capacity of any Node in your cluster. Here is the configuration file for a Pod that has one Container. The Container requests 100 CPU, which is likely to exceed the capacity of any Node in your cluster.

[pods/resource/cpu-request-limit-2.yaml](https://k8s.io/examples/pods/resource/cpu-request-limit-2.yaml)

```
apiVersion: v1
kind: Pod
metadata:
 name: cpu-demo-2
 namespace: cpu-example
spec:
 containers:
 - name: cpu-demo-ctr-2
 image: vish/stress
 resources:
 limits:
 cpu: "100"
 requests:
 cpu: "100"
 args:
 - -cpus
 - "2"
```

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/resource/cpu-request-limit-2.yaml --namespace=cpu-example
```

View the Pod status:

```
kubectl get pod cpu-demo-2 --namespace=cpu-example
```

The output shows that the Pod status is Pending. That is, the Pod has not been scheduled to run on any Node, and it will remain in the Pending state indefinitely:

| NAME       | READY | STATUS  | RESTARTS | AGE |
|------------|-------|---------|----------|-----|
| cpu-demo-2 | 0/1   | Pending | 0        | 7m  |

View detailed information about the Pod, including events:

```
kubectl describe pod cpu-demo-2 --namespace=cpu-example
```

The output shows that the Container cannot be scheduled because of insufficient CPU resources on the Nodes:

Events:

| Reason           | Message                                                                                   |
|------------------|-------------------------------------------------------------------------------------------|
| FailedScheduling | No nodes are available that match all of the following predicates:: Insufficient cpu (3). |

Delete your Pod:

```
kubectl delete pod cpu-demo-2 --namespace=cpu-example
```

## If you do not specify a CPU limit

If you do not specify a CPU limit for a Container, then one of these situations applies:

- The Container has no upper bound on the CPU resources it can use. The Container could use all of the CPU resources available on the Node where it is running.
- The Container is running in a namespace that has a default CPU limit, and the Container is automatically assigned the default limit. Cluster administrators can use a [LimitRange](#) to specify a default value for the CPU limit.

## If you specify a CPU limit but do not specify a CPU request

If you specify a CPU limit for a Container but do not specify a CPU request, Kubernetes automatically assigns a CPU request that matches the limit. Similarly, if a Container specifies its own memory limit, but does not specify a memory request, Kubernetes automatically assigns a memory request that matches the limit.

## Motivation for CPU requests and limits

By configuring the CPU requests and limits of the Containers that run in your cluster, you can make efficient use of the CPU resources available on your cluster Nodes. By keeping a Pod CPU request low, you give the Pod a good chance of being scheduled. By having a CPU limit that is greater than the CPU request, you accomplish two things:

- The Pod can have bursts of activity where it makes use of CPU resources that happen to be available.
- The amount of CPU resources a Pod can use during a burst is limited to some reasonable amount.

## Clean up

Delete your namespace:

```
kubectl delete namespace cpu-example
```

# Configure GMSA for Windows Pods and containers

FEATURE STATE: Kubernetes v1.18 [stable]

This page shows how to configure [Group Managed Service Accounts](#) (GMSA) for Pods and containers that will run on Windows nodes. Group Managed Service Accounts are a specific type of Active Directory account that provides automatic password management, simplified service principal name (SPN) management, and the ability to delegate the management to other administrators across multiple servers.

In Kubernetes, GMSA credential specs are configured at a Kubernetes cluster-wide scope as Custom Resources. Windows Pods, as well as individual containers within a Pod, can be configured to use a GMSA for domain based functions (e.g. Kerberos authentication) when interacting with other Windows services.

## Before you begin

You need to have a Kubernetes cluster and the `kubectl` command-line tool must be configured to communicate with your cluster. The cluster is expected to have Windows worker nodes. This section covers a set of initial steps required once for each cluster:

### Install the `GMSACredentialSpec` CRD

A [CustomResourceDefinition](#) (CRD) for GMSA credential spec resources needs to be configured on the cluster to define the custom resource type `GMSACredentialSpec`. Download the GMSA CRD [YAML](#) and save it as `gmsa-crd.yaml`. Next, install the CRD with `kubectl apply -f gmsa-crd.yaml`

### Install webhooks to validate GMSA users

Two webhooks need to be configured on the Kubernetes cluster to populate and validate GMSA credential spec references at the Pod or container level:

1. A mutating webhook that expands references to GMSAs (by name from a Pod specification) into the full credential spec in JSON form within the Pod spec.

- A validating webhook ensures all references to GSAs are authorized to be used by the
2. Pod service account.

Installing the above webhooks and associated objects require the steps below:

1. Create a certificate key pair (that will be used to allow the webhook container to communicate to the cluster)
2. Install a secret with the certificate from above.
3. Create a deployment for the core webhook logic.
4. Create the validating and mutating webhook configurations referring to the deployment.

A [script](#) can be used to deploy and configure the GSA webhooks and associated objects mentioned above. The script can be run with a `--dry-run=server` option to allow you to review the changes that would be made to your cluster.

The [YAML template](#) used by the script may also be used to deploy the webhooks and associated objects manually (with appropriate substitutions for the parameters)

## Configure GSAs and Windows nodes in Active Directory

Before Pods in Kubernetes can be configured to use GSAs, the desired GSAs need to be provisioned in Active Directory as described in the [Windows GSA documentation](#). Windows worker nodes (that are part of the Kubernetes cluster) need to be configured in Active Directory to access the secret credentials associated with the desired GSA as described in the [Windows GSA documentation](#).

## Create GSA credential spec resources

With the GSACredentialSpec CRD installed (as described earlier), custom resources containing GSA credential specs can be configured. The GSA credential spec does not contain secret or sensitive data. It is information that a container runtime can use to describe the desired GSA of a container to Windows. GSA credential specs can be generated in YAML format with a utility [PowerShell script](#).

Following are the steps for generating a GSA credential spec YAML manually in JSON format and then converting it:

1. Import the CredentialSpec [module](#): `ipmo CredentialSpec.psm1`
2. Create a credential spec in JSON format using `New-CredentialSpec`. To create a GSA credential spec named `WebApp1`, invoke `New-CredentialSpec -Name WebApp1 -AccountName WebApp1 -Domain $(Get-AddDomain -Current LocalComputer)`
3. Use `Get-CredentialSpec` to show the path of the JSON file.
4. Convert the credspec file from JSON to YAML format and apply the necessary header fields `apiVersion`, `kind`, `metadata` and `credspec` to make it a `GSACredentialSpec` custom resource that can be configured in Kubernetes.

The following YAML configuration describes a GMSA credential spec named gmsa-WebApp1:

```
apiVersion: windows.k8s.io/v1
kind: GMSACredentialSpec
metadata:
 name: gmsa-WebApp1 # This is an arbitrary name but it will be used as a reference
credspec:
 ActiveDirectoryConfig:
 GroupManagedServiceAccounts:
 - Name: WebApp1 # Username of the GMSA account
 Scope: CONTOSO # NETBIOS Domain Name
 - Name: WebApp1 # Username of the GMSA account
 Scope: contoso.com # DNS Domain Name
 CmsPlugins:
 - ActiveDirectory
 DomainJoinConfig:
 DnsName: contoso.com # DNS Domain Name
 DnsTreeName: contoso.com # DNS Domain Name Root
 Guid: 244818ae-87ac-4fcd-92ec-e79e5252348a # GUID
 MachineAccountName: WebApp1 # Username of the GMSA account
 NetBiosName: CONTOSO # NETBIOS Domain Name
 Sid: S-1-5-21-2126449477-2524075714-3094792973 # SID of GMSA
```

The above credential spec resource may be saved as gmsa-Webapp1-credspec.yaml and applied to the cluster using: `kubectl apply -f gmsa-Webapp1-credspec.yml`

## Configure cluster role to enable RBAC on specific GMSA credential specs

A cluster role needs to be defined for each GMSA credential spec resource. This authorizes the use verb on a specific GMSA resource by a subject which is typically a service account. The following example shows a cluster role that authorizes usage of the gmsa-WebApp1 credential spec from above. Save the file as gmsa-webapp1-role.yaml and apply using `kubectl apply -f gmsa-webapp1-role.yaml`

```
Create the Role to read the credspec
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
 name: webapp1-role
rules:
- apiGroups: ["windows.k8s.io"]
 resources: ["gmsacredentialspecs"]
 verbs: ["use"]
 resourceNames: ["gmsa-WebApp1"]
```

## Assign role to service accounts to use specific GMSA credspecs

A service account (that Pods will be configured with) needs to be bound to the cluster role create above. This authorizes the service account to use the desired GMSA credential spec

resource. The following shows the default service account being bound to a cluster role webapp1-role to use gmsa-WebApp1 credential spec resource created above.

```
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
metadata:
 name: allow-default-svc-account-read-on-gmsa-WebApp1
 namespace: default
subjects:
- kind: ServiceAccount
 name: default
 namespace: default
roleRef:
 kind: ClusterRole
 name: webapp1-role
 apiGroup: rbac.authorization.k8s.io
```

## Configure GMSA credential spec reference in Pod spec

The Pod spec field `securityContext.windowsOptions.gmsaCredentialSpecName` is used to specify references to desired GMSA credential spec custom resources in Pod specs. This configures all containers in the Pod spec to use the specified GMSA. A sample Pod spec with the annotation populated to refer to gmsa-WebApp1:

```
apiVersion: apps/v1
kind: Deployment
metadata:
 labels:
 run: with-creds
 name: with-creds
 namespace: default
spec:
 replicas: 1
 selector:
 matchLabels:
 run: with-creds
 template:
 metadata:
 labels:
 run: with-creds
 spec:
 securityContext:
 windowsOptions:
 gmsaCredentialSpecName: gmsa-webapp1
 containers:
 - image: mcr.microsoft.com/windows/servercore/iis:windowsservercore-ltsc2019
 imagePullPolicy: Always
 name: iis
 nodeSelector:
 kubernetes.io/os: windows
```

Individual containers in a Pod spec can also specify the desired GMSA credspec using a per-container securityContext.windowsOptions.gmsaCredentialSpecName field. For example:

```
apiVersion: apps/v1
kind: Deployment
metadata:
 labels:
 run: with-creds
 name: with-creds
 namespace: default
spec:
 replicas: 1
 selector:
 matchLabels:
 run: with-creds
 template:
 metadata:
 labels:
 run: with-creds
 spec:
 containers:
 - image: mcr.microsoft.com/windows/servercore/iis:windowsservercore-ltsc2019
 imagePullPolicy: Always
 name: iis
 securityContext:
 windowsOptions:
 gmsaCredentialSpecName: gmsa-Webapp1
 nodeSelector:
 kubernetes.io/os: windows
```

As Pod specs with GMSA fields populated (as described above) are applied in a cluster, the following sequence of events take place:

1. The mutating webhook resolves and expands all references to GMSA credential spec resources to the contents of the GMSA credential spec.
2. The validating webhook ensures the service account associated with the Pod is authorized for the use verb on the specified GMSA credential spec.
3. The container runtime configures each Windows container with the specified GMSA credential spec so that the container can assume the identity of the GMSA in Active Directory and access services in the domain using that identity.

## Authenticating to network shares using hostname or FQDN

If you are experiencing issues connecting to SMB shares from Pods using hostname or FQDN, but are able to access the shares via their IPv4 address then make sure the following registry key is set on the Windows nodes.

```
reg add "HKLM\SYSTEM\CurrentControlSet\Services\hns\State" /v
EnableCompartmentNamespace /t REG_DWORD /d 1
```

Running Pods will then need to be recreated to pick up the behavior changes. More information on how this registry key is used can be found [here](#)

## Troubleshooting

If you are having difficulties getting GMSA to work in your environment, there are a few troubleshooting steps you can take.

First, make sure the credspec has been passed to the Pod. To do this you will need to exec into one of your Pods and check the output of the `nltest.exe /parentdomain` command.

In the example below the Pod did not get the credspec correctly:

```
kubect exec -it iis-auth-7776966999-n5nzs powershell.exe
```

`nltest.exe /parentdomain` results in the following error:

```
Getting parent domain failed: Status = 1722 0x6ba RPC_S_SERVER_UNAVAILABLE
```

If your Pod did get the credspec correctly, then next check communication with the domain. First, from inside of your Pod, quickly do an `nslookup` to find the root of your domain.

This will tell us 3 things:

1. The Pod can reach the DC
2. The DC can reach the Pod
3. DNS is working correctly.

If the DNS and communication test passes, next you will need to check if the Pod has established secure channel communication with the domain. To do this, again, exec into your Pod and run the `nltest.exe /query` command.

```
nltest.exe /query
```

Results in the following output:

```
I_NetLogonControl failed: Status = 1722 0x6ba RPC_S_SERVER_UNAVAILABLE
```

This tells us that for some reason, the Pod was unable to logon to the domain using the account specified in the credspec. You can try to repair the secure channel by running the following:

```
nltest /sc_reset:domain.example
```

If the command is successful you will see an output similar to this:

```
Flags: 30 HAS_IP HAS_TIMESERV
Trusted DC Name \\dc10.domain.example
Trusted DC Connection Status Status = 0 0x0 NERR_Success
The command completed successfully
```

If the above corrects the error, you can automate the step by adding the following lifecycle hook to your Pod spec. If it did not correct the error, you will need to examine your credspec again and confirm that it is correct and complete.

```
image: registry.domain.example/iis-auth:1809v1
lifecycle:
 postStart:
 exec:
 command: ["powershell.exe","-command","do { Restart-Service -Name netlogon } while
($($Result = (nltest.exe /query)); if ($Result -like '*0x0 NERR_Success*') {return $true} else
{return $false}) -eq $false)"]
 imagePullPolicy: IfNotPresent
```

If you add the lifecycle section shown above to your Pod spec, the Pod will execute the commands listed to restart the netlogon service until the `nltest.exe /query` command exits without error.

## Resize CPU and Memory Resources assigned to Containers

FEATURE STATE: Kubernetes v1.27 [alpha]

This page assumes that you are familiar with [Quality of Service](#) for Kubernetes Pods.

This page shows how to resize CPU and memory resources assigned to containers of a running pod without restarting the pod or its containers. A Kubernetes node allocates resources for a pod based on its requests, and restricts the pod's resource usage based on the limits specified in the pod's containers.

Changing the resource allocation for a running Pod requires the `InPlacePodVerticalScaling` [feature gate](#) to be enabled. The alternative is to delete the Pod and let the [workload controller](#) make a replacement Pod that has a different resource requirement.

For in-place resize of pod resources:

- Container's resource requests and limits are *mutable* for CPU and memory resources.
- `allocatedResources` field in `containerStatuses` of the Pod's status reflects the resources allocated to the pod's containers.
- `resources` field in `containerStatuses` of the Pod's status reflects the actual resource requests and limits that are configured on the running containers as reported by the container runtime.
- `resize` field in the Pod's status shows the status of the last requested pending resize. It can have the following values:
  - `Proposed`: This value indicates an acknowledgement of the requested resize and that the request was validated and recorded.
  - `InProgress`: This value indicates that the node has accepted the resize request and is in the process of applying it to the pod's containers.
  - `Deferred`: This value means that the requested resize cannot be granted at this time, and the node will keep retrying. The resize may be granted when other pods leave and free up node resources.
  - `Infeasible`: is a signal that the node cannot accommodate the requested resize. This can happen if the requested resize exceeds the maximum resources the node can ever allocate for a pod.

### Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version 1.27. To check the version, enter kubectl version.

The InPlacePodVerticalScaling [feature gate](#) must be enabled for your control plane and for all nodes in your cluster.

## Container Resize Policies

Resize policies allow for a more fine-grained control over how pod's containers are resized for CPU and memory resources. For example, the container's application may be able to handle CPU resources resized without being restarted, but resizing memory may require that the application hence the containers be restarted.

To enable this, the Container specification allows users to specify a `resizePolicy`. The following restart policies can be specified for resizing CPU and memory:

- `NotRequired`: Resize the container's resources while it is running.
- `RestartContainer`: Restart the container and apply new resources upon restart.

If `resizePolicy[*].restartPolicy` is not specified, it defaults to `NotRequired`.

### Note:

If the Pod's `restartPolicy` is `Never`, container's resize restart policy must be set to `NotRequired` for all Containers in the Pod.

Below example shows a Pod whose Container's CPU can be resized without restart, but resizing memory requires the container to be restarted.

```
apiVersion: v1
kind: Pod
metadata:
 name: qos-demo-5
 namespace: qos-example
spec:
 containers:
 - name: qos-demo-ctr-5
 image: nginx
 resizePolicy:
 - resourceName: cpu
 restartPolicy: NotRequired
 - resourceName: memory
 restartPolicy: RestartContainer
 resources:
 limits:
```

```
memory: "200Mi"
cpu: "700m"
requests:
 memory: "200Mi"
 cpu: "700m"
```

**Note:**

In the above example, if desired requests or limits for both CPU *and* memory have changed, the container will be restarted in order to resize its memory.

## Create a pod with resource requests and limits

You can create a Guaranteed or Burstable [Quality of Service](#) class pod by specifying requests and/or limits for a pod's containers.

Consider the following manifest for a Pod that has one Container.

[pods/qos/qos-pod-5.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: qos-demo-5
 namespace: qos-example
spec:
 containers:
 - name: qos-demo-ctr-5
 image: nginx
 resources:
 limits:
 memory: "200Mi"
 cpu: "700m"
 requests:
 memory: "200Mi"
 cpu: "700m"
```

Create the pod in the qos-example namespace:

```
kubectl create namespace qos-example
kubectl create -f https://k8s.io/examples/pods/qos/qos-pod-5.yaml
```

This pod is classified as a Guaranteed QoS class requesting 700m CPU and 200Mi memory.

View detailed information about the pod:

```
kubectl get pod qos-demo-5 --output=yaml --namespace=qos-example
```

Also notice that the values of `resizePolicy[*].restartPolicy` defaulted to `NotRequired`, indicating that CPU and memory can be resized while container is running.

```
spec:
 containers:
```

```

...
resizePolicy:
- resourceName: cpu
 restartPolicy: NotRequired
- resourceName: memory
 restartPolicy: NotRequired
resources:
 limits:
 cpu: 700m
 memory: 200Mi
 requests:
 cpu: 700m
 memory: 200Mi
...
containerStatuses:
...
 name: qos-demo-ctr-5
 ready: true
...
 allocatedResources:
 cpu: 700m
 memory: 200Mi
 resources:
 limits:
 cpu: 700m
 memory: 200Mi
 requests:
 cpu: 700m
 memory: 200Mi
 restartCount: 0
 started: true
...
qosClass: Guaranteed

```

## Updating the pod's resources

Let's say the CPU requirements have increased, and 0.8 CPU is now desired. This may be specified manually, or determined and programmatically applied by an entity such as [VerticalPodAutoscaler](#) (VPA).

### Note:

While you can change a Pod's requests and limits to express new desired resources, you cannot change the QoS class in which the Pod was created.

Now, patch the Pod's Container with CPU requests & limits both set to 800m:

```
kubectrl -n qos-example patch pod qos-demo-5 --patch '{"spec":{"containers":[{"name":"qos-demo-ctr-5", "resources":{"requests":{"cpu":"800m"}, "limits":{"cpu":"800m"}}}]}'
```

Query the Pod's detailed information after the Pod has been patched.

```
kubectl get pod qos-demo-5 --output=yaml --namespace=qos-example
```

The Pod's spec below reflects the updated CPU requests and limits.

```
spec:
 containers:
 ...
 resources:
 limits:
 cpu: 800m
 memory: 200Mi
 requests:
 cpu: 800m
 memory: 200Mi
 ...
 containerStatuses:
 ...
 allocatedResources:
 cpu: 800m
 memory: 200Mi
 resources:
 limits:
 cpu: 800m
 memory: 200Mi
 requests:
 cpu: 800m
 memory: 200Mi
 restartCount: 0
 started: true
```

Observe that the `allocatedResources` values have been updated to reflect the new desired CPU requests. This indicates that node was able to accommodate the increased CPU resource needs.

In the Container's status, updated CPU resource values shows that new CPU resources have been applied. The Container's `restartCount` remains unchanged, indicating that container's CPU resources were resized without restarting the container.

## Clean up

Delete your namespace:

```
kubectl delete namespace qos-example
```

# Configure RunAsUserName for Windows pods and containers

FEATURE STATE: Kubernetes v1.18 [stable]

This page shows how to use the `runAsUserName` setting for Pods and containers that will run on Windows nodes. This is roughly equivalent of the Linux-specific `runAsUser` setting, allowing you to run applications in a container as a different username than the default.

## Before you begin

You need to have a Kubernetes cluster and the `kubectl` command-line tool must be configured to communicate with your cluster. The cluster is expected to have Windows worker nodes where pods with containers running Windows workloads will get scheduled.

## Set the Username for a Pod

To specify the username with which to execute the Pod's container processes, include the `securityContext` field ([PodSecurityContext](#)) in the Pod specification, and within it, the `windowsOptions` ([WindowsSecurityContextOptions](#)) field containing the `runAsUserName` field.

The Windows security context options that you specify for a Pod apply to all Containers and init Containers in the Pod.

Here is a configuration file for a Windows Pod that has the `runAsUserName` field set:

[windows/run-as-username-pod.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: run-as-username-pod-demo
spec:
 securityContext:
 windowsOptions:
 runAsUserName: "ContainerUser"
 containers:
 - name: run-as-username-demo
```

```
image: mcr.microsoft.com/windows/servercore:ltsc2019
command: ["ping", "-t", "localhost"]
nodeSelector:
 kubernetes.io/os: windows
```

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/windows/run-as-username-pod.yaml
```

Verify that the Pod's Container is running:

```
kubectl get pod run-as-username-pod-demo
```

Get a shell to the running Container:

```
kubectl exec -it run-as-username-pod-demo -- powershell
```

Check that the shell is running user the correct username:

```
echo $env:USERNAME
```

The output should be:

```
ContainerUser
```

## Set the Username for a Container

To specify the username with which to execute a Container's processes, include the `securityContext` field ([SecurityContext](#)) in the Container manifest, and within it, the `windowsOptions` ([WindowsSecurityContextOptions](#)) field containing the `runAsUserName` field.

The Windows security context options that you specify for a Container apply only to that individual Container, and they override the settings made at the Pod level.

Here is the configuration file for a Pod that has one Container, and the `runAsUserName` field is set at the Pod level and the Container level:

[windows/run-as-username-container.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: run-as-username-container-demo
spec:
 securityContext:
 windowsOptions:
 runAsUserName: "ContainerUser"
 containers:
 - name: run-as-username-demo
 image: mcr.microsoft.com/windows/servercore:ltsc2019
 command: ["ping", "-t", "localhost"]
 securityContext:
 windowsOptions:
 runAsUserName: "ContainerAdministrator"
```

```
nodeSelector:
 kubernetes.io/os: windows
```

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/windows/run-as-username-container.yaml
```

Verify that the Pod's Container is running:

```
kubectl get pod run-as-username-container-demo
```

Get a shell to the running Container:

```
kubectl exec -it run-as-username-container-demo -- powershell
```

Check that the shell is running user the correct username (the one set at the Container level):

```
echo $env:USERNAME
```

The output should be:

```
ContainerAdministrator
```

## Windows Username limitations

In order to use this feature, the value set in the `runAsUserName` field must be a valid username. It must have the following format: `DOMAIN\USER`, where `DOMAIN\` is optional. Windows user names are case insensitive. Additionally, there are some restrictions regarding the `DOMAIN` and `USER`:

- The `runAsUserName` field cannot be empty, and it cannot contain control characters (ASCII values: 0x00-0x1F, 0x7F)
- The `DOMAIN` must be either a NetBios name, or a DNS name, each with their own restrictions:
  - NetBios names: maximum 15 characters, cannot start with `.` (dot), and cannot contain the following characters: `\ / : * ? " < > |`
  - DNS names: maximum 255 characters, contains only alphanumeric characters, dots, and dashes, and it cannot start or end with a `.` (dot) or `-` (dash).
- The `USER` must have at most 20 characters, it cannot contain *only* dots or spaces, and it cannot contain the following characters: `" / \ [ ] : ; | = , + * ? < > @`.

Examples of acceptable values for the `runAsUserName` field: `ContainerAdministrator`, `ContainerUser`, `NT AUTHORITY\NETWORK SERVICE`, `NT AUTHORITY\LOCAL SERVICE`.

For more information about these limitations, check [here](#) and [here](#).

- [Configure GMSA for Windows pods and containers](#)

# Create a Windows HostProcess Pod

FEATURE STATE: Kubernetes v1.26 [stable]

Windows HostProcess containers enable you to run containerized workloads on a Windows host. These containers operate as normal processes but have access to the host network namespace, storage, and devices when given the appropriate user privileges. HostProcess containers can be used to deploy network plugins, storage configurations, device plugins, kube-proxy, and other components to Windows nodes without the need for dedicated proxies or the direct installation of host services.

Administrative tasks such as installation of security patches, event log collection, and more can be performed without requiring cluster operators to log onto each Windows node. HostProcess containers can run as any user that is available on the host or is in the domain of the host machine, allowing administrators to restrict resource access through user permissions. While neither filesystem or process isolation are supported, a new volume is created on the host upon starting the container to give it a clean and consolidated workspace. HostProcess containers can also be built on top of existing Windows base images and do not inherit the same [compatibility requirements](#) as Windows server containers, meaning that the version of the base images does not need to match that of the host. It is, however, recommended that you use the same base image version as your Windows Server container workloads to ensure you do not have any unused images taking up space on the node. HostProcess containers also support [volume mounts](#) within the container volume.

## When should I use a Windows HostProcess container?

- When you need to perform tasks which require the networking namespace of the host. HostProcess containers have access to the host's network interfaces and IP addresses.
- You need access to resources on the host such as the filesystem, event logs, etc.
- Installation of specific device drivers or Windows services.
- Consolidation of administrative tasks and security policies. This reduces the degree of privileges needed by Windows nodes.

## Before you begin

This task guide is specific to Kubernetes v1.30. If you are not running Kubernetes v1.30, check the documentation for that version of Kubernetes.

In Kubernetes 1.30, the HostProcess container feature is enabled by default. The kubelet will communicate with containerd directly by passing the hostprocess flag via CRI. You can use the latest version of containerd (v1.6+) to run HostProcess containers. [How to install containerd.](#)

## Limitations

These limitations are relevant for Kubernetes v1.30:

- HostProcess containers require containerd 1.6 or higher [container runtime](#) and containerd 1.7 is recommended.
- HostProcess pods can only contain HostProcess containers. This is a current limitation of the Windows OS; non-privileged Windows containers cannot share a vNIC with the host IP namespace.

- HostProcess containers run as a process on the host and do not have any degree of isolation other than resource constraints imposed on the HostProcess user account. Neither filesystem or Hyper-V isolation are supported for HostProcess containers.
- Volume mounts are supported and are mounted under the container volume. See [Volume Mounts](#)
- A limited set of host user accounts are available for HostProcess containers by default. See [Choosing a User Account](#).
- Resource limits (disk, memory, cpu count) are supported in the same fashion as processes on the host.
- Both Named pipe mounts and Unix domain sockets are **not** supported and should instead be accessed via their path on the host (e.g. \\.\pipe\\*)

## HostProcess Pod configuration requirements

Enabling a Windows HostProcess pod requires setting the right configurations in the pod security configuration. Of the policies defined in the [Pod Security Standards](#) HostProcess pods are disallowed by the baseline and restricted policies. It is therefore recommended that HostProcess pods run in alignment with the privileged profile.

When running under the privileged policy, here are the configurations which need to be set to enable the creation of a HostProcess pod:

Privileged policy specification

| Control                                                      | Policy                                                                                                                                                                                                                                                                                                                                  |
|--------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

## Example manifest (excerpt)

```
spec:
 securityContext:
 windowsOptions:
 hostProcess: true
 runAsUserName: "NT AUTHORITY\\Local service"
 hostNetwork: true
 containers:
 - name: test
 image: image1:latest
 command:
 - ping
 - -t
 - 127.0.0.1
 nodeSelector:
 "kubernetes.io/os": windows
```

## Volume mounts

HostProcess containers support the ability to mount volumes within the container volume space. Volume mount behavior differs depending on the version of containerd runtime used by on the node.

### Containerd v1.6

Applications running inside the container can access volume mounts directly via relative or absolute paths. An environment variable `$CONTAINER_SANDBOX_MOUNT_POINT` is set upon container creation and provides the absolute host path to the container volume. Relative paths are based upon the `.spec.containers.volumeMounts.mountPath` configuration.

To access service account tokens (for example) the following path structures are supported within the container:

- `.\var\run\secrets\kubernetes.io\serviceaccount\`
- `$CONTAINER_SANDBOX_MOUNT_POINT\var\run\secrets\kubernetes.io\serviceaccount\`

## Containerd v1.7 (and greater)

Applications running inside the container can access volume mounts directly via the volumeMount's specified mountPath (just like Linux and non-HostProcess Windows containers).

For backwards compatibility volumes can also be accessed via using the same relative paths configured by containerd v1.6.

As an example, to access service account tokens within the container you would use one of the following paths:

- c:\var\run\secrets\kubernetes.io\serviceaccount
- /var/run/secrets/kubernetes.io/serviceaccount/
- \$CONTAINER\_SANDBOX\_MOUNT\_POINT\var\run\secrets\kubernetes.io\serviceaccount\

## Resource limits

Resource limits (disk, memory, cpu count) are applied to the job and are job wide. For example, with a limit of 10MB set, the memory allocated for any HostProcess job object will be capped at 10MB. This is the same behavior as other Windows container types. These limits would be specified the same way they are currently for whatever orchestrator or runtime is being used. The only difference is in the disk resource usage calculation used for resource tracking due to the difference in how HostProcess containers are bootstrapped.

## Choosing a user account

### System accounts

By default, HostProcess containers support the ability to run as one of three supported Windows service accounts:

- [LocalSystem](#)
- [LocalService](#)
- [NetworkService](#)

You should select an appropriate Windows service account for each HostProcess container, aiming to limit the degree of privileges so as to avoid accidental (or even malicious) damage to the host. The LocalSystem service account has the highest level of privilege of the three and should be used only if absolutely necessary. Where possible, use the LocalService service account as it is the least privileged of the three options.

### Local accounts

If configured, HostProcess containers can also run as local user accounts which allows for node operators to give fine-grained access to workloads.

To run HostProcess containers as a local user; A local usergroup must first be created on the node and the name of that local usergroup must be specified in the runAsUserName field in the deployment. Prior to initializing the HostProcess container, a new **ephemeral** local user account to be created and joined to the specified usergroup, from which the container is run.

This provides a number a benefits including eliminating the need to manage passwords for local user accounts. An initial HostProcess container running as a service account can be used to prepare the user groups for later HostProcess containers.

**Note:**

Running HostProcess containers as local user accounts requires containerd v1.7+

Example:

1. Create a local user group on the node (this can be done in another HostProcess container).

```
net localgroup hpc-localgroup /add
```

2. Grant access to desired resources on the node to the local usergroup. This can be done with tools like [icacis](#).
3. Set runAsUserName to the name of the local usergroup for the pod or individual containers.

```
securityContext:
 windowsOptions:
 hostProcess: true
 runAsUserName: hpc-localgroup
```

4. Schedule the pod!

## Base Image for HostProcess Containers

HostProcess containers can be built from any of the existing [Windows Container base images](#).

Additionally a new base mage has been created just for HostProcess containers! For more information please check out the [windows-host-process-containers-base-image github project](#).

## Troubleshooting HostProcess containers

- HostProcess containers fail to start with failed to create user process token: failed to logon user: Access is denied.: unknown

Ensure containerd is running as LocalSystem or LocalService service accounts. User accounts (even Administrator accounts) do not have permissions to create logon tokens for any of the supported [user accounts](#).

## Configure Quality of Service for Pods

This page shows how to configure Pods so that they will be assigned particular [Quality of Service \(QoS\) classes](#). Kubernetes uses QoS classes to make decisions about evicting Pods when Node resources are exceeded.

When Kubernetes creates a Pod it assigns one of these QoS classes to the Pod:

- [Guaranteed](#)
- [Burstable](#)
- [BestEffort](#)

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

You also need to be able to create and delete namespaces.

## Create a namespace

Create a namespace so that the resources you create in this exercise are isolated from the rest of your cluster.

```
kubectl create namespace qos-example
```

## Create a Pod that gets assigned a QoS class of Guaranteed

For a Pod to be given a QoS class of Guaranteed:

- Every Container in the Pod must have a memory limit and a memory request.
- For every Container in the Pod, the memory limit must equal the memory request.
- Every Container in the Pod must have a CPU limit and a CPU request.
- For every Container in the Pod, the CPU limit must equal the CPU request.

These restrictions apply to init containers and app containers equally. [Ephemeral containers](#) cannot define resources so these restrictions do not apply.

Here is a manifest for a Pod that has one Container. The Container has a memory limit and a memory request, both equal to 200 MiB. The Container has a CPU limit and a CPU request, both equal to 700 milliCPU:

[pods/qos/qos-pod.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: qos-demo
 namespace: qos-example
spec:
 containers:
 - name: qos-demo-ctr
 image: nginx
```

```
resources:
 limits:
 memory: "200Mi"
 cpu: "700m"
 requests:
 memory: "200Mi"
 cpu: "700m"
```

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/qos/qos-pod.yaml --namespace=qos-example
```

View detailed information about the Pod:

```
kubectl get pod qos-demo --namespace=qos-example --output=yaml
```

The output shows that Kubernetes gave the Pod a QoS class of Guaranteed. The output also verifies that the Pod Container has a memory request that matches its memory limit, and it has a CPU request that matches its CPU limit.

```
spec:
 containers:
 ...
 resources:
 limits:
 cpu: 700m
 memory: 200Mi
 requests:
 cpu: 700m
 memory: 200Mi
 ...
status:
 qosClass: Guaranteed
```

### Note:

If a Container specifies its own memory limit, but does not specify a memory request, Kubernetes automatically assigns a memory request that matches the limit. Similarly, if a Container specifies its own CPU limit, but does not specify a CPU request, Kubernetes automatically assigns a CPU request that matches the limit.

### Clean up

Delete your Pod:

```
kubectl delete pod qos-demo --namespace=qos-example
```

## Create a Pod that gets assigned a QoS class of Burstable

A Pod is given a QoS class of Burstable if:

- The Pod does not meet the criteria for QoS class Guaranteed.

- At least one Container in the Pod has a memory or CPU request or limit.

Here is a manifest for a Pod that has one Container. The Container has a memory limit of 200 MiB and a memory request of 100 MiB.

[pods/qos/qos-pod-2.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: qos-demo-2
 namespace: qos-example
spec:
 containers:
 - name: qos-demo-2-ctr
 image: nginx
 resources:
 limits:
 memory: "200Mi"
 requests:
 memory: "100Mi"
```

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/qos/qos-pod-2.yaml --namespace=qos-example
```

View detailed information about the Pod:

```
kubectl get pod qos-demo-2 --namespace=qos-example --output=yaml
```

The output shows that Kubernetes gave the Pod a QoS class of Burstable:

```
spec:
 containers:
 - image: nginx
 imagePullPolicy: Always
 name: qos-demo-2-ctr
 resources:
 limits:
 memory: 200Mi
 requests:
 memory: 100Mi
 ...
status:
 qosClass: Burstable
```

## Clean up

Delete your Pod:

```
kubectl delete pod qos-demo-2 --namespace=qos-example
```

## Create a Pod that gets assigned a QoS class of BestEffort

For a Pod to be given a QoS class of BestEffort, the Containers in the Pod must not have any memory or CPU limits or requests.

Here is a manifest for a Pod that has one Container. The Container has no memory or CPU limits or requests:

[pods/qos/qos-pod-3.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: qos-demo-3
 namespace: qos-example
spec:
 containers:
 - name: qos-demo-3-ctr
 image: nginx
```

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/qos/qos-pod-3.yaml --namespace=qos-example
```

View detailed information about the Pod:

```
kubectl get pod qos-demo-3 --namespace=qos-example --output=yaml
```

The output shows that Kubernetes gave the Pod a QoS class of BestEffort:

```
spec:
 containers:
 ...
 resources: {}
 ...
status:
 qosClass: BestEffort
```

### Clean up

Delete your Pod:

```
kubectl delete pod qos-demo-3 --namespace=qos-example
```

## Create a Pod that has two Containers

Here is a manifest for a Pod that has two Containers. One container specifies a memory request of 200 MiB. The other Container does not specify any requests or limits.

[pods/qos/qos-pod-4.yaml](#)

```
apiVersion: v1
kind: Pod
```

```
metadata:
 name: qos-demo-4
 namespace: qos-example
spec:
 containers:

 - name: qos-demo-4-ctr-1
 image: nginx
 resources:
 requests:
 memory: "200Mi"

 - name: qos-demo-4-ctr-2
 image: redis
```

Notice that this Pod meets the criteria for QoS class Burstable. That is, it does not meet the criteria for QoS class Guaranteed, and one of its Containers has a memory request.

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/qos/qos-pod-4.yaml --namespace=qos-example
```

View detailed information about the Pod:

```
kubectl get pod qos-demo-4 --namespace=qos-example --output=yaml
```

The output shows that Kubernetes gave the Pod a QoS class of Burstable:

```
spec:
 containers:
 ...
 name: qos-demo-4-ctr-1
 resources:
 requests:
 memory: 200Mi
 ...
 name: qos-demo-4-ctr-2
 resources: {}
 ...
status:
 qosClass: Burstable
```

## Retrieve the QoS class for a Pod

Rather than see all the fields, you can view just the field you need:

```
kubectl --namespace=qos-example get pod qos-demo-4 -o jsonpath='{.status.qosClass}'
```

Burstable

## Clean up

Delete your namespace:

```
kubectl delete namespace qos-example
```

# Assign Extended Resources to a Container

FEATURE STATE: Kubernetes v1.30 [stable]

This page shows how to assign extended resources to a Container.

## Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

Before you do this exercise, do the exercise in [Advertise Extended Resources for a Node](#). That will configure one of your Nodes to advertise a dongle resource.

## Assign an extended resource to a Pod

To request an extended resource, include the `resources:requests` field in your Container manifest. Extended resources are fully qualified with any domain outside of `*.kubernetes.io/`. Valid extended resource names have the form `example.com/foo` where `example.com` is replaced with your organization's domain and `foo` is a descriptive resource name.

Here is the configuration file for a Pod that has one Container:

[pods/resource/extended-resource-pod.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: extended-resource-demo
spec:
 containers:
 - name: extended-resource-demo-ctr
 image: nginx
 resources:
 requests:
 example.com/dongle: 3
 limits:
 example.com/dongle: 3
```

In the configuration file, you can see that the Container requests 3 dongles.

Create a Pod:

```
kubectl apply -f https://k8s.io/examples/pods/resource/extended-resource-pod.yaml
```

Verify that the Pod is running:

```
kubectl get pod extended-resource-demo
```

Describe the Pod:

```
kubectl describe pod extended-resource-demo
```

The output shows dongle requests:

```
Limits:
 example.com/dongle: 3
Requests:
 example.com/dongle: 3
```

## Attempt to create a second Pod

Here is the configuration file for a Pod that has one Container. The Container requests two dongles.

[pods/resource/extended-resource-pod-2.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: extended-resource-demo-2
spec:
 containers:
 - name: extended-resource-demo-2-ctr
 image: nginx
 resources:
 requests:
 example.com/dongle: 2
 limits:
 example.com/dongle: 2
```

Kubernetes will not be able to satisfy the request for two dongles, because the first Pod used three of the four available dongles.

Attempt to create a Pod:

```
kubectl apply -f https://k8s.io/examples/pods/resource/extended-resource-pod-2.yaml
```

Describe the Pod

```
kubectl describe pod extended-resource-demo-2
```

The output shows that the Pod cannot be scheduled, because there is no Node that has 2 dongles available:

```
Conditions:
 Type Status
 PodScheduled False
...
Events:
 ...
 ... Warning FailedScheduling pod (extended-resource-demo-2) failed to fit in any node
fit failure summary on nodes : Insufficient example.com/dongle (1)
```

View the Pod status:

```
kubectl get pod extended-resource-demo-2
```

The output shows that the Pod was created, but not scheduled to run on a Node. It has a status of Pending:

| NAME                     | READY | STATUS  | RESTARTS | AGE |
|--------------------------|-------|---------|----------|-----|
| extended-resource-demo-2 | 0/1   | Pending | 0        | 6m  |

## Clean up

Delete the Pods that you created for this exercise:

```
kubectl delete pod extended-resource-demo
kubectl delete pod extended-resource-demo-2
```

## What's next

# Configure a Pod to Use a Volume for Storage

This page shows how to configure a Pod to use a Volume for storage.

A Container's file system lives only as long as the Container does. So when a Container terminates and restarts, filesystem changes are lost. For more consistent storage that is independent of the Container, you can use a [Volume](#). This is especially important for stateful applications, such as key-value stores (such as Redis) and databases.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

## Configure a volume for a Pod

In this exercise, you create a Pod that runs one Container. This Pod has a Volume of type [emptyDir](#) that lasts for the life of the Pod, even if the Container terminates and restarts. Here is the configuration file for the Pod:

[pods/storage/redis.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: redis
spec:
 containers:
 - name: redis
 image: redis
```

```
volumeMounts:
- name: redis-storage
 mountPath: /data/redis
volumes:
- name: redis-storage
 emptyDir: {}
```

1. Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/storage/redis.yaml
```

2. Verify that the Pod's Container is running, and then watch for changes to the Pod:

```
kubectl get pod redis --watch
```

The output looks like this:

| NAME  | READY | STATUS  | RESTARTS | AGE |
|-------|-------|---------|----------|-----|
| redis | 1/1   | Running | 0        | 13s |

3. In another terminal, get a shell to the running Container:

```
kubectl exec -it redis -- /bin/bash
```

4. In your shell, go to /data/redis, and then create a file:

```
root@redis:/data# cd /data/redis/
root@redis:/data/redis# echo Hello > test-file
```

5. In your shell, list the running processes:

```
root@redis:/data/redis# apt-get update
root@redis:/data/redis# apt-get install procps
root@redis:/data/redis# ps aux
```

The output is similar to this:

| USER  | PID | %CPU | %MEM | VSZ   | RSS  | TTY | STAT | START | TIME | COMMAND             |
|-------|-----|------|------|-------|------|-----|------|-------|------|---------------------|
| redis | 1   | 0.1  | 0.1  | 33308 | 3828 | ?   | Ssl  | 00:46 | 0:00 | redis-server *:6379 |
| root  | 12  | 0.0  | 0.0  | 20228 | 3020 | ?   | Ss   | 00:47 | 0:00 | /bin/bash           |
| root  | 15  | 0.0  | 0.0  | 17500 | 2072 | ?   | R+   | 00:48 | 0:00 | ps aux              |

6. In your shell, kill the Redis process:

```
root@redis:/data/redis# kill <pid>
```

where <pid> is the Redis process ID (PID).

7. In your original terminal, watch for changes to the Redis Pod. Eventually, you will see something like this:

| NAME  | READY | STATUS    | RESTARTS | AGE |
|-------|-------|-----------|----------|-----|
| redis | 1/1   | Running   | 0        | 13s |
| redis | 0/1   | Completed | 0        | 6m  |
| redis | 1/1   | Running   | 1        | 6m  |

At this point, the Container has terminated and restarted. This is because the Redis Pod has a [restartPolicy](#) of Always.

1. Get a shell into the restarted Container:

```
kubectl exec -it redis -- /bin/bash
```

2. In your shell, go to /data/redis, and verify that test-file is still there.

```
root@redis:/data/redis# cd /data/redis/
root@redis:/data/redis# ls
test-file
```

3. Delete the Pod that you created for this exercise:

```
kubectl delete pod redis
```

## What's next

- See [Volume](#).
- See [Pod](#).
- In addition to the local disk storage provided by emptyDir, Kubernetes supports many different network-attached storage solutions, including PD on GCE and EBS on EC2, which are preferred for critical data and will handle details such as mounting and unmounting the devices on the nodes. See [Volumes](#) for more details.

# Configure a Pod to Use a PersistentVolume for Storage

This page shows you how to configure a Pod to use a [PersistentVolumeClaim](#) for storage. Here is a summary of the process:

1. You, as cluster administrator, create a PersistentVolume backed by physical storage. You do not associate the volume with any Pod.
2. You, now taking the role of a developer / cluster user, create a PersistentVolumeClaim that is automatically bound to a suitable PersistentVolume.
3. You create a Pod that uses the above PersistentVolumeClaim for storage.

## Before you begin

- You need to have a Kubernetes cluster that has only one Node, and the [kubectl](#) command-line tool must be configured to communicate with your cluster. If you do not already have a single-node cluster, you can create one by using [Minikube](#).
- Familiarize yourself with the material in [Persistent Volumes](#).

## Create an index.html file on your Node

Open a shell to the single Node in your cluster. How you open a shell depends on how you set up your cluster. For example, if you are using Minikube, you can open a shell to your Node by entering `minikube ssh`.

In your shell on that Node, create a `/mnt/data` directory:

```
This assumes that your Node uses "sudo" to run commands
as the superuser
sudo mkdir /mnt/data
```

In the `/mnt/data` directory, create an `index.html` file:

```
This again assumes that your Node uses "sudo" to run commands
as the superuser
sudo sh -c "echo 'Hello from Kubernetes storage' > /mnt/data/index.html"
```

### Note:

If your Node uses a tool for superuser access other than `sudo`, you can usually make this work if you replace `sudo` with the name of the other tool.

Test that the `index.html` file exists:

```
cat /mnt/data/index.html
```

The output should be:

```
Hello from Kubernetes storage
```

You can now close the shell to your Node.

## Create a PersistentVolume

In this exercise, you create a *hostPath* PersistentVolume. Kubernetes supports *hostPath* for development and testing on a single-node cluster. A *hostPath* PersistentVolume uses a file or directory on the Node to emulate network-attached storage.

In a production cluster, you would not use *hostPath*. Instead a cluster administrator would provision a network resource like a Google Compute Engine persistent disk, an NFS share, or an Amazon Elastic Block Store volume. Cluster administrators can also use [StorageClasses](#) to set up [dynamic provisioning](#).

Here is the configuration file for the *hostPath* PersistentVolume:

[pods/storage/pv-volume.yaml](#)

```
apiVersion: v1
kind: PersistentVolume
metadata:
 name: task-pv-volume
 labels:
```

```
 type: local
spec:
 storageClassName: manual
 capacity:
 storage: 10Gi
 accessModes:
 - ReadWriteOnce
 hostPath:
 path: "/mnt/data"
```

The configuration file specifies that the volume is at `/mnt/data` on the cluster's Node. The configuration also specifies a size of 10 gibibytes and an access mode of `ReadWriteOnce`, which means the volume can be mounted as read-write by a single Node. It defines the [StorageClass name](#) `manual` for the `PersistentVolume`, which will be used to bind `PersistentVolumeClaim` requests to this `PersistentVolume`.

### Note:

This example uses the `ReadWriteOnce` access mode, for simplicity. For production use, the Kubernetes project recommends using the `ReadWriteOncePod` access mode instead.

Create the `PersistentVolume`:

```
kubectl apply -f https://k8s.io/examples/pods/storage/pv-volume.yaml
```

View information about the `PersistentVolume`:

```
kubectl get pv task-pv-volume
```

The output shows that the `PersistentVolume` has a `STATUS` of `Available`. This means it has not yet been bound to a `PersistentVolumeClaim`.

| NAME           | CAPACITY | ACCESSMODES | RECLAIMPOLICY | STATUS    | CLAIM  |
|----------------|----------|-------------|---------------|-----------|--------|
| task-pv-volume | 10Gi     | RWO         | Retain        | Available | manual |

## Create a PersistentVolumeClaim

The next step is to create a `PersistentVolumeClaim`. Pods use `PersistentVolumeClaims` to request physical storage. In this exercise, you create a `PersistentVolumeClaim` that requests a volume of at least three gibibytes that can provide read-write access for at most one Node at a time.

Here is the configuration file for the `PersistentVolumeClaim`:

[pods/storage/pv-claim.yaml](#)

```
apiVersion: v1
kind: PersistentVolumeClaim
metadata:
 name: task-pv-claim
spec:
 storageClassName: manual
 accessModes:
```

```
- ReadWriteOnce
resources:
 requests:
 storage: 3Gi
```

Create the PersistentVolumeClaim:

```
kubectcl apply -f https://k8s.io/examples/pods/storage/pv-claim.yaml
```

After you create the PersistentVolumeClaim, the Kubernetes control plane looks for a PersistentVolume that satisfies the claim's requirements. If the control plane finds a suitable PersistentVolume with the same StorageClass, it binds the claim to the volume.

Look again at the PersistentVolume:

```
kubectcl get pv task-pv-volume
```

Now the output shows a STATUS of Bound.

| NAME           | CAPACITY | ACCESSMODES | RECLAIMPOLICY | STATUS | CLAIM                 |
|----------------|----------|-------------|---------------|--------|-----------------------|
| task-pv-volume | 10Gi     | RWO         | Retain        | Bound  | default/task-pv-claim |
| manual         | 2m       |             |               |        |                       |

Look at the PersistentVolumeClaim:

```
kubectcl get pvc task-pv-claim
```

The output shows that the PersistentVolumeClaim is bound to your PersistentVolume, task-pv-volume.

| NAME          | STATUS | VOLUME         | CAPACITY | ACCESSMODES | STORAGECLASS |
|---------------|--------|----------------|----------|-------------|--------------|
| task-pv-claim | Bound  | task-pv-volume | 10Gi     | RWO         | manual       |
|               |        |                |          |             | 30s          |

## Create a Pod

The next step is to create a Pod that uses your PersistentVolumeClaim as a volume.

Here is the configuration file for the Pod:

[pods/storage/pv-pod.yaml](https://k8s.io/examples/pods/storage/pv-pod.yaml)

```
apiVersion: v1
kind: Pod
metadata:
 name: task-pv-pod
spec:
 volumes:
 - name: task-pv-storage
 persistentVolumeClaim:
 claimName: task-pv-claim
 containers:
 - name: task-pv-container
```

```
image: nginx
ports:
 - containerPort: 80
 name: "http-server"
volumeMounts:
 - mountPath: "/usr/share/nginx/html"
 name: task-pv-storage
```

Notice that the Pod's configuration file specifies a `PersistentVolumeClaim`, but it does not specify a `PersistentVolume`. From the Pod's point of view, the claim is a volume.

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/storage/pv-pod.yaml
```

Verify that the container in the Pod is running:

```
kubectl get pod task-pv-pod
```

Get a shell to the container running in your Pod:

```
kubectl exec -it task-pv-pod -- /bin/bash
```

In your shell, verify that nginx is serving the `index.html` file from the `hostPath` volume:

```
Be sure to run these 3 commands inside the root shell that comes from
running "kubectl exec" in the previous step
apt update
apt install curl
curl http://localhost/
```

The output shows the text that you wrote to the `index.html` file on the `hostPath` volume:

```
Hello from Kubernetes storage
```

If you see that message, you have successfully configured a Pod to use storage from a `PersistentVolumeClaim`.

## Clean up

Delete the Pod, the `PersistentVolumeClaim` and the `PersistentVolume`:

```
kubectl delete pod task-pv-pod
kubectl delete pvc task-pv-claim
kubectl delete pv task-pv-volume
```

If you don't already have a shell open to the Node in your cluster, open a new shell the same way that you did earlier.

In the shell on your Node, remove the file and directory that you created:

```
This assumes that your Node uses "sudo" to run commands
as the superuser
sudo rm /mnt/data/index.html
sudo rmdir /mnt/data
```

You can now close the shell to your Node.

## Mounting the same persistentVolume in two places

[pods/storage/pv-duplicate.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: test
spec:
 containers:
 - name: test
 image: nginx
 volumeMounts:
 # a mount for site-data
 - name: config
 mountPath: /usr/share/nginx/html
 subPath: html
 # another mount for nginx config
 - name: config
 mountPath: /etc/nginx/nginx.conf
 subPath: nginx.conf
 volumes:
 - name: config
 persistentVolumeClaim:
 claimName: test-nfs-claim
```

You can perform 2 volume mounts on your nginx container:

- /usr/share/nginx/html for the static website
- /etc/nginx/nginx.conf for the default config

## Access control

Storage configured with a group ID (GID) allows writing only by Pods using the same GID. Mismatched or missing GIDs cause permission denied errors. To reduce the need for coordination with users, an administrator can annotate a PersistentVolume with a GID. Then the GID is automatically added to any Pod that uses the PersistentVolume.

Use the `pv.beta.kubernetes.io/gid` annotation as follows:

```
apiVersion: v1
kind: PersistentVolume
metadata:
 name: pv1
```

```
annotations:
 pv.beta.kubernetes.io/gid: "1234"
```

When a Pod consumes a PersistentVolume that has a GID annotation, the annotated GID is applied to all containers in the Pod in the same way that GIDs specified in the Pod's security context are. Every GID, whether it originates from a PersistentVolume annotation or the Pod's specification, is applied to the first process run in each container.

**Note:**

When a Pod consumes a PersistentVolume, the GIDs associated with the PersistentVolume are not present on the Pod resource itself.

## What's next

- [PersistentVolumeClaimSpec](#)

# Configure a Pod to Use a Projected Volume for Storage

This page shows how to use a [projected](#) Volume to mount several existing volume sources into the same directory. Currently, secret, configMap, downwardAPI, and serviceAccountToken volumes can be projected.

**Note:**

serviceAccountToken is not a volume type.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter kubectl version.

# Configure a projected volume for a pod

In this exercise, you create username and password [Secrets](#) from local files. You then create a Pod that runs one container, using a [projected](#) Volume to mount the Secrets into the same shared directory.

Here is the configuration file for the Pod:

[pods/storage/projected.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: test-projected-volume
spec:
 containers:
 - name: test-projected-volume
 image: busybox:1.28
 args:
 - sleep
 - "86400"
 volumeMounts:
 - name: all-in-one
 mountPath: "/projected-volume"
 readOnly: true
 volumes:
 - name: all-in-one
 projected:
 sources:
 - secret:
 name: user
 - secret:
 name: pass
```

## 1. Create the Secrets:

```
Create files containing the username and password:
echo -n "admin" > ./username.txt
echo -n "1f2d1e2e67df" > ./password.txt

Package these files into secrets:
kubectl create secret generic user --from-file=./username.txt
kubectl create secret generic pass --from-file=./password.txt
```

## 2. Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/storage/projected.yaml
```

## 3. Verify that the Pod's container is running, and then watch for changes to the Pod:

```
kubectl get --watch pod test-projected-volume
```

The output looks like this:

| NAME                  | READY | STATUS  | RESTARTS | AGE |
|-----------------------|-------|---------|----------|-----|
| test-projected-volume | 1/1   | Running | 0        | 14s |

4. In another terminal, get a shell to the running container:

```
kubectl exec -it test-projected-volume -- /bin/sh
```

5. In your shell, verify that the projected-volume directory contains your projected sources:

```
ls /projected-volume/
```

## Clean up

Delete the Pod and the Secrets:

```
kubectl delete pod test-projected-volume
kubectl delete secret user pass
```

## What's next

- Learn more about [projected](#) volumes.
- Read the [all-in-one volume](#) design document.

# Configure a Security Context for a Pod or Container

A security context defines privilege and access control settings for a Pod or Container. Security context settings include, but are not limited to:

- Discretionary Access Control: Permission to access an object, like a file, is based on [user ID \(UID\) and group ID \(GID\)](#).
- [Security Enhanced Linux \(SELinux\)](#): Objects are assigned security labels.
- Running as privileged or unprivileged.
- [Linux Capabilities](#): Give a process some privileges, but not all the privileges of the root user.
- [AppArmor](#): Use program profiles to restrict the capabilities of individual programs.
- [Seccomp](#): Filter a process's system calls.
- `allowPrivilegeEscalation`: Controls whether a process can gain more privileges than its parent process. This bool directly controls whether the `no_new_privs` flag gets set on the container process. `allowPrivilegeEscalation` is always true when the container:
  - is run as privileged, or
  - has `CAP_SYS_ADMIN`
- `readOnlyRootFilesystem`: Mounts the container's root filesystem as read-only.

The above bullets are not a complete set of security context settings -- please see [SecurityContext](#) for a comprehensive list.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter kubectl version.

## Set the security context for a Pod

To specify security settings for a Pod, include the securityContext field in the Pod specification. The securityContext field is a [PodSecurityContext](#) object. The security settings that you specify for a Pod apply to all Containers in the Pod. Here is a configuration file for a Pod that has a securityContext and an emptyDir volume:

[pods/security/security-context.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: security-context-demo
spec:
 securityContext:
 runAsUser: 1000
 runAsGroup: 3000
 fsGroup: 2000
 volumes:
 - name: sec-ctx-vol
 emptyDir: {}
 containers:
 - name: sec-ctx-demo
 image: busybox:1.28
 command: ["sh", "-c", "sleep 1h"]
 volumeMounts:
 - name: sec-ctx-vol
 mountPath: /data/demo
 securityContext:
 allowPrivilegeEscalation: false
```

In the configuration file, the runAsUser field specifies that for any Containers in the Pod, all processes run with user ID 1000. The runAsGroup field specifies the primary group ID of 3000 for all processes within any containers of the Pod. If this field is omitted, the primary group ID of the containers will be root(0). Any files created will also be owned by user 1000 and group 3000 when runAsGroup is specified. Since fsGroup field is specified, all processes of the

container are also part of the supplementary group ID 2000. The owner for volume /data/demo and any files created in that volume will be Group ID 2000.

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/security/security-context.yaml
```

Verify that the Pod's Container is running:

```
kubectl get pod security-context-demo
```

Get a shell to the running Container:

```
kubectl exec -it security-context-demo -- sh
```

In your shell, list the running processes:

```
ps
```

The output shows that the processes are running as user 1000, which is the value of runAsUser:

```
PID USER TIME COMMAND
 1 1000 0:00 sleep 1h
 6 1000 0:00 sh
...
```

In your shell, navigate to /data, and list the one directory:

```
cd /data
ls -l
```

The output shows that the /data/demo directory has group ID 2000, which is the value of fsGroup.

```
drwxrwsrwx 2 root 2000 4096 Jun 6 20:08 demo
```

In your shell, navigate to /data/demo, and create a file:

```
cd demo
echo hello > testfile
```

List the file in the /data/demo directory:

```
ls -l
```

The output shows that testfile has group ID 2000, which is the value of fsGroup.

```
-rw-r--r-- 1 1000 2000 6 Jun 6 20:08 testfile
```

Run the following command:

```
id
```

The output is similar to this:

```
uid=1000 gid=3000 groups=2000
```

From the output, you can see that `gid` is 3000 which is same as the `runAsGroup` field. If the `runAsGroup` was omitted, the `gid` would remain as 0 (root) and the process will be able to interact with files that are owned by the root(0) group and groups that have the required group permissions for the root (0) group.

Exit your shell:

```
exit
```

## Configure volume permission and ownership change policy for Pods

FEATURE STATE: Kubernetes v1.23 [stable]

By default, Kubernetes recursively changes ownership and permissions for the contents of each volume to match the `fsGroup` specified in a Pod's `securityContext` when that volume is mounted. For large volumes, checking and changing ownership and permissions can take a lot of time, slowing Pod startup. You can use the `fsGroupChangePolicy` field inside a `securityContext` to control the way that Kubernetes checks and manages ownership and permissions for a volume.

**fsGroupChangePolicy** - `fsGroupChangePolicy` defines behavior for changing ownership and permission of the volume before being exposed inside a Pod. This field only applies to volume types that support `fsGroup` controlled ownership and permissions. This field has two possible values:

- *OnRootMismatch*: Only change permissions and ownership if the permission and the ownership of root directory does not match with expected permissions of the volume. This could help shorten the time it takes to change ownership and permission of a volume.
- *Always*: Always change permission and ownership of the volume when volume is mounted.

For example:

```
securityContext:
 runAsUser: 1000
 runAsGroup: 3000
 fsGroup: 2000
 fsGroupChangePolicy: "OnRootMismatch"
```

### Note:

This field has no effect on ephemeral volume types such as [secret](#), [configMap](#), and [emptydir](#).

## Delegating volume permission and ownership change to CSI driver

FEATURE STATE: Kubernetes v1.26 [stable]

If you deploy a [Container Storage Interface \(CSI\)](#) driver which supports the `VOLUME_MOUNT_GROUP` `NodeServiceCapability`, the process of setting file ownership and permissions based on the `fsGroup` specified in the `securityContext` will be performed by the CSI driver instead of Kubernetes. In this case, since Kubernetes doesn't perform any ownership and permission change, `fsGroupChangePolicy` does not take effect, and as specified by CSI, the driver is expected to mount the volume with the provided `fsGroup`, resulting in a volume that is readable/writable by the `fsGroup`.

## Set the security context for a Container

To specify security settings for a Container, include the `securityContext` field in the Container manifest. The `securityContext` field is a [SecurityContext](#) object. Security settings that you specify for a Container apply only to the individual Container, and they override settings made at the Pod level when there is overlap. Container settings do not affect the Pod's Volumes.

Here is the configuration file for a Pod that has one Container. Both the Pod and the Container have a `securityContext` field:

[pods/security/security-context-2.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: security-context-demo-2
spec:
 securityContext:
 runAsUser: 1000
 containers:
 - name: sec-ctx-demo-2
 image: gcr.io/google-samples/node-hello:1.0
 securityContext:
 runAsUser: 2000
 allowPrivilegeEscalation: false
```

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/security/security-context-2.yaml
```

Verify that the Pod's Container is running:

```
kubectl get pod security-context-demo-2
```

Get a shell into the running Container:

```
kubectl exec -it security-context-demo-2 -- sh
```

In your shell, list the running processes:

```
ps aux
```

The output shows that the processes are running as user 2000. This is the value of `runAsUser` specified for the Container. It overrides the value 1000 that is specified for the Pod.

| USER | PID | %CPU | %MEM | VSZ    | RSS   | TTY | STAT | START | TIME | COMMAND                   |
|------|-----|------|------|--------|-------|-----|------|-------|------|---------------------------|
| 2000 | 1   | 0.0  | 0.0  | 4336   | 764   | ?   | Ss   | 20:36 | 0:00 | /bin/sh -c node server.js |
| 2000 | 8   | 0.1  | 0.5  | 772124 | 22604 | ?   | Sl   | 20:36 | 0:00 | node server.js            |
| ...  |     |      |      |        |       |     |      |       |      |                           |

Exit your shell:

```
exit
```

## Set capabilities for a Container

With [Linux capabilities](#), you can grant certain privileges to a process without granting all the privileges of the root user. To add or remove Linux capabilities for a Container, include the capabilities field in the securityContext section of the Container manifest.

First, see what happens when you don't include a capabilities field. Here is configuration file that does not add or remove any Container capabilities:

[pods/security/security-context-3.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: security-context-demo-3
spec:
 containers:
 - name: sec-ctx-3
 image: gcr.io/google-samples/node-hello:1.0
```

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/security/security-context-3.yaml
```

Verify that the Pod's Container is running:

```
kubectl get pod security-context-demo-3
```

Get a shell into the running Container:

```
kubectl exec -it security-context-demo-3 -- sh
```

In your shell, list the running processes:

```
ps aux
```

The output shows the process IDs (PIDs) for the Container:

| USER | PID | %CPU | %MEM | VSZ    | RSS   | TTY | STAT | START | TIME | COMMAND                   |
|------|-----|------|------|--------|-------|-----|------|-------|------|---------------------------|
| root | 1   | 0.0  | 0.0  | 4336   | 796   | ?   | Ss   | 18:17 | 0:00 | /bin/sh -c node server.js |
| root | 5   | 0.1  | 0.5  | 772124 | 22700 | ?   | Sl   | 18:17 | 0:00 | node server.js            |

In your shell, view the status for process 1:

```
cd /proc/1
cat status
```

The output shows the capabilities bitmap for the process:

```
...
CapPrm: 00000000a80425fb
CapEff: 00000000a80425fb
...
```

Make a note of the capabilities bitmap, and then exit your shell:

```
exit
```

Next, run a Container that is the same as the preceding container, except that it has additional capabilities set.

Here is the configuration file for a Pod that runs one Container. The configuration adds the CAP\_NET\_ADMIN and CAP\_SYS\_TIME capabilities:

[pods/security/security-context-4.yaml](https://k8s.io/examples/pods/security/security-context-4.yaml)

```
apiVersion: v1
kind: Pod
metadata:
 name: security-context-demo-4
spec:
 containers:
 - name: sec-ctx-4
 image: gcr.io/google-samples/node-hello:1.0
 securityContext:
 capabilities:
 add: ["NET_ADMIN", "SYS_TIME"]
```

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/security/security-context-4.yaml
```

Get a shell into the running Container:

```
kubectl exec -it security-context-demo-4 -- sh
```

In your shell, view the capabilities for process 1:

```
cd /proc/1
cat status
```

The output shows capabilities bitmap for the process:

```
...
CapPrm: 00000000aa0435fb
CapEff: 00000000aa0435fb
...
```

Compare the capabilities of the two Containers:

```
00000000a80425fb
00000000aa0435fb
```

In the capability bitmap of the first container, bits 12 and 25 are clear. In the second container, bits 12 and 25 are set. Bit 12 is CAP\_NET\_ADMIN, and bit 25 is CAP\_SYS\_TIME. See [capability.h](#) for definitions of the capability constants.

#### Note:

Linux capability constants have the form CAP\_XXX. But when you list capabilities in your container manifest, you must omit the CAP\_ portion of the constant. For example, to add CAP\_SYS\_TIME, include SYS\_TIME in your list of capabilities.

## Set the Seccomp Profile for a Container

To set the Seccomp profile for a Container, include the `seccompProfile` field in the `securityContext` section of your Pod or Container manifest. The `seccompProfile` field is a [SeccompProfile](#) object consisting of `type` and `localhostProfile`. Valid options for `type` include `RuntimeDefault`, `Unconfined`, and `Localhost`. `localhostProfile` must only be set if `type: Localhost`. It indicates the path of the pre-configured profile on the node, relative to the kubelet's configured Seccomp profile location (configured with the `--root-dir` flag).

Here is an example that sets the Seccomp profile to the node's container runtime default profile:

```
...
securityContext:
 seccompProfile:
 type: RuntimeDefault
```

Here is an example that sets the Seccomp profile to a pre-configured file at `<kubelet-root-dir>/seccomp/my-profiles/profile-allow.json`:

```
...
securityContext:
 seccompProfile:
 type: Localhost
 localhostProfile: my-profiles/profile-allow.json
```

## Assign SELinux labels to a Container

To assign SELinux labels to a Container, include the `seLinuxOptions` field in the `securityContext` section of your Pod or Container manifest. The `seLinuxOptions` field is an [SELinuxOptions](#) object. Here's an example that applies an SELinux level:

```
...
securityContext:
 seLinuxOptions:
 level: "s0:c123,c456"
```

## Note:

To assign SELinux labels, the SELinux security module must be loaded on the host operating system.

## Efficient SELinux volume relabeling

FEATURE STATE: Kubernetes v1.28 [beta]

## Note:

Kubernetes v1.27 introduced an early limited form of this behavior that was only applicable to volumes (and PersistentVolumeClaims) using the ReadWriteOncePod access mode.

As an alpha feature, you can enable the SELinuxMount [feature gate](#) to widen that performance improvement to other kinds of PersistentVolumeClaims, as explained in detail below.

By default, the container runtime recursively assigns SELinux label to all files on all Pod volumes. To speed up this process, Kubernetes can change the SELinux label of a volume instantly by using a mount option `-o context=<label>`.

To benefit from this speedup, all these conditions must be met:

- The [feature gates](#) `ReadWriteOncePod` and `SELinuxMountReadWriteOncePod` must be enabled.
- Pod must use PersistentVolumeClaim with applicable accessModes and [feature gates](#):
  - Either the volume has accessModes: `["ReadWriteOncePod"]`, and feature gate `SELinuxMountReadWriteOncePod` is enabled.
  - Or the volume can use any other access modes and both feature gates `SELinuxMountReadWriteOncePod` and `SELinuxMount` must be enabled.
- Pod (or all its Containers that use the PersistentVolumeClaim) must have `seLinuxOptions` set.
- The corresponding PersistentVolume must be either:
  - A volume that uses the legacy in-tree `iscsi`, `rbd` or `fc` volume type.
  - Or a volume that uses a [CSI](#) driver. The CSI driver must announce that it supports mounting with `-o context` by setting `spec.seLinuxMount: true` in its `CSIDriver` instance.

For any other volume types, SELinux relabelling happens another way: the container runtime recursively changes the SELinux label for all inodes (files and directories) in the volume. The more files and directories in the volume, the longer that relabelling takes.

## Managing access to the /proc filesystem

FEATURE STATE: Kubernetes v1.12 [alpha]

For runtimes that follow the OCI runtime specification, containers default to running in a mode where there are multiple paths that are both masked and read-only. The result of this is the container has these paths present inside the container's mount namespace, and they can

function similarly to if the container was an isolated host, but the container process cannot write to them. The list of masked and read-only paths are as follows:

- Masked Paths:

- /proc/asound
- /proc/acpi
- /proc/kcore
- /proc/keys
- /proc/latency\_stats
- /proc/timer\_list
- /proc/timer\_stats
- /proc/sched\_debug
- /proc/scsi
- /sys/firmware

- Read-Only Paths:

- /proc/bus
- /proc/fs
- /proc/irq
- /proc/sys
- /proc/sysrq-trigger

For some Pods, you might want to bypass that default masking of paths. The most common context for wanting this is if you are trying to run containers within a Kubernetes container (within a pod).

The securityContext field procMount allows a user to request a container's /proc be Unmasked, or be mounted as read-write by the container process. This also applies to /sys/firmware which is not in /proc.

```
...
securityContext:
 procMount: Unmasked
```

**Note:**

Setting procMount to Unmasked requires the spec.hostUsers value in the pod spec to be false. In other words: a container that wishes to have an Unmasked /proc or unmasked /sys must also be in a [user namespace](#). Kubernetes v1.12 to v1.29 did not enforce that requirement.

## Discussion

The security context for a Pod applies to the Pod's Containers and also to the Pod's Volumes when applicable. Specifically fsGroup and seLinuxOptions are applied to Volumes as follows:

- fsGroup: Volumes that support ownership management are modified to be owned and writable by the GID specified in fsGroup. See the [Ownership Management design document](#) for more details.
- seLinuxOptions: Volumes that support SELinux labeling are relabeled to be accessible by the label specified under seLinuxOptions. Usually you only need to set the level section.

This sets the [Multi-Category Security \(MCS\)](#) label given to all Containers in the Pod as well as the Volumes.

### Warning:

After you specify an MCS label for a Pod, all Pods with the same label can access the Volume. If you need inter-Pod protection, you must assign a unique MCS label to each Pod.

## Clean up

Delete the Pod:

```
kubectl delete pod security-context-demo
kubectl delete pod security-context-demo-2
kubectl delete pod security-context-demo-3
kubectl delete pod security-context-demo-4
```

# Configure Service Accounts for Pods

Kubernetes offers two distinct ways for clients that run within your cluster, or that otherwise have a relationship to your cluster's [control plane](#) to authenticate to the [API server](#).

A *service account* provides an identity for processes that run in a Pod, and maps to a ServiceAccount object. When you authenticate to the API server, you identify yourself as a particular *user*. Kubernetes recognises the concept of a user, however, Kubernetes itself does **not** have a User API.

This task guide is about ServiceAccounts, which do exist in the Kubernetes API. The guide shows you some ways to configure ServiceAccounts for Pods.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at

least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

## Use the default service account to access the API server

When Pods contact the API server, Pods authenticate as a particular ServiceAccount (for example, default). There is always at least one ServiceAccount in each [namespace](#).

Every Kubernetes namespace contains at least one ServiceAccount: the default ServiceAccount for that namespace, named default. If you do not specify a ServiceAccount when you create a Pod, Kubernetes automatically assigns the ServiceAccount named default in that namespace.

You can fetch the details for a Pod you have created. For example:

```
kubectl get pods/<podname> -o yaml
```

In the output, you see a field `spec.serviceAccountName`. Kubernetes automatically sets that value if you don't specify it when you create a Pod.

An application running inside a Pod can access the Kubernetes API using automatically mounted service account credentials. See [accessing the Cluster](#) to learn more.

When a Pod authenticates as a ServiceAccount, its level of access depends on the [authorization plugin and policy](#) in use.

## Opt out of API credential automounting

If you don't want the [kubelet](#) to automatically mount a ServiceAccount's API credentials, you can opt out of the default behavior. You can opt out of automounting API credentials on `/var/run/secrets/kubernetes.io/serviceaccount/token` for a service account by setting `automountServiceAccountToken: false` on the ServiceAccount:

For example:

```
apiVersion: v1
kind: ServiceAccount
metadata:
 name: build-robot
automountServiceAccountToken: false
...
```

You can also opt out of automounting API credentials for a particular Pod:

```
apiVersion: v1
kind: Pod
metadata:
 name: my-pod
spec:
 serviceAccountName: build-robot
```

```
automountServiceAccountToken: false
...
```

If both the ServiceAccount and the Pod's .spec specify a value for automountServiceAccountToken, the Pod spec takes precedence.

## Use more than one ServiceAccount

Every namespace has at least one ServiceAccount: the default ServiceAccount resource, called default. You can list all ServiceAccount resources in your [current namespace](#) with:

```
kubectl get serviceaccounts
```

The output is similar to this:

| NAME    | SECRETS | AGE |
|---------|---------|-----|
| default | 1       | 1d  |

You can create additional ServiceAccount objects like this:

```
kubectl apply -f - <<EOF
apiVersion: v1
kind: ServiceAccount
metadata:
 name: build-robot
EOF
```

The name of a ServiceAccount object must be a valid [DNS subdomain name](#).

If you get a complete dump of the service account object, like this:

```
kubectl get serviceaccounts/build-robot -o yaml
```

The output is similar to this:

```
apiVersion: v1
kind: ServiceAccount
metadata:
 creationTimestamp: 2019-06-16T00:12:34Z
 name: build-robot
 namespace: default
 resourceVersion: "272500"
 uid: 721ab723-13bc-11e5-aec2-42010af0021e
```

You can use authorization plugins to [set permissions on service accounts](#).

To use a non-default service account, set the spec.serviceAccountName field of a Pod to the name of the ServiceAccount you wish to use.

You can only set the serviceAccountName field when creating a Pod, or in a template for a new Pod. You cannot update the .spec.serviceAccountName field of a Pod that already exists.

**Note:**

The `.spec.serviceAccount` field is a deprecated alias for `.spec.serviceAccountName`. If you want to remove the fields from a workload resource, set both fields to empty explicitly on the [pod template](#).

## Cleanup

If you tried creating build-robot ServiceAccount from the example above, you can clean it up by running:

```
kubectl delete serviceaccount/build-robot
```

## Manually create an API token for a ServiceAccount

Suppose you have an existing service account named "build-robot" as mentioned earlier.

You can get a time-limited API token for that ServiceAccount using kubectl:

```
kubectl create token build-robot
```

The output from that command is a token that you can use to authenticate as that ServiceAccount. You can request a specific token duration using the `--duration` command line argument to `kubectl create token` (the actual duration of the issued token might be shorter, or could even be longer).

When the `ServiceAccountTokenNodeBinding` and `ServiceAccountTokenNodeBindingValidation` features are enabled and the `KUBECTL_NODE_BOUND_TOKENS` environment variable is set to true, it is possible to create a service account token that is directly bound to a Node:

```
KUBECTL_NODE_BOUND_TOKENS=true kubectl create token build-robot --bound-object-kind Node --bound-object-name node-001 --bound-object-uid 123...456
```

The token will be valid until it expires or either the associated Node or service account are deleted.

**Note:**

Versions of Kubernetes before v1.22 automatically created long term credentials for accessing the Kubernetes API. This older mechanism was based on creating token Secrets that could then be mounted into running Pods. In more recent versions, including Kubernetes v1.30, API credentials are obtained directly by using the [TokenRequest](#) API, and are mounted into Pods using a [projected volume](#). The tokens obtained using this method have bounded lifetimes, and are automatically invalidated when the Pod they are mounted into is deleted.

You can still manually create a service account token Secret; for example, if you need a token that never expires. However, using the [TokenRequest](#) subresource to obtain a token to access the API is recommended instead.

## Manually create a long-lived API token for a ServiceAccount

If you want to obtain an API token for a ServiceAccount, you create a new Secret with a special annotation, `kubernetes.io/service-account.name`.

```
kubectl apply -f - <<EOF
apiVersion: v1
kind: Secret
metadata:
 name: build-robot-secret
 annotations:
 kubernetes.io/service-account.name: build-robot
type: kubernetes.io/service-account-token
EOF
```

If you view the Secret using:

```
kubectl get secret/build-robot-secret -o yaml
```

you can see that the Secret now contains an API token for the "build-robot" ServiceAccount.

Because of the annotation you set, the control plane automatically generates a token for that ServiceAccounts, and stores them into the associated Secret. The control plane also cleans up tokens for deleted ServiceAccounts.

```
kubectl describe secrets/build-robot-secret
```

The output is similar to this:

```
Name: build-robot-secret
Namespace: default
Labels: <none>
Annotations: kubernetes.io/service-account.name: build-robot
 kubernetes.io/service-account.uid: da68f9c6-9d26-11e7-b84e-002dc52800da

Type: kubernetes.io/service-account-token

Data
====
ca.crt: 1338 bytes
namespace: 7 bytes
token: ...
```

### Note:

The content of token is elided here.

Take care not to display the contents of a `kubernetes.io/service-account-token` Secret somewhere that your terminal / computer screen could be seen by an onlooker.

When you delete a ServiceAccount that has an associated Secret, the Kubernetes control plane automatically cleans up the long-lived token from that Secret.

## Note:

If you view the ServiceAccount using:

```
kubectl get serviceaccount build-robot -o yaml
```

You can't see the build-robot-secret Secret in the ServiceAccount API objects [.secrets](#) field because that field is only populated with auto-generated Secrets.

## Add ImagePullSecrets to a service account

First, [create an imagePullSecret](#). Next, verify it has been created. For example:

- Create an imagePullSecret, as described in [Specifying ImagePullSecrets on a Pod](#).

```
kubectl create secret docker-registry myregistrykey --docker-server=<registry name> \
 --docker-username=DUMMY_USERNAME --docker-password=DUMMY_DOCKER_
PASSWORD \
 --docker-email=DUMMY_DOCKER_EMAIL
```

- Verify it has been created.

```
kubectl get secrets myregistrykey
```

The output is similar to this:

| NAME          | TYPE                           | DATA | AGE |
|---------------|--------------------------------|------|-----|
| myregistrykey | kubernetes.io/dockerconfigjson | 1    | 1d  |

## Add image pull secret to service account

Next, modify the default service account for the namespace to use this Secret as an imagePullSecret.

```
kubectl patch serviceaccount default -p '{"imagePullSecrets": [{"name": "myregistrykey"}]}'
```

You can achieve the same outcome by editing the object manually:

```
kubectl edit serviceaccount/default
```

The output of the sa.yaml file is similar to this:

Your selected text editor will open with a configuration looking something like this:

```
apiVersion: v1
kind: ServiceAccount
metadata:
 creationTimestamp: 2021-07-07T22:02:39Z
 name: default
 namespace: default
 resourceVersion: "243024"
 uid: 052fb0f4-3d50-11e5-b066-42010af0d7b6
```

Using your editor, delete the line with key `resourceVersion`, add lines for `imagePullSecrets`: and save it. Leave the `uid` value set the same as you found it.

After you made those changes, the edited `ServiceAccount` looks something like this:

```
apiVersion: v1
kind: ServiceAccount
metadata:
 creationTimestamp: 2021-07-07T22:02:39Z
 name: default
 namespace: default
 uid: 052fb0f4-3d50-11e5-b066-42010af0d7b6
imagePullSecrets:
 - name: myregistrykey
```

## Verify that `imagePullSecrets` are set for new Pods

Now, when a new Pod is created in the current namespace and using the default `ServiceAccount`, the new Pod has its `spec.imagePullSecrets` field set automatically:

```
kubectl run nginx --image=<registry name>/nginx --restart=Never
kubectl get pod nginx -o=jsonpath='{.spec.imagePullSecrets[0].name}'
```

The output is:

```
myregistrykey
```

## ServiceAccount token volume projection

FEATURE STATE: Kubernetes v1.20 [stable]

### Note:

To enable and use token request projection, you must specify each of the following command line arguments to `kube-apiserver`:

#### `--service-account-issuer`

defines the Identifier of the service account token issuer. You can specify the `--service-account-issuer` argument multiple times, this can be useful to enable a non-disruptive change of the issuer. When this flag is specified multiple times, the first is used to generate tokens and all are used to determine which issuers are accepted. You must be running Kubernetes v1.22 or later to be able to specify `--service-account-issuer` multiple times.

#### `--service-account-key-file`

specifies the path to a file containing PEM-encoded X.509 private or public keys (RSA or ECDSA), used to verify `ServiceAccount` tokens. The specified file can contain multiple keys, and the flag can be specified multiple times with different files. If specified multiple times, tokens signed by any of the specified keys are considered valid by the Kubernetes API server.

#### `--service-account-signing-key-file`

specifies the path to a file that contains the current private key of the service account token issuer. The issuer signs issued ID tokens with this private key.

--api-audiences (can be omitted)

defines audiences for ServiceAccount tokens. The service account token authenticator validates that tokens used against the API are bound to at least one of these audiences. If api-audiences is specified multiple times, tokens for any of the specified audiences are considered valid by the Kubernetes API server. If you specify the --service-account-issuer command line argument but you don't set --api-audiences, the control plane defaults to a single element audience list that contains only the issuer URL.

The kubelet can also project a ServiceAccount token into a Pod. You can specify desired properties of the token, such as the audience and the validity duration. These properties are *not* configurable on the default ServiceAccount token. The token will also become invalid against the API when either the Pod or the ServiceAccount is deleted.

You can configure this behavior for the spec of a Pod using a [projected volume](#) type called ServiceAccountToken.

The token from this projected volume is a [JSON Web Token](#) (JWT). The JSON payload of this token follows a well defined schema - an example payload for a pod bound token:

```
{
 "aud": [# matches the requested audiences, or the API server's default audiences when none
 "https://kubernetes.default.svc"
],
 "exp": 1731613413,
 "iat": 1700077413,
 "iss": "https://kubernetes.default.svc", # matches the first value passed to the --service-
 account-issuer flag
 "jti": "ea28ed49-2e11-4280-9ec5-bc3d1d84661a", # ServiceAccountTokenJTI feature must be
 enabled for the claim to be present
 "kubernetes.io": {
 "namespace": "kube-system",
 "node": { # ServiceAccountTokenPodNodeInfo feature must be enabled for the API server to
 add this node reference claim
 "name": "127.0.0.1",
 "uid": "58456cb0-dd00-45ed-b797-5578fdceaced"
 },
 "pod": {
 "name": "coredns-69cbfb9798-jv9gn",
 "uid": "778a530c-b3f4-47c0-9cd5-ab018fb64f33"
 },
 "serviceaccount": {
 "name": "coredns",
 "uid": "a087d5a0-e1dd-43ec-93ac-f13d89cd13af"
 },
 "warnafter": 1700081020
 },
 "nbf": 1700077413,
 "sub": "system:serviceaccount:kube-system:coredns"
}
```

## Launch a Pod using service account token projection

To provide a Pod with a token with an audience of `vault` and a validity duration of two hours, you could define a Pod manifest that is similar to:

[pods/pod-projected-svc-token.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: nginx
spec:
 containers:
 - image: nginx
 name: nginx
 volumeMounts:
 - mountPath: /var/run/secrets/tokens
 name: vault-token
 serviceAccountName: build-robot
 volumes:
 - name: vault-token
 projected:
 sources:
 - serviceAccountToken:
 path: vault-token
 expirationSeconds: 7200
 audience: vault
```

Create the Pod:

```
kubectl create -f https://k8s.io/examples/pods/pod-projected-svc-token.yaml
```

The kubelet will: request and store the token on behalf of the Pod; make the token available to the Pod at a configurable file path; and refresh the token as it approaches expiration. The kubelet proactively requests rotation for the token if it is older than 80% of its total time-to-live (TTL), or if the token is older than 24 hours.

The application is responsible for reloading the token when it rotates. It's often good enough for the application to load the token on a schedule (for example: once every 5 minutes), without tracking the actual expiry time.

## Service account issuer discovery

FEATURE STATE: Kubernetes v1.21 [stable]

If you have enabled [token projection](#) for ServiceAccounts in your cluster, then you can also make use of the discovery feature. Kubernetes provides a way for clients to federate as an *identity provider*, so that one or more external systems can act as a *relying party*.

## Note:

The issuer URL must comply with the [OIDC Discovery Spec](#). In practice, this means it must use the https scheme, and should serve an OpenID provider configuration at `{service-account-issuer}/.well-known/openid-configuration`.

If the URL does not comply, ServiceAccount issuer discovery endpoints are not registered or accessible.

When enabled, the Kubernetes API server publishes an OpenID Provider Configuration document via HTTP. The configuration document is published at `/.well-known/openid-configuration`. The OpenID Provider Configuration is sometimes referred to as the *discovery document*. The Kubernetes API server publishes the related JSON Web Key Set (JWKS), also via HTTP, at `/openid/v1/jwks`.

## Note:

The responses served at `/.well-known/openid-configuration` and `/openid/v1/jwks` are designed to be OIDC compatible, but not strictly OIDC compliant. Those documents contain only the parameters necessary to perform validation of Kubernetes service account tokens.

Clusters that use [RBAC](#) include a default ClusterRole called `system:service-account-issuer-discovery`. A default ClusterRoleBinding assigns this role to the `system:serviceaccounts` group, which all ServiceAccounts implicitly belong to. This allows pods running on the cluster to access the service account discovery document via their mounted service account token. Administrators may, additionally, choose to bind the role to `system:authenticated` or `system:unauthenticated` depending on their security requirements and which external systems they intend to federate with.

The JWKS response contains public keys that a relying party can use to validate the Kubernetes service account tokens. Relying parties first query for the OpenID Provider Configuration, and use the `jwks_uri` field in the response to find the JWKS.

In many cases, Kubernetes API servers are not available on the public internet, but public endpoints that serve cached responses from the API server can be made available by users or by service providers. In these cases, it is possible to override the `jwks_uri` in the OpenID Provider Configuration so that it points to the public endpoint, rather than the API server's address, by passing the `--service-account-jwks-uri` flag to the API server. Like the issuer URL, the JWKS URI is required to use the https scheme.

# Pull an Image from a Private Registry

This page shows how to create a Pod that uses a [Secret](#) to pull an image from a private container image registry or repository. There are many private registries in use. This task uses [Docker Hub](#) as an example registry.

This item links to a third party project or product that is not part of Kubernetes itself. [More information](#)

## Before you begin

- You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:
  - [Killercoda](#)
  - [Play with Kubernetes](#)
- To do this exercise, you need the docker command line tool, and a [Docker ID](#) for which you know the password.
- If you are using a different private container registry, you need the command line tool for that registry and any login information for the registry.

## Log in to Docker Hub

On your laptop, you must authenticate with a registry in order to pull a private image.

Use the docker tool to log in to Docker Hub. See the *log in* section of [Docker ID accounts](#) for more information.

```
docker login
```

When prompted, enter your Docker ID, and then the credential you want to use (access token, or the password for your Docker ID).

The login process creates or updates a config.json file that holds an authorization token. Review [how Kubernetes interprets this file](#).

View the config.json file:

```
cat ~/.docker/config.json
```

The output contains a section similar to this:

```
{
 "auths": {
 "https://index.docker.io/v1/": {
 "auth": "c3R...zE2"
 }
 }
}
```

**Note:**

If you use a Docker credentials store, you won't see that auth entry but a credsStore entry with the name of the store as value. In that case, you can create a secret directly. See [Create a Secret by providing credentials on the command line](#).

## Create a Secret based on existing credentials

A Kubernetes cluster uses the Secret of `kubernetes.io/dockerconfigjson` type to authenticate with a container registry to pull a private image.

If you already ran `docker login`, you can copy that credential into Kubernetes:

```
kubectl create secret generic regcred \
 --from-file=.dockerconfigjson=<path/to/.docker/config.json> \
 --type=kubernetes.io/dockerconfigjson
```

If you need more control (for example, to set a namespace or a label on the new secret) then you can customise the Secret before storing it. Be sure to:

- set the name of the data item to `.dockerconfigjson`
- base64 encode the Docker configuration file and then paste that string, unbroken as the value for field `data[".dockerconfigjson"]`
- set type to `kubernetes.io/dockerconfigjson`

Example:

[illegible]

If you get the error message `error: no objects passed to create`, it may mean the base64 encoded string is invalid. If you get an error message like `Secret "myregistrykey" is invalid: data[.dockerconfigjson]: invalid value ...`, it means the base64 encoded string in the data was successfully decoded, but could not be parsed as a `.docker/config.json` file.

# Create a Secret by providing credentials on the command line

Create this Secret, naming it regcred:

```
kubectl create secret docker-registry regcred --docker-server=<your-registry-server> --docker-username=<your-name> --docker-password=<your-pword> --docker-email=<your-email>
```

where:

- <your-registry-server> is your Private Docker Registry FQDN. Use <https://index.docker.io/v1/> for DockerHub.
- <your-name> is your Docker username.
- <your-pword> is your Docker password.
- <your-email> is your Docker email.

You have successfully set your Docker credentials in the cluster as a Secret called regcred.

## Note:

Typing secrets on the command line may store them in your shell history unprotected, and those secrets might also be visible to other users on your PC during the time that kubectl is running.

## Inspecting the Secret regcred

To understand the contents of the regcred Secret you created, start by viewing the Secret in YAML format:

```
kubectl get secret regcred --output=yaml
```

The output is similar to this:

```
apiVersion: v1
kind: Secret
metadata:
 ...
 name: regcred
 ...
data:
 .dockerconfigjson: eyJodHRwczovL2luZGV4L ... J0QUl6RTlifX0=
type: kubernetes.io/dockerconfigjson
```

The value of the .dockerconfigjson field is a base64 representation of your Docker credentials.

To understand what is in the .dockerconfigjson field, convert the secret data to a readable format:

```
kubectl get secret regcred --output="jsonpath={.data.\.dockerconfigjson}" | base64 --decode
```

The output is similar to this:

```
{"auths":{"your.private.registry.example.com":{"username":"janedoe","password":"xxxxxxxxxxxx","email":"jdoe@example.com","auth":"c3R...zE2"}}}
```

To understand what is in the auth field, convert the base64-encoded data to a readable format:

```
echo "c3R...zE2" | base64 --decode
```

The output, username and password concatenated with a :, is similar to this:

```
janedoe:xxxxxxxxxxxx
```

Notice that the Secret data contains the authorization token similar to your local `~/.docker/config.json` file.

You have successfully set your Docker credentials as a Secret called `regcred` in the cluster.

## Create a Pod that uses your Secret

Here is a manifest for an example Pod that needs access to your Docker credentials in `regcred`:

[pods/private-reg-pod.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: private-reg
spec:
 containers:
 - name: private-reg-container
 image: <your-private-image>
 imagePullSecrets:
 - name: regcred
```

Download the above file onto your computer:

```
curl -L -o my-private-reg-pod.yaml https://k8s.io/examples/pods/private-reg-pod.yaml
```

In file `my-private-reg-pod.yaml`, replace `<your-private-image>` with the path to an image in a private registry such as:

```
your.private.registry.example.com/janedoe/jdoe-private:v1
```

To pull the image from the private registry, Kubernetes needs credentials. The `imagePullSecrets` field in the configuration file specifies that Kubernetes should get the credentials from a Secret named `regcred`.

Create a Pod that uses your Secret, and verify that the Pod is running:

```
kubectl apply -f my-private-reg-pod.yaml
kubectl get pod private-reg
```

## Note:

To use image pull secrets for a Pod (or a Deployment, or other object that has a pod template that you are using), you need to make sure that the appropriate Secret does exist in the right namespace. The namespace to use is the same namespace where you defined the Pod.

Also, in case the Pod fails to start with the status `ImagePullBackOff`, view the Pod events:

```
kubectl describe pod private-reg
```

If you then see an event with the reason set to `FailedToRetrieveImagePullSecret`, Kubernetes can't find a Secret with name (`regcred`, in this example). If you specify that a Pod needs image pull credentials, the kubelet checks that it can access that Secret before attempting to pull the image.

Make sure that the Secret you have specified exists, and that its name is spelled properly.

Events:

| ... Reason                          | ... Message                                                                                               |
|-------------------------------------|-----------------------------------------------------------------------------------------------------------|
| -----                               | -----                                                                                                     |
| ... FailedToRetrieveImagePullSecret | ... Unable to retrieve some image pull secrets (<regcred>); attempting to pull the image may not succeed. |

# Configure Liveness, Readiness and Startup Probes

This page shows how to configure liveness, readiness and startup probes for containers.

The [kubelet](#) uses liveness probes to know when to restart a container. For example, liveness probes could catch a deadlock, where an application is running, but unable to make progress. Restarting a container in such a state can help to make the application more available despite bugs.

A common pattern for liveness probes is to use the same low-cost HTTP endpoint as for readiness probes, but with a higher `failureThreshold`. This ensures that the pod is observed as not-ready for some period of time before it is hard killed.

The kubelet uses readiness probes to know when a container is ready to start accepting traffic. A Pod is considered ready when all of its containers are ready. One use of this signal is to control which Pods are used as backends for Services. When a Pod is not ready, it is removed from Service load balancers.

The kubelet uses startup probes to know when a container application has started. If such a probe is configured, liveness and readiness probes do not start until it succeeds, making sure those probes don't interfere with the application startup. This can be used to adopt liveness checks on slow starting containers, avoiding them getting killed by the kubelet before they are up and running.

### Caution:

Liveness probes can be a powerful way to recover from application failures, but they should be used with caution. Liveness probes must be configured carefully to ensure that they truly indicate unrecoverable application failure, for example a deadlock.

### Note:

Incorrect implementation of liveness probes can lead to cascading failures. This results in restarting of container under high load; failed client requests as your application became less scalable; and increased workload on remaining pods due to some failed pods. Understand the difference between readiness and liveness probes and when to apply them for your app.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

## Define a liveness command

Many applications running for long periods of time eventually transition to broken states, and cannot recover except by being restarted. Kubernetes provides liveness probes to detect and remedy such situations.

In this exercise, you create a Pod that runs a container based on the `registry.k8s.io/busybox` image. Here is the configuration file for the Pod:

[pods/probe/exec-liveness.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 labels:
 test: liveness
 name: liveness-exec
spec:
 containers:
 - name: liveness
 image: registry.k8s.io/busybox
 args:
```

```
- /bin/sh
- -c
- touch /tmp/healthy; sleep 30; rm -f /tmp/healthy; sleep 600
livenessProbe:
 exec:
 command:
 - cat
 - /tmp/healthy
 initialDelaySeconds: 5
 periodSeconds: 5
```

In the configuration file, you can see that the Pod has a single Container. The `periodSeconds` field specifies that the kubelet should perform a liveness probe every 5 seconds. The `initialDelaySeconds` field tells the kubelet that it should wait 5 seconds before performing the first probe. To perform a probe, the kubelet executes the command `cat /tmp/healthy` in the target container. If the command succeeds, it returns 0, and the kubelet considers the container to be alive and healthy. If the command returns a non-zero value, the kubelet kills the container and restarts it.

When the container starts, it executes this command:

```
/bin/sh -c "touch /tmp/healthy; sleep 30; rm -f /tmp/healthy; sleep 600"
```

For the first 30 seconds of the container's life, there is a `/tmp/healthy` file. So during the first 30 seconds, the command `cat /tmp/healthy` returns a success code. After 30 seconds, `cat /tmp/healthy` returns a failure code.

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/probe/exec-liveness.yaml
```

Within 30 seconds, view the Pod events:

```
kubectl describe pod liveness-exec
```

The output indicates that no liveness probes have failed yet:

| Type   | Reason    | Age | From              | Message                                               |
|--------|-----------|-----|-------------------|-------------------------------------------------------|
| Normal | Scheduled | 11s | default-scheduler | Successfully assigned default/liveness-exec to node01 |
| Normal | Pulling   | 9s  | kubelet, node01   | Pulling image "registry.k8s.io/busybox"               |
| Normal | Pulled    | 7s  | kubelet, node01   | Successfully pulled image "registry.k8s.io/busybox"   |
| Normal | Created   | 7s  | kubelet, node01   | Created container liveness                            |
| Normal | Started   | 7s  | kubelet, node01   | Started container liveness                            |

After 35 seconds, view the Pod events again:

```
kubectl describe pod liveness-exec
```

At the bottom of the output, there are messages indicating that the liveness probes have failed, and the failed containers have been killed and recreated.

| Type | Reason | Age | From | Message |
|------|--------|-----|------|---------|
|------|--------|-----|------|---------|

|         |           |                   |                   |                                                                                  |
|---------|-----------|-------------------|-------------------|----------------------------------------------------------------------------------|
| Normal  | Scheduled | 57s               | default-scheduler | Successfully assigned default/liveness-exec to node01                            |
| Normal  | Pulling   | 55s               | kubelet, node01   | Pulling image "registry.k8s.io/busybox"                                          |
| Normal  | Pulled    | 53s               | kubelet, node01   | Successfully pulled image "registry.k8s.io/busybox"                              |
| Normal  | Created   | 53s               | kubelet, node01   | Created container liveness                                                       |
| Normal  | Started   | 53s               | kubelet, node01   | Started container liveness                                                       |
| Warning | Unhealthy | 10s (x3 over 20s) | kubelet, node01   | Liveness probe failed: cat: can't open '/tmp/healthy': No such file or directory |
| Normal  | Killing   | 10s               | kubelet, node01   | Container liveness failed liveness probe, will be restarted                      |

Wait another 30 seconds, and verify that the container has been restarted:

```
kubectl get pod liveness-exec
```

The output shows that RESTARTS has been incremented. Note that the RESTARTS counter increments as soon as a failed container comes back to the running state:

| NAME          | READY | STATUS  | RESTARTS | AGE |
|---------------|-------|---------|----------|-----|
| liveness-exec | 1/1   | Running | 1        | 1m  |

## Define a liveness HTTP request

Another kind of liveness probe uses an HTTP GET request. Here is the configuration file for a Pod that runs a container based on the registry.k8s.io/e2e-test-images/agnhost image.

[pods/probe/http-liveness.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 labels:
 test: liveness
 name: liveness-http
spec:
 containers:
 - name: liveness
 image: registry.k8s.io/e2e-test-images/agnhost:2.40
 args:
 - liveness
 livenessProbe:
 httpGet:
 path: /healthz
 port: 8080
 httpHeaders:
 - name: Custom-Header
 value: Awesome
 initialDelaySeconds: 3
 periodSeconds: 3
```

In the configuration file, you can see that the Pod has a single container. The periodSeconds field specifies that the kubelet should perform a liveness probe every 3 seconds. The

`initialDelaySeconds` field tells the kubelet that it should wait 3 seconds before performing the first probe. To perform a probe, the kubelet sends an HTTP GET request to the server that is running in the container and listening on port 8080. If the handler for the server's `/healthz` path returns a success code, the kubelet considers the container to be alive and healthy. If the handler returns a failure code, the kubelet kills the container and restarts it.

Any code greater than or equal to 200 and less than 400 indicates success. Any other code indicates failure.

You can see the source code for the server in [server.go](#).

For the first 10 seconds that the container is alive, the `/healthz` handler returns a status of 200. After that, the handler returns a status of 500.

```
http.HandleFunc("/healthz", func(w http.ResponseWriter, r *http.Request) {
 duration := time.Now().Sub(started)
 if duration.Seconds() > 10 {
 w.WriteHeader(500)
 w.Write([]byte(fmt.Sprintf("error: %v", duration.Seconds())))
 } else {
 w.WriteHeader(200)
 w.Write([]byte("ok"))
 }
})
```

The kubelet starts performing health checks 3 seconds after the container starts. So the first couple of health checks will succeed. But after 10 seconds, the health checks will fail, and the kubelet will kill and restart the container.

To try the HTTP liveness check, create a Pod:

```
kubectl apply -f https://k8s.io/examples/pods/probe/http-liveness.yaml
```

After 10 seconds, view Pod events to verify that liveness probes have failed and the container has been restarted:

```
kubectl describe pod liveness-http
```

In releases after v1.13, local HTTP proxy environment variable settings do not affect the HTTP liveness probe.

## Define a TCP liveness probe

A third type of liveness probe uses a TCP socket. With this configuration, the kubelet will attempt to open a socket to your container on the specified port. If it can establish a connection, the container is considered healthy, if it can't it is considered a failure.

[pods/probe/tcp-liveness-readiness.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: goproxy
 labels:
```

```
 app: goproxy
spec:
 containers:
 - name: goproxy
 image: registry.k8s.io/goproxy:0.1
 ports:
 - containerPort: 8080
 readinessProbe:
 tcpSocket:
 port: 8080
 initialDelaySeconds: 15
 periodSeconds: 10
 livenessProbe:
 tcpSocket:
 port: 8080
 initialDelaySeconds: 15
 periodSeconds: 10
```

As you can see, configuration for a TCP check is quite similar to an HTTP check. This example uses both readiness and liveness probes. The kubelet will send the first readiness probe 15 seconds after the container starts. This will attempt to connect to the goproxy container on port 8080. If the probe succeeds, the Pod will be marked as ready. The kubelet will continue to run this check every 10 seconds.

In addition to the readiness probe, this configuration includes a liveness probe. The kubelet will run the first liveness probe 15 seconds after the container starts. Similar to the readiness probe, this will attempt to connect to the goproxy container on port 8080. If the liveness probe fails, the container will be restarted.

To try the TCP liveness check, create a Pod:

```
kubectl apply -f https://k8s.io/examples/pods/probe/tcp-liveness-readiness.yaml
```

After 15 seconds, view Pod events to verify that liveness probes:

```
kubectl describe pod goproxy
```

## Define a gRPC liveness probe

FEATURE STATE: Kubernetes v1.27 [stable]

If your application implements the [gRPC Health Checking Protocol](#), this example shows how to configure Kubernetes to use it for application liveness checks. Similarly you can configure readiness and startup probes.

Here is an example manifest:

[pods/probe/grpc-liveness.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: etcd-with-grpc
```

```
spec:
 containers:
 - name: etcd
 image: registry.k8s.io/etcd:3.5.1-0
 command: ["/usr/local/bin/etcd", "--data-dir", "/var/lib/etcd", "--listen-client-urls", "http://0.0.0.0:2379", "--advertise-client-urls", "http://127.0.0.1:2379", "--log-level", "debug"]
 ports:
 - containerPort: 2379
 livenessProbe:
 grpc:
 port: 2379
 initialDelaySeconds: 10
```

To use a gRPC probe, port must be configured. If you want to distinguish probes of different types and probes for different features you can use the service field. You can set service to the value liveness and make your gRPC Health Checking endpoint respond to this request differently than when you set service set to readiness. This lets you use the same endpoint for different kinds of container health check rather than listening on two different ports. If you want to specify your own custom service name and also specify a probe type, the Kubernetes project recommends that you use a name that concatenates those. For example: myservice-liveness (using - as a separator).

#### Note:

Unlike HTTP or TCP probes, you cannot specify the health check port by name, and you cannot configure a custom hostname.

Configuration problems (for example: incorrect port or service, unimplemented health checking protocol) are considered a probe failure, similar to HTTP and TCP probes.

To try the gRPC liveness check, create a Pod using the command below. In the example below, the etcd pod is configured to use gRPC liveness probe.

```
kubectl apply -f https://k8s.io/examples/pods/probe/grpc-liveness.yaml
```

After 15 seconds, view Pod events to verify that the liveness check has not failed:

```
kubectl describe pod etcd-with-grpc
```

When using a gRPC probe, there are some technical details to be aware of:

- The probes run against the pod IP address or its hostname. Be sure to configure your gRPC endpoint to listen on the Pod's IP address.
- The probes do not support any authentication parameters (like -tls).
- There are no error codes for built-in probes. All errors are considered as probe failures.
- If ExecProbeTimeout feature gate is set to false, grpc-health-probe does **not** respect the timeoutSeconds setting (which defaults to 1s), while built-in probe would fail on timeout.

## Use a named port

You can use a named [port](#) for HTTP and TCP probes. gRPC probes do not support named ports.

For example:

```
ports:
- name: liveness-port
 containerPort: 8080
```

```
livenessProbe:
 httpGet:
 path: /healthz
 port: liveness-port
```

## Protect slow starting containers with startup probes

Sometimes, you have to deal with legacy applications that might require an additional startup time on their first initialization. In such cases, it can be tricky to set up liveness probe parameters without compromising the fast response to deadlocks that motivated such a probe. The trick is to set up a startup probe with the same command, HTTP or TCP check, with a `failureThreshold` \* `periodSeconds` long enough to cover the worst case startup time.

So, the previous example would become:

```
ports:
- name: liveness-port
 containerPort: 8080
```

```
livenessProbe:
 httpGet:
 path: /healthz
 port: liveness-port
 failureThreshold: 1
 periodSeconds: 10
```

```
startupProbe:
 httpGet:
 path: /healthz
 port: liveness-port
 failureThreshold: 30
 periodSeconds: 10
```

Thanks to the startup probe, the application will have a maximum of 5 minutes ( $30 * 10 = 300s$ ) to finish its startup. Once the startup probe has succeeded once, the liveness probe takes over to provide a fast response to container deadlocks. If the startup probe never succeeds, the container is killed after 300s and subject to the pod's `restartPolicy`.

## Define readiness probes

Sometimes, applications are temporarily unable to serve traffic. For example, an application might need to load large data or configuration files during startup, or depend on external services after startup. In such cases, you don't want to kill the application, but you don't want to send it requests either. Kubernetes provides readiness probes to detect and mitigate these situations. A pod with containers reporting that they are not ready does not receive traffic through Kubernetes Services.

## Note:

Readiness probes runs on the container during its whole lifecycle.

## Caution:

The readiness and liveness probes do not depend on each other to succeed. If you want to wait before executing a readiness probe, you should use `initialDelaySeconds` or a `startupProbe`.

Readiness probes are configured similarly to liveness probes. The only difference is that you use the `readinessProbe` field instead of the `livenessProbe` field.

```
readinessProbe:
 exec:
 command:
 - cat
 - /tmp/healthy
 initialDelaySeconds: 5
 periodSeconds: 5
```

Configuration for HTTP and TCP readiness probes also remains identical to liveness probes.

Readiness and liveness probes can be used in parallel for the same container. Using both can ensure that traffic does not reach a container that is not ready for it, and that containers are restarted when they fail.

## Configure Probes

[Probes](#) have a number of fields that you can use to more precisely control the behavior of startup, liveness and readiness checks:

- `initialDelaySeconds`: Number of seconds after the container has started before startup, liveness or readiness probes are initiated. If a startup probe is defined, liveness and readiness probe delays do not begin until the startup probe has succeeded. If the value of `periodSeconds` is greater than `initialDelaySeconds` then the `initialDelaySeconds` would be ignored. Defaults to 0 seconds. Minimum value is 0.
- `periodSeconds`: How often (in seconds) to perform the probe. Default to 10 seconds. The minimum value is 1.
- `timeoutSeconds`: Number of seconds after which the probe times out. Defaults to 1 second. Minimum value is 1.
- `successThreshold`: Minimum consecutive successes for the probe to be considered successful after having failed. Defaults to 1. Must be 1 for liveness and startup Probes. Minimum value is 1.
- `failureThreshold`: After a probe fails `failureThreshold` times in a row, Kubernetes considers that the overall check has failed: the container is *not* ready/healthy/live. For the case of a startup or liveness probe, if at least `failureThreshold` probes have failed, Kubernetes treats the container as unhealthy and triggers a restart for that specific container. The kubelet honors the setting of `terminationGracePeriodSeconds` for that container. For a failed readiness probe, the kubelet continues running the container that failed checks, and also continues to run more probes; because the check failed, the kubelet sets the Ready [condition](#) on the Pod to false.

- `terminationGracePeriodSeconds`: configure a grace period for the kubelet to wait between triggering a shut down of the failed container, and then forcing the container runtime to stop that container. The default is to inherit the Pod-level value for `terminationGracePeriodSeconds` (30 seconds if not specified), and the minimum value is 1. See [probe-level terminationGracePeriodSeconds](#) for more detail.

### Caution:

Incorrect implementation of readiness probes may result in an ever growing number of processes in the container, and resource starvation if this is left unchecked.

## HTTP probes

[HTTP probes](#) have additional fields that can be set on `httpGet`:

- `host`: Host name to connect to, defaults to the pod IP. You probably want to set "Host" in `httpHeaders` instead.
- `scheme`: Scheme to use for connecting to the host (HTTP or HTTPS). Defaults to "HTTP".
- `path`: Path to access on the HTTP server. Defaults to "/".
- `httpHeaders`: Custom headers to set in the request. HTTP allows repeated headers.
- `port`: Name or number of the port to access on the container. Number must be in the range 1 to 65535.

For an HTTP probe, the kubelet sends an HTTP request to the specified port and path to perform the check. The kubelet sends the probe to the Pod's IP address, unless the address is overridden by the optional `host` field in `httpGet`. If `scheme` field is set to HTTPS, the kubelet sends an HTTPS request skipping the certificate verification. In most scenarios, you do not want to set the `host` field. Here's one scenario where you would set it. Suppose the container listens on 127.0.0.1 and the Pod's `hostNetwork` field is true. Then `host`, under `httpGet`, should be set to 127.0.0.1. If your pod relies on virtual hosts, which is probably the more common case, you should not use `host`, but rather set the `Host` header in `httpHeaders`.

For an HTTP probe, the kubelet sends two request headers in addition to the mandatory `Host` header:

- `User-Agent`: The default value is `kube-probe/1.30`, where 1.30 is the version of the kubelet.
- `Accept`: The default value is `*/*`.

You can override the default headers by defining `httpHeaders` for the probe. For example:

```
livenessProbe:
 httpGet:
 httpHeaders:
 - name: Accept
 value: application/json

startupProbe:
 httpGet:
 httpHeaders:
 - name: User-Agent
 value: MyUserAgent
```

You can also remove these two headers by defining them with an empty value.

```

livenessProbe:
 httpGet:
 httpHeaders:
 - name: Accept
 value: ""

startupProbe:
 httpGet:
 httpHeaders:
 - name: User-Agent
 value: ""

```

## Note:

When the kubelet probes a Pod using HTTP, it only follows redirects if the redirect is to the same host. If the kubelet receives 11 or more redirects during probing, the probe is considered successful and a related Event is created:

```

Events:
 Type Reason Age From Message
 ---- -
Normal Scheduled 29m default-scheduler Successfully assigned default/
httpbin-7b8bc9cb85-bjzwn to daocloud
Normal Pulling 29m kubelet Pulling image "docker.io/kennethreitz/
httpbin"
Normal Pulled 24m kubelet Successfully pulled image "docker.io/
kennethreitz/httpbin" in 5m12.402735213s
Normal Created 24m kubelet Created container httpbin
Normal Started 24m kubelet Started container httpbin
Warning ProbeWarning 4m11s (x1197 over 24m) kubelet Readiness probe warning:
Probe terminated redirects

```

If the kubelet receives a redirect where the hostname is different from the request, the outcome of the probe is treated as successful and kubelet creates an event to report the redirect failure.

## TCP probes

For a TCP probe, the kubelet makes the probe connection at the node, not in the Pod, which means that you can not use a service name in the host parameter since the kubelet is unable to resolve it.

## Probe-level terminationGracePeriodSeconds

FEATURE STATE: Kubernetes v1.28 [stable]

In 1.25 and above, users can specify a probe-level `terminationGracePeriodSeconds` as part of the probe specification. When both a pod- and probe-level `terminationGracePeriodSeconds` are set, the kubelet will use the probe-level value.

When setting the `terminationGracePeriodSeconds`, please note the following:

- The kubelet always honors the probe-level `terminationGracePeriodSeconds` field if it is present on a Pod.

- If you have existing Pods where the `terminationGracePeriodSeconds` field is set and you no longer wish to use per-probe termination grace periods, you must delete those existing Pods.

For example:

```
spec:
 terminationGracePeriodSeconds: 3600 # pod-level
 containers:
 - name: test
 image: ...

 ports:
 - name: liveness-port
 containerPort: 8080

 livenessProbe:
 httpGet:
 path: /healthz
 port: liveness-port
 failureThreshold: 1
 periodSeconds: 60
 # Override pod-level terminationGracePeriodSeconds #
 terminationGracePeriodSeconds: 60
```

Probe-level `terminationGracePeriodSeconds` cannot be set for readiness probes. It will be rejected by the API server.

## What's next

- Learn more about [Container Probes](#).

You can also read the API references for:

- [Pod](#), and specifically:
  - [container\(s\)](#)
  - [probe\(s\)](#)

## Assign Pods to Nodes

This page shows how to assign a Kubernetes Pod to a particular node in a Kubernetes cluster.

### Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

## Add a label to a node

1. List the [nodes](#) in your cluster, along with their labels:

```
kubectl get nodes --show-labels
```

The output is similar to this:

| NAME    | STATUS | ROLES  | AGE | VERSION | LABELS                             |
|---------|--------|--------|-----|---------|------------------------------------|
| worker0 | Ready  | <none> | 1d  | v1.13.0 | ...,kubernetes.io/hostname=worker0 |
| worker1 | Ready  | <none> | 1d  | v1.13.0 | ...,kubernetes.io/hostname=worker1 |
| worker2 | Ready  | <none> | 1d  | v1.13.0 | ...,kubernetes.io/hostname=worker2 |

2. Choose one of your nodes, and add a label to it:

```
kubectl label nodes <your-node-name> disktype=ssd
```

where `<your-node-name>` is the name of your chosen node.

3. Verify that your chosen node has a `disktype=ssd` label:

```
kubectl get nodes --show-labels
```

The output is similar to this:

| NAME    | STATUS | ROLES  | AGE | VERSION | LABELS                                          |
|---------|--------|--------|-----|---------|-------------------------------------------------|
| worker0 | Ready  | <none> | 1d  | v1.13.0 | ...,disktype=ssd,kubernetes.io/hostname=worker0 |
| worker1 | Ready  | <none> | 1d  | v1.13.0 | ...,kubernetes.io/hostname=worker1              |
| worker2 | Ready  | <none> | 1d  | v1.13.0 | ...,kubernetes.io/hostname=worker2              |

In the preceding output, you can see that the worker0 node has a `disktype=ssd` label.

## Create a pod that gets scheduled to your chosen node

This pod configuration file describes a pod that has a node selector, `disktype: ssd`. This means that the pod will get scheduled on a node that has a `disktype=ssd` label.

[pods/pod-nginx.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: nginx
 labels:
 env: test
spec:
 containers:
 - name: nginx
 image: nginx
 imagePullPolicy: IfNotPresent
```

```
nodeSelector:
 disktype: ssd
```

1. Use the configuration file to create a pod that will get scheduled on your chosen node:

```
kubectl apply -f https://k8s.io/examples/pods/pod-nginx.yaml
```

2. Verify that the pod is running on your chosen node:

```
kubectl get pods --output=wide
```

The output is similar to this:

| NAME  | READY | STATUS  | RESTARTS | AGE | IP         | NODE    |
|-------|-------|---------|----------|-----|------------|---------|
| nginx | 1/1   | Running | 0        | 13s | 10.200.0.4 | worker0 |

## Create a pod that gets scheduled to specific node

You can also schedule a pod to one specific node via setting nodeName.

[pods/pod-nginx-specific-node.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: nginx
spec:
 nodeName: foo-node # schedule pod to specific node
 containers:
 - name: nginx
 image: nginx
 imagePullPolicy: IfNotPresent
```

Use the configuration file to create a pod that will get scheduled on foo-node only.

## What's next

- Learn more about [labels and selectors](#).
- Learn more about [nodes](#).

## Assign Pods to Nodes using Node Affinity

This page shows how to assign a Kubernetes Pod to a particular node using Node Affinity in a Kubernetes cluster.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at

least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version v1.10. To check the version, enter `kubectl version`.

## Add a label to a node

1. List the nodes in your cluster, along with their labels:

```
kubectl get nodes --show-labels
```

The output is similar to this:

| NAME    | STATUS | ROLES  | AGE | VERSION | LABELS                             |
|---------|--------|--------|-----|---------|------------------------------------|
| worker0 | Ready  | <none> | 1d  | v1.13.0 | ...,kubernetes.io/hostname=worker0 |
| worker1 | Ready  | <none> | 1d  | v1.13.0 | ...,kubernetes.io/hostname=worker1 |
| worker2 | Ready  | <none> | 1d  | v1.13.0 | ...,kubernetes.io/hostname=worker2 |

2. Choose one of your nodes, and add a label to it:

```
kubectl label nodes <your-node-name> disktype=ssd
```

where <your-node-name> is the name of your chosen node.

3. Verify that your chosen node has a disktype=ssd label:

```
kubectl get nodes --show-labels
```

The output is similar to this:

| NAME    | STATUS | ROLES  | AGE | VERSION | LABELS                                          |
|---------|--------|--------|-----|---------|-------------------------------------------------|
| worker0 | Ready  | <none> | 1d  | v1.13.0 | ...,disktype=ssd,kubernetes.io/hostname=worker0 |
| worker1 | Ready  | <none> | 1d  | v1.13.0 | ...,kubernetes.io/hostname=worker1              |
| worker2 | Ready  | <none> | 1d  | v1.13.0 | ...,kubernetes.io/hostname=worker2              |

In the preceding output, you can see that the worker0 node has a disktype=ssd label.

## Schedule a Pod using required node affinity

This manifest describes a Pod that has a requiredDuringSchedulingIgnoredDuringExecution node affinity, disktype: ssd. This means that the pod will get scheduled only on a node that has a disktype=ssd label.

[pods/pod-nginx-required-affinity.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
```

```

name: nginx
spec:
 affinity:
 nodeAffinity:
 requiredDuringSchedulingIgnoredDuringExecution:
 nodeSelectorTerms:
 - matchExpressions:
 - key: disktype
 operator: In
 values:
 - ssd
 containers:
 - name: nginx
 image: nginx
 imagePullPolicy: IfNotPresent

```

1. Apply the manifest to create a Pod that is scheduled onto your chosen node:

```
kubectl apply -f https://k8s.io/examples/pods/pod-nginx-required-affinity.yaml
```

2. Verify that the pod is running on your chosen node:

```
kubectl get pods --output=wide
```

The output is similar to this:

| NAME  | READY | STATUS  | RESTARTS | AGE | IP         | NODE    |
|-------|-------|---------|----------|-----|------------|---------|
| nginx | 1/1   | Running | 0        | 13s | 10.200.0.4 | worker0 |

## Schedule a Pod using preferred node affinity

This manifest describes a Pod that has a `preferredDuringSchedulingIgnoredDuringExecution` node affinity, `disktype: ssd`. This means that the pod will prefer a node that has a `disktype=ssd` label.

[pods/pod-nginx-preferred-affinity.yaml](#)

```

apiVersion: v1
kind: Pod
metadata:
 name: nginx
spec:
 affinity:
 nodeAffinity:
 preferredDuringSchedulingIgnoredDuringExecution:
 - weight: 1
 preference:
 matchExpressions:
 - key: disktype
 operator: In
 values:
 - ssd
 containers:

```

```
- name: nginx
 image: nginx
 imagePullPolicy: IfNotPresent
```

1. Apply the manifest to create a Pod that is scheduled onto your chosen node:

```
kubectl apply -f https://k8s.io/examples/pods/pod-nginx-preferred-affinity.yaml
```

2. Verify that the pod is running on your chosen node:

```
kubectl get pods --output=wide
```

The output is similar to this:

| NAME  | READY | STATUS  | RESTARTS | AGE | IP         | NODE    |
|-------|-------|---------|----------|-----|------------|---------|
| nginx | 1/1   | Running | 0        | 13s | 10.200.0.4 | worker0 |

## What's next

Learn more about [Node Affinity](#).

# Configure Pod Initialization

This page shows how to use an Init Container to initialize a Pod before an application Container runs.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

## Create a Pod that has an Init Container

In this exercise you create a Pod that has one application Container and one Init Container. The init container runs to completion before the application container starts.

Here is the configuration file for the Pod:

[pods/init-containers.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: init-demo
```

```
spec:
 containers:
 - name: nginx
 image: nginx
 ports:
 - containerPort: 80
 volumeMounts:
 - name: workdir
 mountPath: /usr/share/nginx/html
 # These containers are run during pod initialization
 initContainers:
 - name: install
 image: busybox:1.28
 command:
 - wget
 - "-O"
 - "/work-dir/index.html"
 - "http://info.cern.ch"
 volumeMounts:
 - name: workdir
 mountPath: "/work-dir"
 dnsPolicy: Default
 volumes:
 - name: workdir
 emptyDir: {}
```

In the configuration file, you can see that the Pod has a Volume that the init container and the application container share.

The init container mounts the shared Volume at /work-dir, and the application container mounts the shared Volume at /usr/share/nginx/html. The init container runs the following command and then terminates:

```
wget -O /work-dir/index.html http://info.cern.ch
```

Notice that the init container writes the index.html file in the root directory of the nginx server.

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/init-containers.yaml
```

Verify that the nginx container is running:

```
kubectl get pod init-demo
```

The output shows that the nginx container is running:

| NAME      | READY | STATUS  | RESTARTS | AGE |
|-----------|-------|---------|----------|-----|
| init-demo | 1/1   | Running | 0        | 1m  |

Get a shell into the nginx container running in the init-demo Pod:

```
kubectl exec -it init-demo -- /bin/bash
```

In your shell, send a GET request to the nginx server:

```
root@nginx:~# apt-get update
root@nginx:~# apt-get install curl
root@nginx:~# curl localhost
```

The output shows that nginx is serving the web page that was written by the init container:

```
<html><head></head><body><header>
<title>http://info.cern.ch</title>
</header>

<h1>http://info.cern.ch - home of the first website</h1>
...
Browse the first website</
a>
...
```

- Learn more about [Debugging Init Containers](#)

# Attach Handlers to Container Lifecycle Events

This page shows how to attach handlers to Container lifecycle events. Kubernetes supports the postStart and preStop events. Kubernetes sends the postStart event immediately after a Container is started, and it sends the preStop event immediately before the Container is terminated. A Container may specify one handler per event.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

## Define postStart and preStop handlers

In this exercise, you create a Pod that has one Container. The Container has handlers for the postStart and preStop events.

Here is the configuration file for the Pod:

[pods/lifecycle-events.yaml](https://k8s.io/examples/pods/lifecycle-events.yaml)

```
apiVersion: v1
kind: Pod
metadata:
 name: lifecycle-demo
spec:
 containers:
 - name: lifecycle-demo-container
 image: nginx
 lifecycle:
 postStart:
 exec:
 command: ["/bin/sh", "-c", "echo Hello from the postStart handler > /usr/share/message"]
 preStop:
 exec:
 command: ["/bin/sh", "-c", "nginx -s quit; while killall -0 nginx; do sleep 1; done"]
```

In the configuration file, you can see that the postStart command writes a message file to the Container's /usr/share directory. The preStop command shuts down nginx gracefully. This is helpful if the Container is being terminated because of a failure.

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/lifecycle-events.yaml
```

Verify that the Container in the Pod is running:

```
kubectl get pod lifecycle-demo
```

Get a shell into the Container running in your Pod:

```
kubectl exec -it lifecycle-demo -- /bin/bash
```

In your shell, verify that the postStart handler created the message file:

```
root@lifecycle-demo:/# cat /usr/share/message
```

The output shows the text written by the postStart handler:

```
Hello from the postStart handler
```

## Discussion

Kubernetes sends the postStart event immediately after the Container is created. There is no guarantee, however, that the postStart handler is called before the Container's entrypoint is called. The postStart handler runs asynchronously relative to the Container's code, but Kubernetes' management of the container blocks until the postStart handler completes. The Container's status is not set to RUNNING until the postStart handler completes.

Kubernetes sends the `preStop` event immediately before the Container is terminated. Kubernetes' management of the Container blocks until the `preStop` handler completes, unless the Pod's grace period expires. For more details, see [Pod Lifecycle](#).

#### Note:

Kubernetes only sends the `preStop` event when a Pod or a container in the Pod is *terminated*. This means that the `preStop` hook is not invoked when the Pod is *completed*. About this limitation, please see [Container hooks](#) for the detail.

# Configure a Pod to Use a ConfigMap

Many applications rely on configuration which is used during either application initialization or runtime. Most times, there is a requirement to adjust values assigned to configuration parameters. ConfigMaps are a Kubernetes mechanism that let you inject configuration data into application [pods](#).

The ConfigMap concept allow you to decouple configuration artifacts from image content to keep containerized applications portable. For example, you can download and run the same [container image](#) to spin up containers for the purposes of local development, system test, or running a live end-user workload.

This page provides a series of usage examples demonstrating how to create ConfigMaps and configure Pods using data stored in ConfigMaps.

## Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

You need to have the `wget` tool installed. If you have a different tool such as `curl`, and you do not have `wget`, you will need to adapt the step that downloads example data.

# Create a ConfigMap

You can use either `kubectl create configmap` or a ConfigMap generator in `kustomization.yaml` to create a ConfigMap.

## Create a ConfigMap using `kubectl create configmap`

Use the `kubectl create configmap` command to create ConfigMaps from [directories](#), [files](#), or [literal values](#):

```
kubectl create configmap <map-name> <data-source>
```

where `<map-name>` is the name you want to assign to the ConfigMap and `<data-source>` is the directory, file, or literal value to draw the data from. The name of a ConfigMap object must be a valid [DNS subdomain name](#).

When you are creating a ConfigMap based on a file, the key in the `<data-source>` defaults to the basename of the file, and the value defaults to the file content.

You can use [kubectl describe](#) or [kubectl get](#) to retrieve information about a ConfigMap.

## Create a ConfigMap from a directory

You can use `kubectl create configmap` to create a ConfigMap from multiple files in the same directory. When you are creating a ConfigMap based on a directory, `kubectl` identifies files whose filename is a valid key in the directory and packages each of those files into the new ConfigMap. Any directory entries except regular files are ignored (for example: subdirectories, symlinks, devices, pipes, and more).

### Note:

Each filename being used for ConfigMap creation must consist of only acceptable characters, which are: letters (A to Z and a to z), digits (0 to 9), '-', '\_', or '.'. If you use `kubectl create configmap` with a directory where any of the file names contains an unacceptable character, the `kubectl` command may fail.

The `kubectl` command does not print an error when it encounters an invalid filename.

Create the local directory:

```
mkdir -p configure-pod-container/configmap/
```

Now, download the sample configuration and create the ConfigMap:

```
Download the sample files into `configure-pod-container/configmap/` directory
wget https://kubernetes.io/examples/configmap/game.properties -O configure-pod-container/
configmap/game.properties
wget https://kubernetes.io/examples/configmap/ui.properties -O configure-pod-container/
configmap/ui.properties
```

```
Create the ConfigMap
```

```
kubectl create configmap game-config --from-file=configure-pod-container/configmap/
```

The above command packages each file, in this case, `game.properties` and `ui.properties` in the `configure-pod-container/configmap/` directory into the `game-config` ConfigMap. You can display details of the ConfigMap using the following command:

```
kubectl describe configmaps game-config
```

The output is similar to this:

```
Name: game-config
Namespace: default
Labels: <none>
Annotations: <none>

Data
====
game.properties:

enemies=aliens
lives=3
enemies.cheat=true
enemies.cheat.level=noGoodRotten
secret.code.passphrase=UDDLRBABAS
secret.code.allowed=true
secret.code.lives=30
ui.properties:

color.good=purple
color.bad=yellow
allow.textmode=true
how.nice.to.look=fairlyNice
```

The `game.properties` and `ui.properties` files in the `configure-pod-container/configmap/` directory are represented in the `data` section of the ConfigMap.

```
kubectl get configmaps game-config -o yaml
```

The output is similar to this:

```
apiVersion: v1
kind: ConfigMap
metadata:
 creationTimestamp: 2022-02-18T18:52:05Z
 name: game-config
 namespace: default
 resourceVersion: "516"
 uid: b4952dc3-d670-11e5-8cd0-68f728db1985
data:
 game.properties: |
 enemies=aliens
 lives=3
 enemies.cheat=true
 enemies.cheat.level=noGoodRotten
 secret.code.passphrase=UDDLRBABAS
 secret.code.allowed=true
```

```
secret.code.lives=30
ui.properties: |
 color.good=purple
 color.bad=yellow
 allow.textmode=true
 how.nice.to.look=fairlyNice
```

## Create ConfigMaps from files

You can use `kubect`l create configmap to create a ConfigMap from an individual file, or from multiple files.

For example,

```
kubect
```

l create configmap game-config-2 --from-file=configure-pod-container/configmap/
game.properties

would produce the following ConfigMap:

```
kubect
```

l describe configmaps game-config-2

where the output is similar to this:

```
Name: game-config-2
Namespace: default
Labels: <none>
Annotations: <none>

Data
====
game.properties:

enemies=aliens
lives=3
enemies.cheat=true
enemies.cheat.level=noGoodRotten
secret.code.passphrase=UDDLRRLRBABAS
secret.code.allowed=true
secret.code.lives=30
```

You can pass in the `--from-file` argument multiple times to create a ConfigMap from multiple data sources.

```
kubect
```

l create configmap game-config-2 --from-file=configure-pod-container/configmap/
game.properties --from-file=configure-pod-container/configmap/ui.properties

You can display details of the game-config-2 ConfigMap using the following command:

```
kubect
```

l describe configmaps game-config-2

The output is similar to this:

```
Name: game-config-2
Namespace: default
```

```
Labels: <none>
Annotations: <none>
```

Data

====

game.properties:

----

enemies=aliens

lives=3

enemies.cheat=true

enemies.cheat.level=noGoodRotten

secret.code.passphrase=UDDLRBABAS

secret.code.allowed=true

secret.code.lives=30

ui.properties:

----

color.good=purple

color.bad=yellow

allow.textmode=true

how.nice.to.look=fairlyNice

Use the option `--from-env-file` to create a ConfigMap from an env-file, for example:

```
Env-files contain a list of environment variables.
These syntax rules apply:
Each line in an env file has to be in VAR=VAL format.
Lines beginning with # (i.e. comments) are ignored.
Blank lines are ignored.
There is no special handling of quotation marks (i.e. they will be part of the ConfigMap
value)).

Download the sample files into `configure-pod-container/configmap/` directory
wget https://kubernetes.io/examples/configmap/game-env-file.properties -O configure-pod-
container/configmap/game-env-file.properties
wget https://kubernetes.io/examples/configmap/ui-env-file.properties -O configure-pod-
container/configmap/ui-env-file.properties

The env-file `game-env-file.properties` looks like below
cat configure-pod-container/configmap/game-env-file.properties
enemies=aliens
lives=3
allowed="true"

This comment and the empty line above it are ignored
```

```
kubectl create configmap game-config-env-file \
 --from-env-file=configure-pod-container/configmap/game-env-file.properties
```

would produce a ConfigMap. View the ConfigMap:

```
kubectl get configmap game-config-env-file -o yaml
```

the output is similar to:

```
apiVersion: v1
kind: ConfigMap
metadata:
 creationTimestamp: 2019-12-27T18:36:28Z
 name: game-config-env-file
 namespace: default
 resourceVersion: "809965"
 uid: d9d1ca5b-eb34-11e7-887b-42010a8002b8
data:
 allowed: "true"
 enemies: aliens
 lives: "3"
```

Starting with Kubernetes v1.23, `kubectl` supports the `--from-env-file` argument to be specified multiple times to create a ConfigMap from multiple data sources.

```
kubectl create configmap config-multi-env-files \
 --from-env-file=configure-pod-container/configmap/game-env-file.properties \
 --from-env-file=configure-pod-container/configmap/ui-env-file.properties
```

would produce the following ConfigMap:

```
kubectl get configmap config-multi-env-files -o yaml
```

where the output is similar to this:

```
apiVersion: v1
kind: ConfigMap
metadata:
 creationTimestamp: 2019-12-27T18:38:34Z
 name: config-multi-env-files
 namespace: default
 resourceVersion: "810136"
 uid: 252c4572-eb35-11e7-887b-42010a8002b8
data:
 allowed: "true"
 color: purple
 enemies: aliens
 how: fairlyNice
 lives: "3"
 textmode: "true"
```

## Define the key to use when creating a ConfigMap from a file

You can define a key other than the file name to use in the data section of your ConfigMap when using the `--from-file` argument:

```
kubectl create configmap game-config-3 --from-file=<my-key-name>=<path-to-file>
```

where `<my-key-name>` is the key you want to use in the ConfigMap and `<path-to-file>` is the location of the data source file you want the key to represent.

For example:

```
kubectl create configmap game-config-3 --from-file=game-special-key=configure-pod-container/configmap/game.properties
```

would produce the following ConfigMap:

```
kubectl get configmaps game-config-3 -o yaml
```

where the output is similar to this:

```
apiVersion: v1
kind: ConfigMap
metadata:
 creationTimestamp: 2022-02-18T18:54:22Z
 name: game-config-3
 namespace: default
 resourceVersion: "530"
 uid: 05f8da22-d671-11e5-8cd0-68f728db1985
data:
 game-special-key: |
 enemies=aliens
 lives=3
 enemies.cheat=true
 enemies.cheat.level=noGoodRotten
 secret.code.passphrase=UDDLRBABAS
 secret.code.allowed=true
 secret.code.lives=30
```

## Create ConfigMaps from literal values

You can use `kubectl create configmap` with the `--from-literal` argument to define a literal value from the command line:

```
kubectl create configmap special-config --from-literal=special.how=very --from-literal=special.type=charm
```

You can pass in multiple key-value pairs. Each pair provided on the command line is represented as a separate entry in the data section of the ConfigMap.

```
kubectl get configmaps special-config -o yaml
```

The output is similar to this:

```
apiVersion: v1
kind: ConfigMap
metadata:
 creationTimestamp: 2022-02-18T19:14:38Z
 name: special-config
 namespace: default
 resourceVersion: "651"
 uid: dadce046-d673-11e5-8cd0-68f728db1985
data:
 special.how: very
 special.type: charm
```

## Create a ConfigMap from generator

You can also create a ConfigMap from generators and then apply it to create the object in the cluster's API server. You should specify the generators in a kustomization.yaml file within a directory.

### Generate ConfigMaps from files

For example, to generate a ConfigMap from files `configure-pod-container/configmap/game.properties`

```
Create a kustomization.yaml file with ConfigMapGenerator
cat <<EOF >./kustomization.yaml
configMapGenerator:
- name: game-config-4
 options:
 labels:
 game-config: config-4
 files:
 - configure-pod-container/configmap/game.properties
EOF
```

Apply the kustomization directory to create the ConfigMap object:

```
kubectl apply -k .
```

```
configmap/game-config-4-m9dm2f92bt created
```

You can check that the ConfigMap was created like this:

```
kubectl get configmap
```

NAME	DATA	AGE
game-config-4-m9dm2f92bt	1	37s

and also:

```
kubectl describe configmaps/game-config-4-m9dm2f92bt
```

```
Name: game-config-4-m9dm2f92bt
Namespace: default
Labels: game-config=config-4
Annotations: kubectl.kubernetes.io/last-applied-configuration:
 {"apiVersion":"v1","data":
{"game.properties":{"enemies=aliens\nlives=3\nenemies.cheat=true\nenemies.cheat.level=noGoo
dRotten\nsecret.code.p...

Data
====
game.properties:

enemies=aliens
lives=3
enemies.cheat=true
```

```
enemies.cheat.level=noGoodRotten
secret.code.passphrase=UUDDLRLRBABAS
secret.code.allowed=true
secret.code.lives=30
Events: <none>
```

Notice that the generated ConfigMap name has a suffix appended by hashing the contents. This ensures that a new ConfigMap is generated each time the content is modified.

### Define the key to use when generating a ConfigMap from a file

You can define a key other than the file name to use in the ConfigMap generator. For example, to generate a ConfigMap from files `configure-pod-container/configmap/game.properties` with the key `game-special-key`

```
Create a kustomization.yaml file with ConfigMapGenerator
cat <<EOF >./kustomization.yaml
configMapGenerator:
- name: game-config-5
 options:
 labels:
 game-config: config-5
 files:
 - game-special-key=configure-pod-container/configmap/game.properties
EOF
```

Apply the kustomization directory to create the ConfigMap object.

```
kubectl apply -k .
```

```
configmap/game-config-5-m67dt67794 created
```

### Generate ConfigMaps from literals

This example shows you how to create a ConfigMap from two literal key/value pairs: `special.type=charm` and `special.how=very`, using Kustomize and kubectl. To achieve this, you can specify the ConfigMap generator. Create (or replace) `kustomization.yaml` so that it has the following contents:

```

kustomization.yaml contents for creating a ConfigMap from literals
configMapGenerator:
- name: special-config-2
 literals:
 - special.how=very
 - special.type=charm
```

Apply the kustomization directory to create the ConfigMap object:

```
kubectl apply -k .
```

```
configmap/special-config-2-c92b5mmcf2 created
```

## Interim cleanup

Before proceeding, clean up some of the ConfigMaps you made:

```
kubectrl delete configmap special-config
kubectrl delete configmap env-config
kubectrl delete configmap -l 'game-config in (config-4,config-5)'
```

Now that you have learned to define ConfigMaps, you can move on to the next section, and learn how to use these objects with Pods.

---

## Define container environment variables using ConfigMap data

### Define a container environment variable with data from a single ConfigMap

1. Define an environment variable as a key-value pair in a ConfigMap:

```
kubectrl create configmap special-config --from-literal=special.how=very
```

2. Assign the special.how value defined in the ConfigMap to the SPECIAL\_LEVEL\_KEY environment variable in the Pod specification.

[pods/pod-single-configmap-env-variable.yaml](https://kubernetes.io/examples/pods/pod-single-configmap-env-variable.yaml)

```
apiVersion: v1
kind: Pod
metadata:
 name: dapi-test-pod
spec:
 containers:
 - name: test-container
 image: registry.k8s.io/busybox
 command: ["/bin/sh", "-c", "env"]
 env:
 # Define the environment variable
 - name: SPECIAL_LEVEL_KEY
 valueFrom:
 configMapKeyRef:
 # The ConfigMap containing the value you want to assign to
 SPECIAL_LEVEL_KEY
 name: special-config
 # Specify the key associated with the value
 key: special.how
 restartPolicy: Never
```

Create the Pod:

```
kubectrl create -f https://kubernetes.io/examples/pods/pod-single-configmap-env-
variable.yaml
```

Now, the Pod's output includes environment variable `SPECIAL_LEVEL_KEY=very`.

## Define container environment variables with data from multiple ConfigMaps

As with the previous example, create the ConfigMaps first. Here is the manifest you will use:

[configmap/configmaps.yaml](#)

```
apiVersion: v1
kind: ConfigMap
metadata:
 name: special-config
 namespace: default
data:
 special.how: very

apiVersion: v1
kind: ConfigMap
metadata:
 name: env-config
 namespace: default
data:
 log_level: INFO
```

- Create the ConfigMap:

```
kubectl create -f https://kubernetes.io/examples/configmap/configmaps.yaml
```

- Define the environment variables in the Pod specification.

[pods/pod-multiple-configmap-env-variable.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: dapi-test-pod
spec:
 containers:
 - name: test-container
 image: registry.k8s.io/busybox
 command: ["/bin/sh", "-c", "env"]
 env:
 - name: SPECIAL_LEVEL_KEY
 valueFrom:
 configMapKeyRef:
 name: special-config
 key: special.how
 - name: LOG_LEVEL
 valueFrom:
 configMapKeyRef:
 name: env-config
```

```
 key: log_level
restartPolicy: Never
```

Create the Pod:

```
kubectl create -f https://kubernetes.io/examples/pods/pod-multiple-configmap-env-variable.yaml
```

Now, the Pod's output includes environment variables SPECIAL\_LEVEL\_KEY=very and LOG\_LEVEL=INFO.

Once you're happy to move on, delete that Pod:

```
kubectl delete pod dapi-test-pod --now
```

## Configure all key-value pairs in a ConfigMap as container environment variables

- Create a ConfigMap containing multiple key-value pairs.

[configmap/configmap-multikeys.yaml](https://kubernetes.io/examples/configmap/configmap-multikeys.yaml)

```
apiVersion: v1
kind: ConfigMap
metadata:
 name: special-config
 namespace: default
data:
 SPECIAL_LEVEL: very
 SPECIAL_TYPE: charm
```

Create the ConfigMap:

```
kubectl create -f https://kubernetes.io/examples/configmap/configmap-multikeys.yaml
```

- Use envFrom to define all of the ConfigMap's data as container environment variables. The key from the ConfigMap becomes the environment variable name in the Pod.

[pods/pod-configmap-envFrom.yaml](https://kubernetes.io/examples/pods/pod-configmap-envFrom.yaml)

```
apiVersion: v1
kind: Pod
metadata:
 name: dapi-test-pod
spec:
 containers:
 - name: test-container
 image: registry.k8s.io/busybox
 command: ["/bin/sh", "-c", "env"]
 envFrom:
 - configMapRef:
 name: special-config
 restartPolicy: Never
```

Create the Pod:

```
kubectl create -f https://kubernetes.io/examples/pods/pod-configmap-envFrom.yaml
```

Now, the Pod's output includes environment variables `SPECIAL_LEVEL=very` and `SPECIAL_TYPE=charm`.

Once you're happy to move on, delete that Pod:

```
kubectl delete pod dapi-test-pod --now
```

## Use ConfigMap-defined environment variables in Pod commands

You can use ConfigMap-defined environment variables in the command and args of a container using the `$(VAR_NAME)` Kubernetes substitution syntax.

For example, the following Pod manifest:

[pods/pod-configmap-env-var-valueFrom.yaml](https://kubernetes.io/examples/pods/pod-configmap-env-var-valueFrom.yaml)

```
apiVersion: v1
kind: Pod
metadata:
 name: dapi-test-pod
spec:
 containers:
 - name: test-container
 image: registry.k8s.io/busybox
 command: ["/bin/echo", "$(SPECIAL_LEVEL_KEY) $(SPECIAL_TYPE_KEY)"]
 env:
 - name: SPECIAL_LEVEL_KEY
 valueFrom:
 configMapKeyRef:
 name: special-config
 key: SPECIAL_LEVEL
 - name: SPECIAL_TYPE_KEY
 valueFrom:
 configMapKeyRef:
 name: special-config
 key: SPECIAL_TYPE
 restartPolicy: Never
```

Create that Pod, by running:

```
kubectl create -f https://kubernetes.io/examples/pods/pod-configmap-env-var-valueFrom.yaml
```

That pod produces the following output from the test-container container:

```
kubectl logs dapi-test-pod
```

```
very charm
```

Once you're happy to move on, delete that Pod:

```
kubectl delete pod dapi-test-pod --now
```

## Add ConfigMap data to a Volume

As explained in [Create ConfigMaps from files](#), when you create a ConfigMap using `--from-file`, the filename becomes a key stored in the data section of the ConfigMap. The file contents become the key's value.

The examples in this section refer to a ConfigMap named `special-config`:

[configmap/configmap-multikeys.yaml](#)

```
apiVersion: v1
kind: ConfigMap
metadata:
 name: special-config
 namespace: default
data:
 SPECIAL_LEVEL: very
 SPECIAL_TYPE: charm
```

Create the ConfigMap:

```
kubectl create -f https://kubernetes.io/examples/configmap/configmap-multikeys.yaml
```

## Populate a Volume with data stored in a ConfigMap

Add the ConfigMap name under the `volumes` section of the Pod specification. This adds the ConfigMap data to the directory specified as `volumeMounts.mountPath` (in this case, `/etc/config`). The `command` section lists directory files with names that match the keys in ConfigMap.

[pods/pod-configmap-volume.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: dapi-test-pod
spec:
 containers:
 - name: test-container
 image: registry.k8s.io/busybox
 command: ["/bin/sh", "-c", "ls /etc/config/"]
 volumeMounts:
 - name: config-volume
 mountPath: /etc/config
 volumes:
 - name: config-volume
 configMap:
 # Provide the name of the ConfigMap containing the files you want
 # to add to the container
```

```
name: special-config
restartPolicy: Never
```

Create the Pod:

```
kubectl create -f https://kubernetes.io/examples/pods/pod-configmap-volume.yaml
```

When the pod runs, the command `ls /etc/config/` produces the output below:

```
SPECIAL_LEVEL
SPECIAL_TYPE
```

Text data is exposed as files using the UTF-8 character encoding. To use some other character encoding, use `binaryData` (see [ConfigMap object](#) for more details).

### Note:

If there are any files in the `/etc/config` directory of that container image, the volume mount will make those files from the image inaccessible.

Once you're happy to move on, delete that Pod:

```
kubectl delete pod dapi-test-pod --now
```

## Add ConfigMap data to a specific path in the Volume

Use the `path` field to specify the desired file path for specific ConfigMap items. In this case, the `SPECIAL_LEVEL` item will be mounted in the `config-volume` volume at `/etc/config/keys`.

[pods/pod-configmap-volume-specific-key.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: dapi-test-pod
spec:
 containers:
 - name: test-container
 image: registry.k8s.io/busybox
 command: ["/bin/sh", "-c", "cat /etc/config/keys"]
 volumeMounts:
 - name: config-volume
 mountPath: /etc/config
 volumes:
 - name: config-volume
 configMap:
 name: special-config
 items:
 - key: SPECIAL_LEVEL
 path: keys
 restartPolicy: Never
```

Create the Pod:

```
kubectl create -f https://kubernetes.io/examples/pods/pod-configmap-volume-specific-key.yaml
```

When the pod runs, the command `cat /etc/config/keys` produces the output below:

```
very
```

### Caution:

Like before, all previous files in the `/etc/config/` directory will be deleted.

Delete that Pod:

```
kubectl delete pod dapi-test-pod --now
```

## Project keys to specific paths and file permissions

You can project keys to specific paths. Refer to the corresponding section in the [Secrets](#) guide for the syntax.

You can set POSIX permissions for keys. Refer to the corresponding section in the [Secrets](#) guide for the syntax.

## Optional references

A ConfigMap reference may be marked *optional*. If the ConfigMap is non-existent, the mounted volume will be empty. If the ConfigMap exists, but the referenced key is non-existent, the path will be absent beneath the mount point. See [Optional ConfigMaps](#) for more details.

## Mounted ConfigMaps are updated automatically

When a mounted ConfigMap is updated, the projected content is eventually updated too. This applies in the case where an optionally referenced ConfigMap comes into existence after a pod has started.

Kubelet checks whether the mounted ConfigMap is fresh on every periodic sync. However, it uses its local TTL-based cache for getting the current value of the ConfigMap. As a result, the total delay from the moment when the ConfigMap is updated to the moment when new keys are projected to the pod can be as long as kubelet sync period (1 minute by default) + TTL of ConfigMaps cache (1 minute by default) in kubelet. You can trigger an immediate refresh by updating one of the pod's annotations.

### Note:

A container using a ConfigMap as a [subPath](#) volume will not receive ConfigMap updates.

## Understanding ConfigMaps and Pods

The ConfigMap API resource stores configuration data as key-value pairs. The data can be consumed in pods or provide the configurations for system components such as controllers. ConfigMap is similar to [Secrets](#), but provides a means of working with strings that don't contain sensitive information. Users and system components alike can store configuration data in ConfigMap.

## Note:

ConfigMaps should reference properties files, not replace them. Think of the ConfigMap as representing something similar to the Linux `/etc` directory and its contents. For example, if you create a [Kubernetes Volume](#) from a ConfigMap, each data item in the ConfigMap is represented by an individual file in the volume.

The ConfigMap's `data` field contains the configuration data. As shown in the example below, this can be simple (like individual properties defined using `--from-literal`) or complex (like configuration files or JSON blobs defined using `--from-file`).

```
apiVersion: v1
kind: ConfigMap
metadata:
 creationTimestamp: 2016-02-18T19:14:38Z
 name: example-config
 namespace: default
data:
 # example of a simple property defined using --from-literal
 example.property.1: hello
 example.property.2: world
 # example of a complex property defined using --from-file
 example.property.file: |-
 property.1=value-1
 property.2=value-2
 property.3=value-3
```

When `kubectl` creates a ConfigMap from inputs that are not ASCII or UTF-8, the tool puts these into the `binaryData` field of the ConfigMap, and not in `data`. Both text and binary data sources can be combined in one ConfigMap.

If you want to view the `binaryData` keys (and their values) in a ConfigMap, you can run `kubectl get configmap -o jsonpath='{.binaryData}' <name>`.

Pods can load data from a ConfigMap that uses either `data` or `binaryData`.

## Optional ConfigMaps

You can mark a reference to a ConfigMap as *optional* in a Pod specification. If the ConfigMap doesn't exist, the configuration for which it provides data in the Pod (for example: environment variable, mounted volume) will be empty. If the ConfigMap exists, but the referenced key is non-existent the data is also empty.

For example, the following Pod specification marks an environment variable from a ConfigMap as optional:

```
apiVersion: v1
kind: Pod
metadata:
 name: dapi-test-pod
spec:
 containers:
 - name: test-container
```

```
image: gcr.io/google_containers/busybox
command: ["/bin/sh", "-c", "env"]
env:
- name: SPECIAL_LEVEL_KEY
 valueFrom:
 configMapKeyRef:
 name: a-config
 key: akey
 optional: true # mark the variable as optional
restartPolicy: Never
```

If you run this pod, and there is no ConfigMap named a-config, the output is empty. If you run this pod, and there is a ConfigMap named a-config but that ConfigMap doesn't have a key named akey, the output is also empty. If you do set a value for akey in the a-config ConfigMap, this pod prints that value and then terminates.

You can also mark the volumes and files provided by a ConfigMap as optional. Kubernetes always creates the mount paths for the volume, even if the referenced ConfigMap or key doesn't exist. For example, the following Pod specification marks a volume that references a ConfigMap as optional:

```
apiVersion: v1
kind: Pod
metadata:
 name: dapi-test-pod
spec:
 containers:
 - name: test-container
 image: gcr.io/google_containers/busybox
 command: ["/bin/sh", "-c", "ls /etc/config"]
 volumeMounts:
 - name: config-volume
 mountPath: /etc/config
 volumes:
 - name: config-volume
 configMap:
 name: no-config
 optional: true # mark the source ConfigMap as optional
 restartPolicy: Never
```

## Restrictions

- You must create the ConfigMap object before you reference it in a Pod specification. Alternatively, mark the ConfigMap reference as optional in the Pod spec (see [Optional ConfigMaps](#)). If you reference a ConfigMap that doesn't exist and you don't mark the reference as optional, the Pod won't start. Similarly, references to keys that don't exist in the ConfigMap will also prevent the Pod from starting, unless you mark the key references as optional.
- If you use envFrom to define environment variables from ConfigMaps, keys that are considered invalid will be skipped. The pod will be allowed to start, but the invalid names will be recorded in the event log (InvalidVariableNames). The log message lists each skipped key. For example:

```
kubectl get events
```

The output is similar to this:

LASTSEEN	FIRSTSEEN	COUNT	NAME	KIND	SUBOBJECT	TYPE
REASON			SOURCE			MESSAGE
0s	0s	1	dapi-test-pod	Pod		Warning
InvalidEnvironmentVariableNames {kubelet, 127.0.0.1} Keys [1badkey, 2alsobad] from the EnvFrom configMap default/myconfig were skipped since they are considered invalid environment variable names.						

- ConfigMaps reside in a specific [Namespace](#). Pods can only refer to ConfigMaps that are in the same namespace as the Pod.
- You can't use ConfigMaps for [static pods](#), because the kubelet does not support this.

## Cleaning up

Delete the ConfigMaps and Pods that you made:

```
kubectl delete configmaps/game-config configmaps/game-config-2 configmaps/game-config-3 \
 configmaps/game-config-env-file
kubectl delete pod dapi-test-pod --now
```

```
You might already have removed the next set
kubectl delete configmaps/special-config configmaps/env-config
kubectl delete configmap -l 'game-config in (config-4,config-5)'
```

If you created a directory `configure-pod-container` and no longer need it, you should remove that too, or move it into the trash can / deleted files location.

## What's next

- Follow a real world example of [Configuring Redis using a ConfigMap](#).
- Follow an example of [Updating configuration via a ConfigMap](#).

# Share Process Namespace between Containers in a Pod

This page shows how to configure process namespace sharing for a pod. When process namespace sharing is enabled, processes in a container are visible to all other containers in the same pod.

You can use this feature to configure cooperating containers, such as a log handler sidecar container, or to troubleshoot container images that don't include debugging utilities like a shell.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

## Configure a Pod

Process namespace sharing is enabled using the `shareProcessNamespace` field of `.spec` for a Pod. For example:

[pods/share-process-namespace.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: nginx
spec:
 shareProcessNamespace: true
 containers:
 - name: nginx
 image: nginx
 - name: shell
 image: busybox:1.28
 command: ["sleep", "3600"]
 securityContext:
 capabilities:
 add:
 - SYS_PTRACE
 stdin: true
 tty: true
```

1. Create the pod nginx on your cluster:

```
kubectl apply -f https://k8s.io/examples/pods/share-process-namespace.yaml
```

2. Attach to the shell container and run ps:

```
kubectl attach -it nginx -c shell
```

If you don't see a command prompt, try pressing enter. In the container shell:

```
run this inside the "shell" container
ps ax
```

The output is similar to this:

```
PID USER TIME COMMAND
1 root 0:00 /pause
```

```
8 root 0:00 nginx: master process nginx -g daemon off;
14 101 0:00 nginx: worker process
15 root 0:00 sh
21 root 0:00 ps ax
```

You can signal processes in other containers. For example, send `SIGHUP` to `nginx` to restart the worker process. This requires the `SYS_PTRACE` capability.

```
run this inside the "shell" container
kill -HUP 8 # change "8" to match the PID of the nginx leader process, if necessary
ps ax
```

The output is similar to this:

```
PID USER TIME COMMAND
 1 root 0:00 /pause
 8 root 0:00 nginx: master process nginx -g daemon off;
15 root 0:00 sh
22 101 0:00 nginx: worker process
23 root 0:00 ps ax
```

It's even possible to access the file system of another container using the `/proc/$pid/root` link.

```
run this inside the "shell" container
change "8" to the PID of the Nginx process, if necessary
head /proc/8/root/etc/nginx/nginx.conf
```

The output is similar to this:

```
user nginx;
worker_processes 1;

error_log /var/log/nginx/error.log warn;
pid /var/run/nginx.pid;

events {
 worker_connections 1024;
```

## Understanding process namespace sharing

Pods share many resources so it makes sense they would also share a process namespace. Some containers may expect to be isolated from others, though, so it's important to understand the differences:

1. **The container process no longer has PID 1.** Some containers refuse to start without PID 1 (for example, containers using `systemd`) or run commands like `kill -HUP 1` to signal the container process. In pods with a shared process namespace, `kill -HUP 1` will signal the pod sandbox (`/pause` in the above example).
2. **Processes are visible to other containers in the pod.** This includes all information visible in `/proc`, such as passwords that were passed as arguments or environment variables. These are protected only by regular Unix permissions.

- Container filesystems are visible to other containers in the pod through the /proc/\$pid/root link.** This makes debugging easier, but it also means that filesystem secrets are protected only by filesystem permissions.

# Use a User Namespace With a Pod

FEATURE STATE: Kubernetes v1.30 [beta]

This page shows how to configure a user namespace for pods. This allows you to isolate the user running inside the container from the one in the host.

A process running as root in a container can run as a different (non-root) user in the host; in other words, the process has full privileges for operations inside the user namespace, but is unprivileged for operations outside the namespace.

You can use this feature to reduce the damage a compromised container can do to the host or other pods in the same node. There are [several security vulnerabilities](#) rated either **HIGH** or **CRITICAL** that were not exploitable when user namespaces is active. It is expected user namespace will mitigate some future vulnerabilities too.

Without using a user namespace a container running as root, in the case of a container breakout, has root privileges on the node. And if some capability were granted to the container, the capabilities are valid on the host too. None of this is true when user namespaces are used.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercoda](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version v1.25. To check the version, enter kubectl version.

This item links to a third party project or product that is not part of Kubernetes itself. [More information](#)

- The node OS needs to be Linux
- You need to exec commands in the host
- You need to be able to exec into pods
- You need to enable the UserNamespacesSupport [feature gate](#)

### Note:

The feature gate to enable user namespaces was previously named UserNamespacesStatelessPodsSupport, when only stateless pods were supported. Only Kubernetes v1.25 through to v1.27 recognise UserNamespacesStatelessPodsSupport.

The cluster that you're using **must** include at least one node that meets the [requirements](#) for using user namespaces with Pods.

If you have a mixture of nodes and only some of the nodes provide user namespace support for Pods, you also need to ensure that the user namespace Pods are [scheduled](#) to suitable nodes.

## Run a Pod that uses a user namespace

A user namespace for a pod is enabled setting the `hostUsers` field of `.spec` to `false`. For example:

[pods/user-namespaces-stateless.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: userns
spec:
 hostUsers: false
 containers:
 - name: shell
 command: ["sleep", "infinity"]
 image: debian
```

1. Create the pod on your cluster:

```
kubectl apply -f https://k8s.io/examples/pods/user-namespaces-stateless.yaml
```

2. Attach to the container and run `readlink /proc/self/ns/user`:

```
kubectl attach -it userns bash
```

Run this command:

```
readlink /proc/self/ns/user
```

The output is similar to:

```
user:[4026531837]
```

Also run:

```
cat /proc/self/uid_map
```

The output is similar to:

```
0 833617920 65536
```

Then, open a shell in the host and run the same commands.

The `readlink` command shows the user namespace the process is running in. It should be different when it is run on the host and inside the container.

The last number of the `uid_map` file inside the container must be 65536, on the host it must be a bigger number.

If you are running the kubelet inside a user namespace, you need to compare the output from running the command in the pod to the output of running in the host:

```
readlink /proc/$pid/ns/user
```

replacing \$pid with the kubelet PID.

## Create static Pods

*Static Pods* are managed directly by the kubelet daemon on a specific node, without the [API server](#) observing them. Unlike Pods that are managed by the control plane (for example, a [Deployment](#)); instead, the kubelet watches each static Pod (and restarts it if it fails).

Static Pods are always bound to one [Kubelet](#) on a specific node.

The kubelet automatically tries to create a [mirror Pod](#) on the Kubernetes API server for each static Pod. This means that the Pods running on a node are visible on the API server, but cannot be controlled from there. The Pod names will be suffixed with the node hostname with a leading hyphen.

### Note:

If you are running clustered Kubernetes and are using static Pods to run a Pod on every node, you should probably be using a [DaemonSet](#) instead.

### Note:

The spec of a static Pod cannot refer to other API objects (e.g., [ServiceAccount](#), [ConfigMap](#), [Secret](#), etc).

### Note:

Static pods do not support [ephemeral containers](#).

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter kubectl version.

This page assumes you're using [CRI-O](#) to run Pods, and that your nodes are running the Fedora operating system. Instructions for other distributions or Kubernetes installations may vary.

# Create a static pod

You can configure a static Pod with either a [file system hosted configuration file](#) or a [web hosted configuration file](#).

## Filesystem-hosted static Pod manifest

Manifests are standard Pod definitions in JSON or YAML format in a specific directory. Use the `staticPodPath: <the directory>` field in the [kubelet configuration file](#), which periodically scans the directory and creates/deletes static Pods as YAML/JSON files appear/disappear there. Note that the kubelet will ignore files starting with dots when scanning the specified directory.

For example, this is how to start a simple web server as a static Pod:

1. Choose a node where you want to run the static Pod. In this example, it's `my-node1`.

```
ssh my-node1
```

2. Choose a directory, say `/etc/kubernetes/manifests` and place a web server Pod definition there, for example `/etc/kubernetes/manifests/static-web.yaml`:

```
Run this command on the node where kubelet is running
mkdir -p /etc/kubernetes/manifests/
cat <<EOF >/etc/kubernetes/manifests/static-web.yaml
apiVersion: v1
kind: Pod
metadata:
 name: static-web
 labels:
 role: myrole
spec:
 containers:
 - name: web
 image: nginx
 ports:
 - name: web
 containerPort: 80
 protocol: TCP
EOF
```

3. Configure the kubelet on that node to set a `staticPodPath` value in the [kubelet configuration file](#).  
See [Set Kubelet Parameters Via A Configuration File](#) for more information.

An alternative and deprecated method is to configure the kubelet on that node to look for static Pod manifests locally, using a command line argument. To use the deprecated approach, start the kubelet with the `--pod-manifest-path=/etc/kubernetes/manifests/` argument.

4. Restart the kubelet. On Fedora, you would run:

```
Run this command on the node where the kubelet is running
systemctl restart kubelet
```

## Web-hosted static pod manifest

Kubelet periodically downloads a file specified by `--manifest-url=<URL>` argument and interprets it as a JSON/YAML file that contains Pod definitions. Similar to how [filesystem-hosted manifests](#) work, the kubelet refetches the manifest on a schedule. If there are changes to the list of static Pods, the kubelet applies them.

To use this approach:

1. Create a YAML file and store it on a web server so that you can pass the URL of that file to the kubelet.

```
apiVersion: v1
kind: Pod
metadata:
 name: static-web
 labels:
 role: myrole
spec:
 containers:
 - name: web
 image: nginx
 ports:
 - name: web
 containerPort: 80
 protocol: TCP
```

2. Configure the kubelet on your selected node to use this web manifest by running it with `--manifest-url=<manifest-url>`. On Fedora, edit `/etc/kubernetes/kubelet` to include this line:

```
KUBELET_ARGS="--cluster-dns=10.254.0.10 --cluster-domain=kube.local --manifest-
url=<manifest-url>"
```

3. Restart the kubelet. On Fedora, you would run:

```
Run this command on the node where the kubelet is running
systemctl restart kubelet
```

## Observe static pod behavior

When the kubelet starts, it automatically starts all defined static Pods. As you have defined a static Pod and restarted the kubelet, the new static Pod should already be running.

You can view running containers (including static Pods) by running (on the node):

```
Run this command on the node where the kubelet is running
crictl ps
```

The output might be something like:

CONTAINER POD ID	IMAGE	CREATED	STATE	NAME	ATTEMPT
---------------------	-------	---------	-------	------	---------

```
129fd7d382018 docker.io/library/nginx@sha256:... 11 minutes ago Running web 0
34533c6729106
```

**Note:**

crictl outputs the image URI and SHA-256 checksum. NAME will look more like: docker.io/library/nginx@sha256:0d17b565c37bcbd895e9d92315a05c1c3c9a29f762b011a10c54a66cd53c9b31.

You can see the mirror Pod on the API server:

```
kubectl get pods
```

NAME	READY	STATUS	RESTARTS	AGE
static-web-my-node1	1/1	Running	0	2m

**Note:**

Make sure the kubelet has permission to create the mirror Pod in the API server. If not, the creation request is rejected by the API server.

[Labels](#) from the static Pod are propagated into the mirror Pod. You can use those labels as normal via [selectors](#), etc.

If you try to use kubectl to delete the mirror Pod from the API server, the kubelet *doesn't* remove the static Pod:

```
kubectl delete pod static-web-my-node1
```

```
pod "static-web-my-node1" deleted
```

You can see that the Pod is still running:

```
kubectl get pods
```

NAME	READY	STATUS	RESTARTS	AGE
static-web-my-node1	1/1	Running	0	4s

Back on your node where the kubelet is running, you can try to stop the container manually. You'll see that, after a time, the kubelet will notice and will restart the Pod automatically:

```
Run these commands on the node where the kubelet is running
crictl stop 129fd7d382018 # replace with the ID of your container
sleep 20
crictl ps
```

CONTAINER POD ID	IMAGE	CREATED	STATE	NAME	ATTEMPT
89db4553e1eeb 34533c6729106	docker.io/library/nginx@sha256:...	19 seconds ago	Running	web	1

Once you identify the right container, you can get the logs for that container with crictl:

```
Run these commands on the node where the container is running
crictl logs <container_id>
```

```
10.240.0.48 - - [16/Nov/2022:12:45:49 +0000] "GET / HTTP/1.1" 200 612 "-" "curl/7.47.0" "-"
10.240.0.48 - - [16/Nov/2022:12:45:50 +0000] "GET / HTTP/1.1" 200 612 "-" "curl/7.47.0" "-"
10.240.0.48 - - [16/Nov/2022:12:45:51 +0000] "GET / HTTP/1.1" 200 612 "-" "curl/7.47.0" "-"
```

To find more about how to debug using `crictl`, please visit [Debugging Kubernetes nodes with crictl](#).

## Dynamic addition and removal of static pods

The running kubelet periodically scans the configured directory (`/etc/kubernetes/manifests` in our example) for changes and adds/removes Pods as files appear/disappear in this directory.

```
This assumes you are using filesystem-hosted static Pod configuration
Run these commands on the node where the container is running
#
mv /etc/kubernetes/manifests/static-web.yaml /tmp
sleep 20
crictl ps
You see that no nginx container is running
mv /tmp/static-web.yaml /etc/kubernetes/manifests/
sleep 20
crictl ps
```

CONTAINER POD ID	IMAGE	CREATED	STATE	NAME	ATTEMPT
f427638871c35 34533c6729106	docker.io/library/nginx@sha256:...	19 seconds ago	Running	web	1

- [Generate static Pod manifests for control plane components](#)
- [Generate static Pod manifest for local etcd](#)
- [Debugging Kubernetes nodes with crictl](#)
- [Learn more about crictl](#).
- [Map docker CLI commands to crictl](#).
- [Set up etcd instances as static pods managed by a kubelet](#)

## Translate a Docker Compose File to Kubernetes Resources

What's Kompose? It's a conversion tool for all things compose (namely Docker Compose) to container orchestrators (Kubernetes or OpenShift).

More information can be found on the Kompose website at <http://kompose.io>.

## Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at

least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

## Install Kompose

We have multiple ways to install Kompose. Our preferred method is downloading the binary from the latest GitHub release.

- [GitHub download](#)
- [Build from source](#)
- [CentOS package](#)
- [Fedora package](#)
- [Homebrew \(macOS\)](#)

Kompose is released via GitHub on a three-week cycle, you can see all current releases on the [GitHub release page](#).

```
Linux
curl -L https://github.com/kubernetes/kompose/releases/download/v1.26.0/kompose-linux-amd64 -o kompose

macOS
curl -L https://github.com/kubernetes/kompose/releases/download/v1.26.0/kompose-darwin-amd64 -o kompose

Windows
curl -L https://github.com/kubernetes/kompose/releases/download/v1.26.0/kompose-windows-amd64.exe -o kompose.exe

chmod +x kompose
sudo mv ./kompose /usr/local/bin/kompose
```

Alternatively, you can download the [tarball](#).

Installing using go get pulls from the master branch with the latest development changes.

```
go get -u github.com/kubernetes/kompose
```

Kompose is in [EPEL](#) CentOS repository. If you don't have [EPEL](#) repository already installed and enabled you can do it by running `sudo yum install epel-release`.

If you have [EPEL](#) enabled in your system, you can install Kompose like any other package.

```
sudo yum -y install kompose
```

Kompose is in Fedora 24, 25 and 26 repositories. You can install it like any other package.

```
sudo dnf -y install kompose
```

On macOS you can install the latest release via [Homebrew](#):

```
brew install kompose
```

## Use Kompose

In a few steps, we'll take you from Docker Compose to Kubernetes. All you need is an existing docker-compose.yml file.

1. Go to the directory containing your docker-compose.yml file. If you don't have one, test using this one.

```
version: "2"

services:

 redis-master:
 image: registry.k8s.io/redis:e2e
 ports:
 - "6379"

 redis-slave:
 image: gcr.io/google_samples/gb-redisslave:v3
 ports:
 - "6379"
 environment:
 - GET_HOSTS_FROM=dns

 frontend:
 image: gcr.io/google-samples/gb-frontend:v4
 ports:
 - "80:80"
 environment:
 - GET_HOSTS_FROM=dns
 labels:
 kompose.service.type: LoadBalancer
```

2. To convert the docker-compose.yml file to files that you can use with kubectl, run kompose convert and then kubectl apply -f <output file>.

```
kompose convert
```

The output is similar to:

```
INFO Kubernetes file "frontend-tcp-service.yaml" created
INFO Kubernetes file "redis-master-service.yaml" created
INFO Kubernetes file "redis-slave-service.yaml" created
INFO Kubernetes file "frontend-deployment.yaml" created
INFO Kubernetes file "redis-master-deployment.yaml" created
INFO Kubernetes file "redis-slave-deployment.yaml" created
```

```
kubectl apply -f frontend-tcp-service.yaml,redis-master-service.yaml,redis-slave-
service.yaml,frontend-deployment.yaml,redis-master-deployment.yaml,redis-slave-
deployment.yaml
```

The output is similar to:

```
service/frontend-tcp created
service/redis-master created
service/redis-slave created
deployment.apps/frontend created
deployment.apps/redis-master created
deployment.apps/redis-slave created
```

Your deployments are running in Kubernetes.

### 3. Access your application.

If you're already using minikube for your development process:

```
minikube service frontend
```

Otherwise, let's look up what IP your service is using!

```
kubectl describe svc frontend
```

```
Name: frontend-tcp
Namespace: default
Labels: io.kompose.service=frontend-tcp
Annotations: kompose.cmd: kompose convert
 kompose.service.type: LoadBalancer
 kompose.version: 1.26.0 (40646f47)
Selector: io.kompose.service=frontend
Type: LoadBalancer
IP Family Policy: SingleStack
IP Families: IPv4
IP: 10.43.67.174
IPs: 10.43.67.174
Port: 80 80/TCP
TargetPort: 80/TCP
NodePort: 80 31254/TCP
Endpoints: 10.42.0.25:80
Session Affinity: None
External Traffic Policy: Cluster
Events:
 Type Reason Age From Message
 ---- -
Normal EnsuringLoadBalancer 62s service-controller Ensuring load balancer
Normal AppliedDaemonSet 62s service-controller Applied LoadBalancer
DaemonSet kube-system/svclb-frontend-tcp-9362d276
```

If you're using a cloud provider, your IP will be listed next to LoadBalancer Ingress.

```
curl http://192.0.2.89
```

Clean-up.

4.

After you are finished testing out the example application deployment, simply run the following command in your shell to delete the resources used.

```
kubectl delete -f frontend-tcp-service.yaml,redis-master-service.yaml,redis-slave-
service.yaml,frontend-deployment.yaml,redis-master-deployment.yaml,redis-slave-
deployment.yaml
```

## User Guide

- CLI
  - [kompose convert](#)
- Documentation
  - [Alternative Conversions](#)
  - [Labels](#)
  - [Restart](#)
  - [Docker Compose Versions](#)

Kompose has support for two providers: OpenShift and Kubernetes. You can choose a targeted provider using global option `--provider`. If no provider is specified, Kubernetes is set by default.

## kompose convert

Kompose supports conversion of V1, V2, and V3 Docker Compose files into Kubernetes and OpenShift objects.

### Kubernetes kompose convert example

```
kompose --file docker-voting.yml convert
```

```
WARN Unsupported key networks - ignoring
WARN Unsupported key build - ignoring
INFO Kubernetes file "worker-svc.yaml" created
INFO Kubernetes file "db-svc.yaml" created
INFO Kubernetes file "redis-svc.yaml" created
INFO Kubernetes file "result-svc.yaml" created
INFO Kubernetes file "vote-svc.yaml" created
INFO Kubernetes file "redis-deployment.yaml" created
INFO Kubernetes file "result-deployment.yaml" created
INFO Kubernetes file "vote-deployment.yaml" created
INFO Kubernetes file "worker-deployment.yaml" created
INFO Kubernetes file "db-deployment.yaml" created
```

```
ls
```

```
db-deployment.yaml docker-compose.yml docker-gitlab.yml redis-deployment.yaml
result-deployment.yaml vote-deployment.yaml worker-deployment.yaml
db-svc.yaml docker-voting.yml redis-svc.yaml result-svc.yaml vote-
svc.yaml worker-svc.yaml
```

You can also provide multiple docker-compose files at the same time:

```
kompose -f docker-compose.yml -f docker-guestbook.yml convert
```

```
INFO Kubernetes file "frontend-service.yaml" created
INFO Kubernetes file "mlbparks-service.yaml" created
INFO Kubernetes file "mongodb-service.yaml" created
INFO Kubernetes file "redis-master-service.yaml" created
INFO Kubernetes file "redis-slave-service.yaml" created
INFO Kubernetes file "frontend-deployment.yaml" created
INFO Kubernetes file "mlbparks-deployment.yaml" created
INFO Kubernetes file "mongodb-deployment.yaml" created
INFO Kubernetes file "mongodb-claim0-persistentvolumeclaim.yaml" created
INFO Kubernetes file "redis-master-deployment.yaml" created
INFO Kubernetes file "redis-slave-deployment.yaml" created
```

```
ls
```

```
mlbparks-deployment.yaml mongodb-service.yaml redis-slave-
service.jsonmlbparks-service.yaml
frontend-deployment.yaml mongodb-claim0-persistentvolumeclaim.yaml redis-master-
service.yaml
frontend-service.yaml mongodb-deployment.yaml redis-slave-deployment.yaml
redis-master-deployment.yaml
```

When multiple docker-compose files are provided the configuration is merged. Any configuration that is common will be overridden by subsequent file.

## OpenShift kompose convert example

```
kompose --provider openshift --file docker-voting.yml convert
```

```
WARN [worker] Service cannot be created because of missing port.
INFO OpenShift file "vote-service.yaml" created
INFO OpenShift file "db-service.yaml" created
INFO OpenShift file "redis-service.yaml" created
INFO OpenShift file "result-service.yaml" created
INFO OpenShift file "vote-deploymentconfig.yaml" created
INFO OpenShift file "vote-imagestream.yaml" created
INFO OpenShift file "worker-deploymentconfig.yaml" created
INFO OpenShift file "worker-imagestream.yaml" created
INFO OpenShift file "db-deploymentconfig.yaml" created
INFO OpenShift file "db-imagestream.yaml" created
INFO OpenShift file "redis-deploymentconfig.yaml" created
INFO OpenShift file "redis-imagestream.yaml" created
INFO OpenShift file "result-deploymentconfig.yaml" created
INFO OpenShift file "result-imagestream.yaml" created
```

It also supports creating buildconfig for build directive in a service. By default, it uses the remote repo for the current git branch as the source repo, and the current branch as the source branch for the build. You can specify a different source repo and branch using `--build-repo` and `--build-branch` options respectively.

```
kompose --provider openshift --file buildconfig/docker-compose.yml convert
```

```
WARN [foo] Service cannot be created because of missing port.
INFO OpenShift Buildconfig using git@github.com:rtnpro/kompose.git::master as source.
INFO OpenShift file "foo-deploymentconfig.yaml" created
INFO OpenShift file "foo-imagestream.yaml" created
INFO OpenShift file "foo-buildconfig.yaml" created
```

#### Note:

If you are manually pushing the OpenShift artifacts using `oc create -f`, you need to ensure that you push the imagestream artifact before the buildconfig artifact, to workaround this OpenShift issue: <https://github.com/openshift/origin/issues/4518>.

## Alternative Conversions

The default kompose transformation will generate Kubernetes [Deployments](#) and [Services](#), in yaml format. You have alternative option to generate json with `-j`. Also, you can alternatively generate [Replication Controllers](#) objects, [Daemon Sets](#), or [Helm](#) charts.

```
kompose convert -j
INFO Kubernetes file "redis-svc.json" created
INFO Kubernetes file "web-svc.json" created
INFO Kubernetes file "redis-deployment.json" created
INFO Kubernetes file "web-deployment.json" created
```

The `*-deployment.json` files contain the Deployment objects.

```
kompose convert --replication-controller
INFO Kubernetes file "redis-svc.yaml" created
INFO Kubernetes file "web-svc.yaml" created
INFO Kubernetes file "redis-replicationcontroller.yaml" created
INFO Kubernetes file "web-replicationcontroller.yaml" created
```

The `*-replicationcontroller.yaml` files contain the Replication Controller objects. If you want to specify replicas (default is 1), use `--replicas` flag: `kompose convert --replication-controller --replicas 3`.

```
kompose convert --daemon-set
INFO Kubernetes file "redis-svc.yaml" created
INFO Kubernetes file "web-svc.yaml" created
INFO Kubernetes file "redis-daemonset.yaml" created
INFO Kubernetes file "web-daemonset.yaml" created
```

The `*-daemonset.yaml` files contain the DaemonSet objects.

If you want to generate a Chart to be used with [Helm](#) run:

```
kompose convert -c

INFO Kubernetes file "web-svc.yaml" created
INFO Kubernetes file "redis-svc.yaml" created
INFO Kubernetes file "web-deployment.yaml" created
INFO Kubernetes file "redis-deployment.yaml" created
chart created in "./docker-compose/"
```

```
tree docker-compose/
```

```
docker-compose
├── Chart.yaml
├── README.md
└── templates
 ├── redis-deployment.yaml
 ├── redis-svc.yaml
 ├── web-deployment.yaml
 └── web-svc.yaml
```

The chart structure is aimed at providing a skeleton for building your Helm charts.

## Labels

kompose supports Kompose-specific labels within the `docker-compose.yml` file in order to explicitly define a service's behavior upon conversion.

- `kompose.service.type` defines the type of service to be created.

For example:

```
version: "2"
services:
 nginx:
 image: nginx
 dockerfile: foobar
 build: ./foobar
 cap_add:
 - ALL
 container_name: foobar
 labels:
 kompose.service.type: nodeport
```

- `kompose.service.expose` defines if the service needs to be made accessible from outside the cluster or not. If the value is set to `"true"`, the provider sets the endpoint automatically, and for any other value, the value is set as the hostname. If multiple ports are defined in a service, the first one is chosen to be the exposed.
  - For the Kubernetes provider, an ingress resource is created and it is assumed that an ingress controller has already been configured.
  - For the OpenShift provider, a route is created.

For example:

```
version: "2"
services:
 web:
 image: tuna/docker-counter23
 ports:
 - "5000:5000"
 links:
 - redis
```

```
labels:
 kompose.service.expose: "counter.example.com"
redis:
 image: redis:3.0
ports:
 - "6379"
```

The currently supported options are:

Key	Value
kompose.service.type	nodeport / clusterip / loadbalancer
kompose.service.expose	true / hostname

**Note:**

The kompose.service.type label should be defined with ports only, otherwise kompose will fail.

## Restart

If you want to create normal pods without controllers you can use restart construct of docker-compose to define that. Follow table below to see what happens on the restart value.

docker-compose restart	object created	Pod restartPolicy
""	controller object	Always
always	controller object	Always
on-failure	Pod	OnFailure
no	Pod	Never

**Note:**

The controller object could be deployment or replicationcontroller.

For example, the pival service will become pod down here. This container calculated value of pi.

```
version: '2'

services:
 pival:
 image: perl
 command: ["perl", "-Mbignum=bpi", "-wle", "print bpi(2000)"]
 restart: "on-failure"
```

## Warning about Deployment Configurations

If the Docker Compose file has a volume specified for a service, the Deployment (Kubernetes) or DeploymentConfig (OpenShift) strategy is changed to "Recreate" instead of "RollingUpdate" (default). This is done to avoid multiple instances of a service from accessing a volume at the same time.

If the Docker Compose file has service name with `_` in it (for example, `web_service`), then it will be replaced by `-` and the service name will be renamed accordingly (for example, `web-service`). Kompose does this because "Kubernetes" doesn't allow `_` in object name.

Please note that changing service name might break some docker-compose files.

## Docker Compose Versions

Kompose supports Docker Compose versions: 1, 2 and 3. We have limited support on versions 2.1 and 3.2 due to their experimental nature.

A full list on compatibility between all three versions is listed in our [conversion document](#) including a list of all incompatible Docker Compose keys.

# Enforce Pod Security Standards by Configuring the Built-in Admission Controller

Kubernetes provides a built-in [admission controller](#) to enforce the [Pod Security Standards](#). You can configure this admission controller to set cluster-wide defaults and [exemptions](#).

## Before you begin

Following an alpha release in Kubernetes v1.22, Pod Security Admission became available by default in Kubernetes v1.23, as a beta. From version 1.25 onwards, Pod Security Admission is generally available.

To check the version, enter `kubectl version`.

If you are not running Kubernetes 1.30, you can switch to viewing this page in the documentation for the Kubernetes version that you are running.

## Configure the Admission Controller

### Note:

`pod-security.admission.config.k8s.io/v1` configuration requires v1.25+. For v1.23 and v1.24, use [v1beta1](#). For v1.22, use [v1alpha1](#).

```
apiVersion: apiserver.config.k8s.io/v1
kind: AdmissionConfiguration
plugins:
- name: PodSecurity
 configuration:
 apiVersion: pod-security.admission.config.k8s.io/v1 # see compatibility note
 kind: PodSecurityConfiguration
 # Defaults applied when a mode label is not set.
 #
```

```
Level label values must be one of:
- "privileged" (default)
- "baseline"
- "restricted"
#
Version label values must be one of:
- "latest" (default)
- specific version like "v1.30"
defaults:
 enforce: "privileged"
 enforce-version: "latest"
 audit: "privileged"
 audit-version: "latest"
 warn: "privileged"
 warn-version: "latest"
exemptions:
 # Array of authenticated usernames to exempt.
 usernames: []
 # Array of runtime class names to exempt.
 runtimeClasses: []
 # Array of namespaces to exempt.
 namespaces: []
```

#### Note:

The above manifest needs to be specified via the `--admission-control-config-file` to kube-apiserver.

## Enforce Pod Security Standards with Namespace Labels

Namespaces can be labeled to enforce the [Pod Security Standards](#). The three policies [privileged](#), [baseline](#) and [restricted](#) broadly cover the security spectrum and are implemented by the [Pod Security admission controller](#).

### Before you begin

Pod Security Admission was available by default in Kubernetes v1.23, as a beta. From version 1.25 onwards, Pod Security Admission is generally available.

To check the version, enter `kubectl version`.

### Requiring the baseline Pod Security Standard with namespace labels

This manifest defines a Namespace `my-baseline-namespace` that:

- *Blocks* any pods that don't satisfy the baseline policy requirements.

- Generates a user-facing warning and adds an audit annotation to any created pod that does not meet the restricted policy requirements.
- Pins the versions of the baseline and restricted policies to v1.30.

```
apiVersion: v1
kind: Namespace
metadata:
 name: my-baseline-namespace
 labels:
 pod-security.kubernetes.io/enforce: baseline
 pod-security.kubernetes.io/enforce-version: v1.30

 # We are setting these to our _desired_ `enforce` level.
 pod-security.kubernetes.io/audit: restricted
 pod-security.kubernetes.io/audit-version: v1.30
 pod-security.kubernetes.io/warn: restricted
 pod-security.kubernetes.io/warn-version: v1.30
```

## Add labels to existing namespaces with kubectl label

### Note:

When an enforce policy (or version) label is added or changed, the admission plugin will test each pod in the namespace against the new policy. Violations are returned to the user as warnings.

It is helpful to apply the `--dry-run` flag when initially evaluating security profile changes for namespaces. The Pod Security Standard checks will still be run in *dry run* mode, giving you information about how the new policy would treat existing pods, without actually updating a policy.

```
kubectl label --dry-run=server --overwrite ns --all \
 pod-security.kubernetes.io/enforce=baseline
```

### Applying to all namespaces

If you're just getting started with the Pod Security Standards, a suitable first step would be to configure all namespaces with audit annotations for a stricter level such as baseline:

```
kubectl label --overwrite ns --all \
 pod-security.kubernetes.io/audit=baseline \
 pod-security.kubernetes.io/warn=baseline
```

Note that this is not setting an enforce level, so that namespaces that haven't been explicitly evaluated can be distinguished. You can list namespaces without an explicitly set enforce level using this command:

```
kubectl get namespaces --selector='!pod-security.kubernetes.io/enforce'
```

## Applying to a single namespace

You can update a specific namespace as well. This command adds the `enforce=restricted` policy to my-existing-namespace, pinning the restricted policy version to v1.30.

```
kubectrl label --overwrite ns my-existing-namespace \
 pod-security.kubernetes.io/enforce=restricted \
 pod-security.kubernetes.io/enforce-version=v1.30
```

# Migrate from PodSecurityPolicy to the Built-In PodSecurity Admission Controller

This page describes the process of migrating from PodSecurityPolicies to the built-in PodSecurity admission controller. This can be done effectively using a combination of dry-run and audit and warn modes, although this becomes harder if mutating PSPs are used.

## Before you begin

Your Kubernetes server must be at or later than version v1.22. To check the version, enter `kubectrl version`.

If you are currently running a version of Kubernetes other than 1.30, you may want to switch to viewing this page in the documentation for the version of Kubernetes that you are actually running.

This page assumes you are already familiar with the basic [Pod Security Admission](#) concepts.

## Overall approach

There are multiple strategies you can take for migrating from PodSecurityPolicy to Pod Security Admission. The following steps are one possible migration path, with a goal of minimizing both the risks of a production outage and of a security gap.

1. Decide whether Pod Security Admission is the right fit for your use case.
2. Review namespace permissions
3. Simplify & standardize PodSecurityPolicies
4. Update namespaces
  1. Identify an appropriate Pod Security level
  2. Verify the Pod Security level
  3. Enforce the Pod Security level
  4. Bypass PodSecurityPolicy
5. Review namespace creation processes
6. Disable PodSecurityPolicy

## 0. Decide whether Pod Security Admission is right for you

Pod Security Admission was designed to meet the most common security needs out of the box, and to provide a standard set of security levels across clusters. However, it is less flexible than PodSecurityPolicy. Notably, the following features are supported by PodSecurityPolicy but not Pod Security Admission:

- **Setting default security constraints** - Pod Security Admission is a non-mutating admission controller, meaning it won't modify pods before validating them. If you were relying on this aspect of PSP, you will need to either modify your workloads to meet the Pod Security constraints, or use a [Mutating Admission Webhook](#) to make those changes. See [Simplify & Standardize PodSecurityPolicies](#) below for more detail.
- **Fine-grained control over policy definition** - Pod Security Admission only supports [3 standard levels](#). If you require more control over specific constraints, then you will need to use a [Validating Admission Webhook](#) to enforce those policies.
- **Sub-namespace policy granularity** - PodSecurityPolicy lets you bind different policies to different Service Accounts or users, even within a single namespace. This approach has many pitfalls and is not recommended, but if you require this feature anyway you will need to use a 3rd party webhook instead. The exception to this is if you only need to completely exempt specific users or [RuntimeClasses](#), in which case Pod Security Admission does expose some [static configuration for exemptions](#).

Even if Pod Security Admission does not meet all of your needs it was designed to be *complementary* to other policy enforcement mechanisms, and can provide a useful fallback running alongside other admission webhooks.

## 1. Review namespace permissions

Pod Security Admission is controlled by [labels on namespaces](#). This means that anyone who can update (or patch or create) a namespace can also modify the Pod Security level for that namespace, which could be used to bypass a more restrictive policy. Before proceeding, ensure that only trusted, privileged users have these namespace permissions. It is not recommended to grant these powerful permissions to users that shouldn't have elevated permissions, but if you must you will need to use an [admission webhook](#) to place additional restrictions on setting Pod Security labels on Namespace objects.

## 2. Simplify & standardize PodSecurityPolicies

In this section, you will reduce mutating PodSecurityPolicies and remove options that are outside the scope of the Pod Security Standards. You should make the changes recommended here to an offline copy of the original PodSecurityPolicy being modified. The cloned PSP should have a different name that is alphabetically before the original (for example, prepend a 0 to it). Do not create the new policies in Kubernetes yet - that will be covered in the [Rollout the updated policies](#) section below.

### 2.a. Eliminate purely mutating fields

If a PodSecurityPolicy is mutating pods, then you could end up with pods that don't meet the Pod Security level requirements when you finally turn PodSecurityPolicy off. In order to avoid

this, you should eliminate all PSP mutation prior to switching over. Unfortunately PSP does not cleanly separate mutating & validating fields, so this is not a straightforward migration.

You can start by eliminating the fields that are purely mutating, and don't have any bearing on the validating policy. These fields (also listed in the [Mapping PodSecurityPolicies to Pod Security Standards](#) reference) are:

- `.spec.defaultAllowPrivilegeEscalation`
- `.spec.runtimeClass.defaultRuntimeClassName`
- `.metadata.annotations['seccomp.security.alpha.kubernetes.io/defaultProfileName']`
- `.metadata.annotations['apparmor.security.beta.kubernetes.io/defaultProfileName']`
- `.spec.defaultAddCapabilities` - Although technically a mutating & validating field, these should be merged into `.spec.allowedCapabilities` which performs the same validation without mutation.

### **Caution:**

Removing these could result in workloads missing required configuration, and cause problems. See [Rollout the updated policies](#) below for advice on how to roll these changes out safely.

## **2.b. Eliminate options not covered by the Pod Security Standards**

There are several fields in PodSecurityPolicy that are not covered by the Pod Security Standards. If you must enforce these options, you will need to supplement Pod Security Admission with an [admission webhook](#), which is outside the scope of this guide.

First, you can remove the purely validating fields that the Pod Security Standards do not cover. These fields (also listed in the [Mapping PodSecurityPolicies to Pod Security Standards](#) reference with "no opinion") are:

- `.spec.allowedHostPaths`
- `.spec.allowedFlexVolumes`
- `.spec.allowedCSIDrivers`
- `.spec.forbiddenSysctls`
- `.spec.runtimeClass`

You can also remove the following fields, that are related to POSIX / UNIX group controls.

### **Caution:**

If any of these use the MustRunAs strategy they may be mutating! Removing these could result in workloads not setting the required groups, and cause problems. See [Rollout the updated policies](#) below for advice on how to roll these changes out safely.

- `.spec.runAsGroup`
- `.spec.supplementalGroups`
- `.spec.fsGroup`

The remaining mutating fields are required to properly support the Pod Security Standards, and will need to be handled on a case-by-case basis later:

- `.spec.requiredDropCapabilities` - Required to drop ALL for the Restricted profile.

- `.spec.seLinux` - (Only mutating with the `MustRunAs` rule) required to enforce the SELinux requirements of the Baseline & Restricted profiles.
- `.spec.runAsUser` - (Non-mutating with the `RunAsAny` rule) required to enforce `RunAsNonRoot` for the Restricted profile.
- `.spec.allowPrivilegeEscalation` - (Only mutating if set to false) required for the Restricted profile.

## 2.c. Rollout the updated PSPs

Next, you can rollout the updated policies to your cluster. You should proceed with caution, as removing the mutating options may result in workloads missing required configuration.

For each updated PodSecurityPolicy:

1. Identify pods running under the original PSP. This can be done using the `kubernetes.io/psp` annotation. For example, using `kubectl`:

```
PSP_NAME="original" # Set the name of the PSP you're checking for
kubectl get pods --all-namespaces -o jsonpath="{range .items[?
(@.metadata.annotations.kubernetes.io\psp=='$PSP_NAME')]}{.metadata.namespace}
{.metadata.name}}{'\n'}{end}"
```

2. Compare these running pods against the original pod spec to determine whether PodSecurityPolicy has modified the pod. For pods created by a [workload resource](#) you can compare the pod with the PodTemplate in the controller resource. If any changes are identified, the original Pod or PodTemplate should be updated with the desired configuration. The fields to review are:
  - `.metadata.annotations['container.apparmor.security.beta.kubernetes.io/*']` (replace \* with each container name)
  - `.spec.runtimeClassName`
  - `.spec.securityContext.fsGroup`
  - `.spec.securityContext.seccompProfile`
  - `.spec.securityContext.seLinuxOptions`
  - `.spec.securityContext.supplementalGroups`
  - On containers, under `.spec.containers[*]` and `.spec.initContainers[*]`:
    - `.securityContext.allowPrivilegeEscalation`
    - `.securityContext.capabilities.add`
    - `.securityContext.capabilities.drop`
    - `.securityContext.readOnlyRootFilesystem`
    - `.securityContext.runAsGroup`
    - `.securityContext.runAsNonRoot`
    - `.securityContext.runAsUser`
    - `.securityContext.seccompProfile`
    - `.securityContext.seLinuxOptions`
3. Create the new PodSecurityPolicies. If any Roles or ClusterRoles are granting use on all PSPs this could cause the new PSPs to be used instead of their mutating counter-parts.
4. Update your authorization to grant access to the new PSPs. In RBAC this means updating any Roles or ClusterRoles that grant the use permission on the original PSP to also grant it to the updated PSP.
5. Verify: after some soak time, rerun the command from step 1 to see if any pods are still using the original PSPs. Note that pods need to be recreated after the new policies have been rolled out before they can be fully verified.

6. (optional) Once you have verified that the original PSPs are no longer in use, you can delete them.

## 3. Update Namespaces

The following steps will need to be performed on every namespace in the cluster. Commands referenced in these steps use the `$NAMESPACE` variable to refer to the namespace being updated.

### 3.a. Identify an appropriate Pod Security level

Start reviewing the [Pod Security Standards](#) and familiarizing yourself with the 3 different levels.

There are several ways to choose a Pod Security level for your namespace:

1. **By security requirements for the namespace** - If you are familiar with the expected access level for the namespace, you can choose an appropriate level based on those requirements, similar to how one might approach this on a new cluster.
2. **By existing PodSecurityPolicies** - Using the [Mapping PodSecurityPolicies to Pod Security Standards](#) reference you can map each PSP to a Pod Security Standard level. If your PSPs aren't based on the Pod Security Standards, you may need to decide between choosing a level that is at least as permissive as the PSP, and a level that is at least as restrictive. You can see which PSPs are in use for pods in a given namespace with this command:

```
kubectl get pods -n $NAMESPACE -o jsonpath="{.items[*].metadata.annotations.kubernetes.io\psp}" | tr " " "\n" | sort -u
```

3. **By existing pods** - Using the strategies under [Verify the Pod Security level](#), you can test out both the Baseline and Restricted levels to see whether they are sufficiently permissive for existing workloads, and chose the least-privileged valid level.

#### Caution:

Options 2 & 3 above are based on *existing* pods, and may miss workloads that aren't currently running, such as CronJobs, scale-to-zero workloads, or other workloads that haven't rolled out.

### 3.b. Verify the Pod Security level

Once you have selected a Pod Security level for the namespace (or if you're trying several), it's a good idea to test it out first (you can skip this step if using the Privileged level). Pod Security includes several tools to help test and safely roll out profiles.

First, you can dry-run the policy, which will evaluate pods currently running in the namespace against the applied policy, without making the new policy take effect:

```
$LEVEL is the level to dry-run, either "baseline" or "restricted".
kubectl label --dry-run=server --overwrite ns $NAMESPACE pod-security.kubernetes.io/
enforce=$LEVEL
```

This command will return a warning for any *existing* pods that are not valid under the proposed level.

The second option is better for catching workloads that are not currently running: audit mode. When running under audit-mode (as opposed to enforcing), pods that violate the policy level are recorded in the audit logs, which can be reviewed later after some soak time, but are not forbidden. Warning mode works similarly, but returns the warning to the user immediately. You can set the audit level on a namespace with this command:

```
kubectl label --overwrite ns $NAMESPACE pod-security.kubernetes.io/audit=$LEVEL
```

If either of these approaches yield unexpected violations, you will need to either update the violating workloads to meet the policy requirements, or relax the namespace Pod Security level.

### 3.c. Enforce the Pod Security level

When you are satisfied that the chosen level can safely be enforced on the namespace, you can update the namespace to enforce the desired level:

```
kubectl label --overwrite ns $NAMESPACE pod-security.kubernetes.io/enforce=$LEVEL
```

### 3.d. Bypass PodSecurityPolicy

Finally, you can effectively bypass PodSecurityPolicy at the namespace level by binding the fully [privileged PSP](#) to all service accounts in the namespace.

```
The following cluster-scoped commands are only needed once.
kubectl apply -f privileged-psp.yaml
kubectl create clusterrole privileged-psp --verb use --resource podsecuritypolicies.policy --
resource-name privileged

Per-namespace disable
kubectl create -n $NAMESPACE rolebinding disable-psp --clusterrole privileged-psp --group
system:serviceaccounts:$NAMESPACE
```

Since the privileged PSP is non-mutating, and the PSP admission controller always prefers non-mutating PSPs, this will ensure that pods in this namespace are no longer being modified or restricted by PodSecurityPolicy.

The advantage to disabling PodSecurityPolicy on a per-namespace basis like this is if a problem arises you can easily roll the change back by deleting the RoleBinding. Just make sure the pre-existing PodSecurityPolicies are still in place!

```
Undo PodSecurityPolicy disablement.
kubectl delete -n $NAMESPACE rolebinding disable-psp
```

## 4. Review namespace creation processes

Now that existing namespaces have been updated to enforce Pod Security Admission, you should ensure that your processes and/or policies for creating new namespaces are updated to ensure that an appropriate Pod Security profile is applied to new namespaces.

You can also statically configure the Pod Security admission controller to set a default enforce, audit, and/or warn level for unlabeled namespaces. See [Configure the Admission Controller](#) for more information.

## 5. Disable PodSecurityPolicy

Finally, you're ready to disable PodSecurityPolicy. To do so, you will need to modify the admission configuration of the API server: [How do I turn off an admission controller?](#).

To verify that the PodSecurityPolicy admission controller is no longer enabled, you can manually run a test by impersonating a user without access to any PodSecurityPolicies (see the [PodSecurityPolicy example](#)), or by verifying in the API server logs. At startup, the API server outputs log lines listing the loaded admission controller plugins:

```
I0218 00:59:44.903329 13 plugins.go:158] Loaded 16 mutating admission controller(s)
successfully in the following order:
NamespaceLifecycle,LimitRanger,ServiceAccount,NodeRestriction,TaintNodesByCondition,Priority,DefaultTolerationSeconds,ExtendedResourceToleration,PersistentVolumeLabel,DefaultStorageClass,StorageObjectInUseProtection,RuntimeClass,DefaultIngressClass,MutatingAdmissionWebhook.
I0218 00:59:44.903350 13 plugins.go:161] Loaded 14 validating admission controller(s)
successfully in the following order:
LimitRanger,ServiceAccount,PodSecurity,Priority,PersistentVolumeClaimResize,RuntimeClass,CertificateApproval,CertificateSigning,CertificateSubjectRestriction,DenyServiceExternalIPs,ValidatingAdmissionWebhook,ResourceQuota.
```

You should see PodSecurity (in the validating admission controllers), and neither list should contain PodSecurityPolicy.

Once you are certain the PSP admission controller is disabled (and after sufficient soak time to be confident you won't need to roll back), you are free to delete your PodSecurityPolicies and any associated Roles, ClusterRoles, RoleBindings and ClusterRoleBindings (just make sure they don't grant any other unrelated permissions).

## Monitoring, Logging, and Debugging

Set up monitoring and logging to troubleshoot a cluster, or debug a containerized application.

Sometimes things go wrong. This guide is aimed at making them right. It has two sections:

- [Debugging your application](#) - Useful for users who are deploying code into Kubernetes and wondering why it is not working.
- [Debugging your cluster](#) - Useful for cluster administrators and people whose Kubernetes cluster is unhappy.

You should also check the known issues for the [release](#) you're using.

## Getting help

If your problem isn't answered by any of the guides above, there are variety of ways for you to get help from the Kubernetes community.

## Questions

The documentation on this site has been structured to provide answers to a wide range of questions. [Concepts](#) explain the Kubernetes architecture and how each component works, while [Setup](#) provides practical instructions for getting started. [Tasks](#) show how to accomplish commonly used tasks, and [Tutorials](#) are more comprehensive walkthroughs of real-world, industry-specific, or end-to-end development scenarios. The [Reference](#) section provides detailed documentation on the [Kubernetes API](#) and command-line interfaces (CLIs), such as [kubectl](#).

## Help! My question isn't covered! I need help now!

### Stack Exchange, Stack Overflow, or Server Fault

If you have questions related to *software development* for your containerized app, you can ask those on [Stack Overflow](#).

If you have Kubernetes questions related to *cluster management* or *configuration*, you can ask those on [Server Fault](#).

There are also several more specific Stack Exchange network sites which might be the right place to ask Kubernetes questions in areas such as [DevOps](#), [Software Engineering](#), or [InfoSec](#).

Someone else from the community may have already asked a similar question or may be able to help with your problem.

The Kubernetes team will also monitor [posts tagged Kubernetes](#). If there aren't any existing questions that help, **please ensure that your question is [on-topic on Stack Overflow](#), [Server Fault](#), or the Stack Exchange Network site you're asking on**, and read through the guidance on [how to ask a new question](#), before asking a new one!

### Slack

Many people from the Kubernetes community hang out on Kubernetes Slack in the [#kubernetes-users](#) channel. Slack requires registration; you can [request an invitation](#), and registration is open to everyone). Feel free to come and ask any and all questions. Once registered, access the [Kubernetes organisation in Slack](#) via your web browser or via Slack's own dedicated app.

Once you are registered, browse the growing list of channels for various subjects of interest. For example, people new to Kubernetes may also want to join the [#kubernetes-novice](#) channel. As another example, developers should join the [#kubernetes-contributors](#) channel.

There are also many country specific / local language channels. Feel free to join these channels for localized support and info:

Country / language specific Slack channels

## Forum

You're welcome to join the official Kubernetes Forum: [discuss.kubernetes.io](https://discuss.kubernetes.io).

## Bugs and feature requests

If you have what looks like a bug, or you would like to make a feature request, please use the [GitHub issue tracking system](#).

Before you file an issue, please search existing issues to see if your issue is already covered.

If filing a bug, please include detailed information about how to reproduce the problem, such as:

- Kubernetes version: kubectl version
- Cloud provider, OS distro, network configuration, and container runtime version
- Steps to reproduce the problem

# Troubleshooting Applications

Debugging common containerized application issues.

This doc contains a set of resources for fixing issues with containerized applications. It covers things like common issues with Kubernetes resources (like Pods, Services, or StatefulSets), advice on making sense of container termination messages, and ways to debug running containers.

[Get a Shell to a Running Container](#)

# Debug Pods

This guide is to help users debug applications that are deployed into Kubernetes and not behaving correctly. This is *not* a guide for people who want to debug their cluster. For that you should check out [this guide](#).

## Diagnosing the problem

The first step in troubleshooting is triage. What is the problem? Is it your Pods, your Replication Controller or your Service?

- [Debugging Pods](#)
- [Debugging Replication Controllers](#)
- [Debugging Services](#)

## Debugging Pods

The first step in debugging a Pod is taking a look at it. Check the current state of the Pod and recent events with the following command:

```
kubectl describe pods ${POD_NAME}
```

Look at the state of the containers in the pod. Are they all Running? Have there been recent restarts?

Continue debugging depending on the state of the pods.

### My pod stays pending

If a Pod is stuck in Pending it means that it can not be scheduled onto a node. Generally this is because there are insufficient resources of one type or another that prevent scheduling. Look at the output of the `kubectl describe ...` command above. There should be messages from the scheduler about why it can not schedule your pod. Reasons include:

- **You don't have enough resources:** You may have exhausted the supply of CPU or Memory in your cluster, in this case you need to delete Pods, adjust resource requests, or add new nodes to your cluster. See [Compute Resources document](#) for more information.
- **You are using hostPort:** When you bind a Pod to a hostPort there are a limited number of places that pod can be scheduled. In most cases, hostPort is unnecessary, try using a Service object to expose your Pod. If you do require hostPort then you can only schedule as many Pods as there are nodes in your Kubernetes cluster.

### My pod stays waiting

If a Pod is stuck in the Waiting state, then it has been scheduled to a worker node, but it can't run on that machine. Again, the information from `kubectl describe ...` should be informative.

The most common cause of `Waiting` pods is a failure to pull the image. There are three things to check:

- Make sure that you have the name of the image correct.
- Have you pushed the image to the registry?
- Try to manually pull the image to see if the image can be pulled. For example, if you use Docker on your PC, run `docker pull <image>`.

### **My pod stays terminating**

If a Pod is stuck in the `Terminating` state, it means that a deletion has been issued for the Pod, but the control plane is unable to delete the Pod object.

This typically happens if the Pod has a [finalizer](#) and there is an [admission webhook](#) installed in the cluster that prevents the control plane from removing the finalizer.

To identify this scenario, check if your cluster has any `ValidatingWebhookConfiguration` or `MutatingWebhookConfiguration` that target `UPDATE` operations for pods resources.

If the webhook is provided by a third-party:

- Make sure you are using the latest version.
- Disable the webhook for `UPDATE` operations.
- Report an issue with the corresponding provider.

If you are the author of the webhook:

- For a mutating webhook, make sure it never changes immutable fields on `UPDATE` operations. For example, changes to containers are usually not allowed.
- For a validating webhook, make sure that your validation policies only apply to new changes. In other words, you should allow Pods with existing violations to pass validation. This allows Pods that were created before the validating webhook was installed to continue running.

### **My pod is crashing or otherwise unhealthy**

Once your pod has been scheduled, the methods described in [Debug Running Pods](#) are available for debugging.

### **My pod is running but not doing what I told it to do**

If your pod is not behaving as you expected, it may be that there was an error in your pod description (e.g. `mypod.yaml` file on your local machine), and that the error was silently ignored when you created the pod. Often a section of the pod description is nested incorrectly, or a key name is typed incorrectly, and so the key is ignored. For example, if you misspelled `command` as `commnd` then the pod will be created but will not use the command line you intended it to use.

The first thing to do is to delete your pod and try creating it again with the `--validate` option. For example, run `kubectl apply --validate -f mypod.yaml`. If you misspelled `command` as `commnd` then will give an error like this:

```
I0805 10:43:25.129850 46757 schema.go:126] unknown field: commnd
I0805 10:43:25.129973 46757 schema.go:129] this may be a false alarm, see https://github.com/
kubernetes/kubernetes/issues/6842
pods/mypod
```

The next thing to check is whether the pod on the apiserver matches the pod you meant to create (e.g. in a yaml file on your local machine). For example, run `kubectl get pods/mypod -o yaml > mypod-on-apiserver.yaml` and then manually compare the original pod description, `mypod.yaml` with the one you got back from apiserver, `mypod-on-apiserver.yaml`. There will typically be some lines on the "apiserver" version that are not on the original version. This is expected. However, if there are lines on the original that are not on the apiserver version, then this may indicate a problem with your pod spec.

## Debugging Replication Controllers

Replication controllers are fairly straightforward. They can either create Pods or they can't. If they can't create pods, then please refer to the [instructions above](#) to debug your pods.

You can also use `kubectl describe rc ${CONTROLLER_NAME}` to introspect events related to the replication controller.

## Debugging Services

Services provide load balancing across a set of pods. There are several common problems that can make Services not work properly. The following instructions should help debug Service problems.

First, verify that there are endpoints for the service. For every Service object, the apiserver makes an endpoints resource available.

You can view this resource with:

```
kubectl get endpoints ${SERVICE_NAME}
```

Make sure that the endpoints match up with the number of pods that you expect to be members of your service. For example, if your Service is for an nginx container with 3 replicas, you would expect to see three different IP addresses in the Service's endpoints.

### My service is missing endpoints

If you are missing endpoints, try listing pods using the labels that Service uses. Imagine that you have a Service where the labels are:

```
...
spec:
 - selector:
 name: nginx
 type: frontend
```

You can use:

```
kubectl get pods --selector=name=nginx,type=frontend
```

to list pods that match this selector. Verify that the list matches the Pods that you expect to provide your Service. Verify that the pod's containerPort matches up with the Service's targetPort

### Network traffic is not forwarded

Please see [debugging service](#) for more information.

## What's next

If none of the above solves your problem, follow the instructions in [Debugging Service document](#) to make sure that your Service is running, has Endpoints, and your Pods are actually serving; you have DNS working, iptables rules installed, and kube-proxy does not seem to be misbehaving.

You may also visit [troubleshooting document](#) for more information.

# Debug Services

An issue that comes up rather frequently for new installations of Kubernetes is that a Service is not working properly. You've run your Pods through a Deployment (or other workload controller) and created a Service, but you get no response when you try to access it. This document will hopefully help you to figure out what's going wrong.

## Running commands in a Pod

For many steps here you will want to see what a Pod running in the cluster sees. The simplest way to do this is to run an interactive busybox Pod:

```
kubectrl run -it --rm --restart=Never busybox --image=gcr.io/google-containers/busybox sh
```

### Note:

If you don't see a command prompt, try pressing enter.

If you already have a running Pod that you prefer to use, you can run a command in it using:

```
kubectrl exec <POD-NAME> -c <CONTAINER-NAME> -- <COMMAND>
```

## Setup

For the purposes of this walk-through, let's run some Pods. Since you're probably debugging your own Service you can substitute your own details, or you can follow along and get a second data point.

```
kubectrl create deployment hostnames --image=registry.k8s.io/serve_hostname
```

```
deployment.apps/hostnames created
```

kubectl commands will print the type and name of the resource created or mutated, which can then be used in subsequent commands.

Let's scale the deployment to 3 replicas.

```
kubectl scale deployment hostnames --replicas=3
```

```
deployment.apps/hostnames scaled
```

Note that this is the same as if you had started the Deployment with the following YAML:

```
apiVersion: apps/v1
kind: Deployment
metadata:
 labels:
 app: hostnames
 name: hostnames
spec:
 selector:
 matchLabels:
 app: hostnames
 replicas: 3
 template:
 metadata:
 labels:
 app: hostnames
 spec:
 containers:
 - name: hostnames
 image: registry.k8s.io/serve_hostname
```

The label "app" is automatically set by kubectl create deployment to the name of the Deployment.

You can confirm your Pods are running:

```
kubectl get pods -l app=hostnames
```

NAME	READY	STATUS	RESTARTS	AGE
hostnames-632524106-bbpiw	1/1	Running	0	2m
hostnames-632524106-ly40y	1/1	Running	0	2m
hostnames-632524106-tlaok	1/1	Running	0	2m

You can also confirm that your Pods are serving. You can get the list of Pod IP addresses and test them directly.

```
kubectl get pods -l app=hostnames \
-o go-template='{{range .items}}{{.status.podIP}}{"\n"}}{{end}}'
```

```
10.244.0.5
10.244.0.6
10.244.0.7
```

The example container used for this walk-through serves its own hostname via HTTP on port 9376, but if you are debugging your own app, you'll want to use whatever port number your Pods are listening on.

From within a pod:

```
for ep in 10.244.0.5:9376 10.244.0.6:9376 10.244.0.7:9376; do
 wget -qO- $ep
done
```

This should produce something like:

```
hostnames-632524106-bbpiw
hostnames-632524106-ly40y
hostnames-632524106-tlaok
```

If you are not getting the responses you expect at this point, your Pods might not be healthy or might not be listening on the port you think they are. You might find `kubect` logs to be useful for seeing what is happening, or perhaps you need to `kubect` exec directly into your Pods and debug from there.

Assuming everything has gone to plan so far, you can start to investigate why your Service doesn't work.

## Does the Service exist?

The astute reader will have noticed that you did not actually create a Service yet - that is intentional. This is a step that sometimes gets forgotten, and is the first thing to check.

What would happen if you tried to access a non-existent Service? If you have another Pod that consumes this Service by name you would get something like:

```
wget -O- hostnames
```

```
Resolving hostnames (hostnames)... failed: Name or service not known.
wget: unable to resolve host address 'hostnames'
```

The first thing to check is whether that Service actually exists:

```
kubect
```

 get svc hostnames

```
No resources found.
Error from server (NotFound): services "hostnames" not found
```

Let's create the Service. As before, this is for the walk-through - you can use your own Service's details here.

```
kubect
```

 expose deployment hostnames --port=80 --target-port=9376

```
service/hostnames exposed
```

And read it back:

```
kubect
```

 get svc hostnames

NAME	TYPE	CLUSTER-IP	EXTERNAL-IP	PORT(S)	AGE
hostnames	ClusterIP	10.0.1.175	<none>	80/TCP	5s

Now you know that the Service exists.

As before, this is the same as if you had started the Service with YAML:

```
apiVersion: v1
kind: Service
metadata:
 labels:
 app: hostnames
 name: hostnames
spec:
 selector:
 app: hostnames
 ports:
 - name: default
 protocol: TCP
 port: 80
 targetPort: 9376
```

In order to highlight the full range of configuration, the Service you created here uses a different port number than the Pods. For many real-world Services, these values might be the same.

## Any Network Policy Ingress rules affecting the target Pods?

If you have deployed any Network Policy Ingress rules which may affect incoming traffic to `hostnames-*` Pods, these need to be reviewed.

Please refer to [Network Policies](#) for more details.

## Does the Service work by DNS name?

One of the most common ways that clients consume a Service is through a DNS name.

From a Pod in the same Namespace:

```
nslookup hostnames
```

```
Address 1: 10.0.0.10 kube-dns.kube-system.svc.cluster.local
```

```
Name: hostnames
```

```
Address 1: 10.0.1.175 hostnames.default.svc.cluster.local
```

If this fails, perhaps your Pod and Service are in different Namespaces, try a namespace-qualified name (again, from within a Pod):

```
nslookup hostnames.default
```

```
Address 1: 10.0.0.10 kube-dns.kube-system.svc.cluster.local
```

```
Name: hostnames.default
```

```
Address 1: 10.0.1.175 hostnames.default.svc.cluster.local
```

If this works, you'll need to adjust your app to use a cross-namespace name, or run your app and Service in the same Namespace. If this still fails, try a fully-qualified name:

```
nslookup hostnames.default.svc.cluster.local
```

```
Address 1: 10.0.0.10 kube-dns.kube-system.svc.cluster.local
```

```
Name: hostnames.default.svc.cluster.local
```

```
Address 1: 10.0.1.175 hostnames.default.svc.cluster.local
```

Note the suffix here: "default.svc.cluster.local". The "default" is the Namespace you're operating in. The "svc" denotes that this is a Service. The "cluster.local" is your cluster domain, which COULD be different in your own cluster.

You can also try this from a Node in the cluster:

#### **Note:**

10.0.0.10 is the cluster's DNS Service IP, yours might be different.

```
nslookup hostnames.default.svc.cluster.local 10.0.0.10
```

```
Server: 10.0.0.10
```

```
Address: 10.0.0.10#53
```

```
Name: hostnames.default.svc.cluster.local
```

```
Address: 10.0.1.175
```

If you are able to do a fully-qualified name lookup but not a relative one, you need to check that your /etc/resolv.conf file in your Pod is correct. From within a Pod:

```
cat /etc/resolv.conf
```

You should see something like:

```
nameserver 10.0.0.10
```

```
search default.svc.cluster.local svc.cluster.local cluster.local example.com
```

```
options ndots:5
```

The nameserver line must indicate your cluster's DNS Service. This is passed into kubelet with the --cluster-dns flag.

The search line must include an appropriate suffix for you to find the Service name. In this case it is looking for Services in the local Namespace ("default.svc.cluster.local"), Services in all Namespaces ("svc.cluster.local"), and lastly for names in the cluster ("cluster.local"). Depending on your own install you might have additional records after that (up to 6 total). The cluster suffix is passed into kubelet with the --cluster-domain flag. Throughout this document, the cluster suffix is assumed to be "cluster.local". Your own clusters might be configured differently, in which case you should change that in all of the previous commands.

The options line must set ndots high enough that your DNS client library considers search paths at all. Kubernetes sets this to 5 by default, which is high enough to cover all of the DNS names it generates.

## Does any Service work by DNS name?

If the above still fails, DNS lookups are not working for your Service. You can take a step back and see what else is not working. The Kubernetes master Service should always work. From within a Pod:

```
nslookup kubernetes.default
```

```
Server: 10.0.0.10
Address 1: 10.0.0.10 kube-dns.kube-system.svc.cluster.local

Name: kubernetes.default
Address 1: 10.0.0.1 kubernetes.default.svc.cluster.local
```

If this fails, please see the [kube-proxy](#) section of this document, or even go back to the top of this document and start over, but instead of debugging your own Service, debug the DNS Service.

## Does the Service work by IP?

Assuming you have confirmed that DNS works, the next thing to test is whether your Service works by its IP address. From a Pod in your cluster, access the Service's IP (from `kubectl get` above).

```
for i in $(seq 1 3); do
 wget -qO- 10.0.1.175:80
done
```

This should produce something like:

```
hostnames-632524106-bbpiw
hostnames-632524106-ly40y
hostnames-632524106-tlaok
```

If your Service is working, you should get correct responses. If not, there are a number of things that could be going wrong. Read on.

## Is the Service defined correctly?

It might sound silly, but you should really double and triple check that your Service is correct and matches your Pod's port. Read back your Service and verify it:

```
kubectl get service hostnames -o json
```

```
{
 "kind": "Service",
 "apiVersion": "v1",
 "metadata": {
```

```

 "name": "hostnames",
 "namespace": "default",
 "uid": "428c8b6c-24bc-11e5-936d-42010af0a9bc",
 "resourceVersion": "347189",
 "creationTimestamp": "2015-07-07T15:24:29Z",
 "labels": {
 "app": "hostnames"
 }
 },
 "spec": {
 "ports": [
 {
 "name": "default",
 "protocol": "TCP",
 "port": 80,
 "targetPort": 9376,
 "nodePort": 0
 }
],
 "selector": {
 "app": "hostnames"
 },
 "clusterIP": "10.0.1.175",
 "type": "ClusterIP",
 "sessionAffinity": "None"
 },
 "status": {
 "loadBalancer": {}
 }
}

```

- Is the Service port you are trying to access listed in `spec.ports[]`?
- Is the `targetPort` correct for your Pods (some Pods use a different port than the Service)?
- If you meant to use a numeric port, is it a number (9376) or a string "9376"?
- If you meant to use a named port, do your Pods expose a port with the same name?
- Is the port's protocol correct for your Pods?

## Does the Service have any Endpoints?

If you got this far, you have confirmed that your Service is correctly defined and is resolved by DNS. Now let's check that the Pods you ran are actually being selected by the Service.

Earlier you saw that the Pods were running. You can re-check that:

```
kubectl get pods -l app=hostnames
```

NAME	READY	STATUS	RESTARTS	AGE
hostnames-632524106-bbpiw	1/1	Running	0	1h
hostnames-632524106-ly40y	1/1	Running	0	1h
hostnames-632524106-tlaok	1/1	Running	0	1h

The `-l app=hostnames` argument is a label selector configured on the Service.

The "AGE" column says that these Pods are about an hour old, which implies that they are running fine and not crashing.

The "RESTARTS" column says that these pods are not crashing frequently or being restarted. Frequent restarts could lead to intermittent connectivity issues. If the restart count is high, read more about how to [debug pods](#).

Inside the Kubernetes system is a control loop which evaluates the selector of every Service and saves the results into a corresponding Endpoints object.

```
kubectl get endpoints hostnames
```

NAME	ENDPOINTS
hostnames	10.244.0.5:9376,10.244.0.6:9376,10.244.0.7:9376

This confirms that the endpoints controller has found the correct Pods for your Service. If the ENDPOINTS column is <none>, you should check that the spec.selector field of your Service actually selects for metadata.labels values on your Pods. A common mistake is to have a typo or other error, such as the Service selecting for app=hostnames, but the Deployment specifying run=hostnames, as in versions previous to 1.18, where the kubectl run command could have been also used to create a Deployment.

## Are the Pods working?

At this point, you know that your Service exists and has selected your Pods. At the beginning of this walk-through, you verified the Pods themselves. Let's check again that the Pods are actually working - you can bypass the Service mechanism and go straight to the Pods, as listed by the Endpoints above.

### Note:

These commands use the Pod port (9376), rather than the Service port (80).

From within a Pod:

```
for ep in 10.244.0.5:9376 10.244.0.6:9376 10.244.0.7:9376; do
 wget -qO- $ep
done
```

This should produce something like:

```
hostnames-632524106-bbpiw
hostnames-632524106-ly40y
hostnames-632524106-tlaok
```

You expect each Pod in the Endpoints list to return its own hostname. If this is not what happens (or whatever the correct behavior is for your own Pods), you should investigate what's happening there.

# Is the kube-proxy working?

If you get here, your Service is running, has Endpoints, and your Pods are actually serving. At this point, the whole Service proxy mechanism is suspect. Let's confirm it, piece by piece.

The default implementation of Services, and the one used on most clusters, is kube-proxy. This is a program that runs on every node and configures one of a small set of mechanisms for providing the Service abstraction. If your cluster does not use kube-proxy, the following sections will not apply, and you will have to investigate whatever implementation of Services you are using.

## Is kube-proxy running?

Confirm that kube-proxy is running on your Nodes. Running directly on a Node, you should get something like the below:

```
ps auxw | grep kube-proxy
```

```
root 4194 0.4 0.1 101864 17696 ? Sl Jul04 25:43 /usr/local/bin/kube-proxy --master=https://kubernetes-master --kubeconfig=/var/lib/kube-proxy/kubeconfig --v=2
```

Next, confirm that it is not failing something obvious, like contacting the master. To do this, you'll have to look at the logs. Accessing the logs depends on your Node OS. On some OSes it is a file, such as /var/log/kube-proxy.log, while other OSes use journalctl to access logs. You should see something like:

```
I1027 22:14:53.995134 5063 server.go:200] Running in resource-only container "/kube-proxy"
I1027 22:14:53.998163 5063 server.go:247] Using iptables Proxier.
I1027 22:14:54.038140 5063 proxier.go:352] Setting endpoints for "kube-system/kube-dns:dns-tcp" to [10.244.1.3:53]
I1027 22:14:54.038164 5063 proxier.go:352] Setting endpoints for "kube-system/kube-dns:dns" to [10.244.1.3:53]
I1027 22:14:54.038209 5063 proxier.go:352] Setting endpoints for "default/kubernetes:https" to [10.240.0.2:443]
I1027 22:14:54.038238 5063 proxier.go:429] Not syncing iptables until Services and Endpoints have been received from master
I1027 22:14:54.040048 5063 proxier.go:294] Adding new service "default/kubernetes:https" at 10.0.0.1:443/TCP
I1027 22:14:54.040154 5063 proxier.go:294] Adding new service "kube-system/kube-dns:dns" at 10.0.0.10:53/UDP
I1027 22:14:54.040223 5063 proxier.go:294] Adding new service "kube-system/kube-dns:dns-tcp" at 10.0.0.10:53/TCP
```

If you see error messages about not being able to contact the master, you should double-check your Node configuration and installation steps.

One of the possible reasons that kube-proxy cannot run correctly is that the required conntrack binary cannot be found. This may happen on some Linux systems, depending on how you are installing the cluster, for example, you are installing Kubernetes from scratch. If this is the case, you need to manually install the conntrack package (e.g. `sudo apt install conntrack` on Ubuntu) and then retry.

Kube-proxy can run in one of a few modes. In the log listed above, the line Using iptables Proxier indicates that kube-proxy is running in "iptables" mode. The most common other mode is "ipvs".

## Iptables mode

In "iptables" mode, you should see something like the following on a Node:

```
iptables-save | grep hostnames
```

```
-A KUBE-SEP-57KPRZ3JQVENLNBR -s 10.244.3.6/32 -m comment --comment "default/
hostnames:" -j MARK --set-xmark 0x00004000/0x00004000
-A KUBE-SEP-57KPRZ3JQVENLNBR -p tcp -m comment --comment "default/hostnames:" -m
tcp -j DNAT --to-destination 10.244.3.6:9376
-A KUBE-SEP-WNBA2IHDGP2BOBGZ -s 10.244.1.7/32 -m comment --comment "default/
hostnames:" -j MARK --set-xmark 0x00004000/0x00004000
-A KUBE-SEP-WNBA2IHDGP2BOBGZ -p tcp -m comment --comment "default/hostnames:" -m
tcp -j DNAT --to-destination 10.244.1.7:9376
-A KUBE-SEP-X3P2623AGDH6CDF3 -s 10.244.2.3/32 -m comment --comment "default/
hostnames:" -j MARK --set-xmark 0x00004000/0x00004000
-A KUBE-SEP-X3P2623AGDH6CDF3 -p tcp -m comment --comment "default/hostnames:" -m
tcp -j DNAT --to-destination 10.244.2.3:9376
-A KUBE-SERVICES -d 10.0.1.175/32 -p tcp -m comment --comment "default/hostnames: cluster
IP" -m tcp --dport 80 -j KUBE-SVC-NWV5X2332I4OT4T3
-A KUBE-SVC-NWV5X2332I4OT4T3 -m comment --comment "default/hostnames:" -m statistic
--mode random --probability 0.33332999982 -j KUBE-SEP-WNBA2IHDGP2BOBGZ
-A KUBE-SVC-NWV5X2332I4OT4T3 -m comment --comment "default/hostnames:" -m statistic
--mode random --probability 0.50000000000 -j KUBE-SEP-X3P2623AGDH6CDF3
-A KUBE-SVC-NWV5X2332I4OT4T3 -m comment --comment "default/hostnames:" -j KUBE-
SEP-57KPRZ3JQVENLNBR
```

For each port of each Service, there should be 1 rule in KUBE-SERVICES and one KUBE-SVC-`<hash>` chain. For each Pod endpoint, there should be a small number of rules in that KUBE-SVC-`<hash>` and one KUBE-SEP-`<hash>` chain with a small number of rules in it. The exact rules will vary based on your exact config (including node-ports and load-balancers).

## IPVS mode

In "ipvs" mode, you should see something like the following on a Node:

```
ipvsadm -ln
```

```
Prot LocalAddress:Port Scheduler Flags
-> RemoteAddress:Port Forward Weight ActiveConn InActConn
...
TCP 10.0.1.175:80 rr
-> 10.244.0.5:9376 Masq 1 0 0
-> 10.244.0.6:9376 Masq 1 0 0
-> 10.244.0.7:9376 Masq 1 0 0
...
```

For each port of each Service, plus any NodePorts, external IPs, and load-balancer IPs, kube-proxy will create a virtual server. For each Pod endpoint, it will create corresponding real

servers. In this example, service hostnames(10.0.1.175:80) has 3 endpoints(10.244.0.5:9376, 10.244.0.6:9376, 10.244.0.7:9376).

## Is kube-proxy proxying?

Assuming you do see one the above cases, try again to access your Service by IP from one of your Nodes:

```
curl 10.0.1.175:80
```

```
hostnames-632524106-bbpiw
```

If this still fails, look at the kube-proxy logs for specific lines like:

```
Setting endpoints for default/hostnames:default to [10.244.0.5:9376 10.244.0.6:9376 10.244.0.7:9376]
```

If you don't see those, try restarting kube-proxy with the `-v` flag set to 4, and then look at the logs again.

## Edge case: A Pod fails to reach itself via the Service IP

This might sound unlikely, but it does happen and it is supposed to work.

This can happen when the network is not properly configured for "hairpin" traffic, usually when kube-proxy is running in iptables mode and Pods are connected with bridge network. The Kubelet exposes a hairpin-mode [flag](#) that allows endpoints of a Service to loadbalance back to themselves if they try to access their own Service VIP. The hairpin-mode flag must either be set to hairpin-veth or promiscuous-bridge.

The common steps to trouble shoot this are as follows:

- Confirm hairpin-mode is set to hairpin-veth or promiscuous-bridge. You should see something like the below. hairpin-mode is set to promiscuous-bridge in the following example.

```
ps auxw | grep kubelet
```

```
root 3392 1.1 0.8 186804 65208 ? Sl 00:51 11:11 /usr/local/bin/kubelet --enable-debugging-handlers=true --config=/etc/kubernetes/manifests --allow-privileged=True --v=4 --cluster-dns=10.0.0.10 --cluster-domain=cluster.local --configure-cbr0=true --cgroup-root=/ --system-cgroups=/system --hairpin-mode=promiscuous-bridge --runtime-cgroups=/docker-daemon --kubelet-cgroups=/kubelet --babysit-daemons=true --max-pods=110 --serialize-image-pulls=false --outofdisk-transition-frequency=0
```

- Confirm the effective hairpin-mode. To do this, you'll have to look at kubelet log. Accessing the logs depends on your Node OS. On some OSes it is a file, such as `/var/log/kubelet.log`, while other OSes use `journalctl` to access logs. Please be noted that the effective hairpin mode may not match `--hairpin-mode` flag due to compatibility. Check if there is any log lines with key word hairpin in kubelet.log. There should be log lines indicating the effective hairpin mode, like something below.

```
I0629 00:51:43.648698 3252 kubelet.go:380] Hairpin mode set to "promiscuous-bridge"
```

- If the effective hairpin mode is `hairpin-veth`, ensure the Kubelet has the permission to operate in `/sys` on node. If everything works properly, you should see something like:

```
for intf in /sys/devices/virtual/net/cbr0/brif/*; do cat $intf/hairpin_mode; done
```

```
1
1
1
1
```

- If the effective hairpin mode is `promiscuous-bridge`, ensure Kubelet has the permission to manipulate linux bridge on node. If `cbr0` bridge is used and configured properly, you should see:

```
ifconfig cbr0 |grep PROMISC
```

```
UP BROADCAST RUNNING PROMISC MULTICAST MTU:1460 Metric:1
```

- Seek help if none of above works out.

## Seek help

If you get this far, something very strange is happening. Your Service is running, has Endpoints, and your Pods are actually serving. You have DNS working, and kube-proxy does not seem to be misbehaving. And yet your Service is not working. Please let us know what is going on, so we can help investigate!

Contact us on [Slack](#) or [Forum](#) or [GitHub](#).

## What's next

Visit the [troubleshooting overview document](#) for more information.

# Debug a StatefulSet

This task shows you how to debug a StatefulSet.

## Before you begin

- You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster.
- You should have a StatefulSet running that you want to investigate.

## Debugging a StatefulSet

In order to list all the pods which belong to a StatefulSet, which have a label `app.kubernetes.io/name=MyApp` set on them, you can use the following:

```
kubectl get pods -l app.kubernetes.io/name=MyApp
```

If you find that any Pods listed are in Unknown or Terminating state for an extended period of time, refer to the [Deleting StatefulSet Pods](#) task for instructions on how to deal with them. You can debug individual Pods in a StatefulSet using the [Debugging Pods](#) guide.

## What's next

Learn more about [debugging an init-container](#).

# Determine the Reason for Pod Failure

This page shows how to write and read a Container termination message.

Termination messages provide a way for containers to write information about fatal events to a location where it can be easily retrieved and surfaced by tools like dashboards and monitoring software. In most cases, information that you put in a termination message should also be written to the general [Kubernetes logs](#).

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

## Writing and reading a termination message

In this exercise, you create a Pod that runs one container. The manifest for that Pod specifies a command that runs when the container starts:

[debug/termination.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: termination-demo
spec:
 containers:
 - name: termination-demo-container
 image: debian
 command: ["/bin/sh"]
 args: ["-c", "sleep 10 && echo Sleep expired > /dev/termination-log"]
```

1. Create a Pod based on the YAML configuration file:

```
kubectl apply -f https://k8s.io/examples/debug/termination.yaml
```

In the YAML file, in the `command` and `args` fields, you can see that the container sleeps for 10 seconds and then writes "Sleep expired" to the `/dev/termination-log` file. After the container writes the "Sleep expired" message, it terminates.

2. Display information about the Pod:

```
kubectl get pod termination-demo
```

Repeat the preceding command until the Pod is no longer running.

3. Display detailed information about the Pod:

```
kubectl get pod termination-demo --output=yaml
```

The output includes the "Sleep expired" message:

```
apiVersion: v1
kind: Pod
...
 lastState:
 terminated:
 containerID: ...
 exitCode: 0
 finishedAt: ...
 message: |
 Sleep expired
 ...
```

4. Use a Go template to filter the output so that it includes only the termination message:

```
kubectl get pod termination-demo -o go-template="{{range .status.containerStatuses}}
{{.lastState.terminated.message}}{{end}}"
```

If you are running a multi-container Pod, you can use a Go template to include the container's name. By doing so, you can discover which of the containers is failing:

```
kubectl get pod multi-container-pod -o go-template='{{range .status.containerStatuses}}{{printf
"%s:\n%s\n\n" .name .lastState.terminated.message}}{{end}}'
```

## Customizing the termination message

Kubernetes retrieves termination messages from the termination message file specified in the `terminationMessagePath` field of a Container, which has a default value of `/dev/termination-log`. By customizing this field, you can tell Kubernetes to use a different file. Kubernetes use the contents from the specified file to populate the Container's status message on both success and failure.

The termination message is intended to be brief final status, such as an assertion failure message. The kubelet truncates messages that are longer than 4096 bytes.

The total message length across all containers is limited to 12KiB, divided equally among each container. For example, if there are 12 containers (`initContainers` or `containers`), each has 1024 bytes of available termination message space.

The default termination message path is `/dev/termination-log`. You cannot set the termination message path after a Pod is launched.

In the following example, the container writes termination messages to `/tmp/my-log` for Kubernetes to retrieve:

```
apiVersion: v1
kind: Pod
metadata:
 name: msg-path-demo
spec:
 containers:
 - name: msg-path-demo-container
 image: debian
 terminationMessagePath: "/tmp/my-log"
```

Moreover, users can set the `terminationMessagePolicy` field of a Container for further customization. This field defaults to "File" which means the termination messages are retrieved only from the termination message file. By setting the `terminationMessagePolicy` to "FallbackToLogsOnError", you can tell Kubernetes to use the last chunk of container log output if the termination message file is empty and the container exited with an error. The log output is limited to 2048 bytes or 80 lines, whichever is smaller.

## What's next

- See the `terminationMessagePath` field in [Container](#).
- See [ImagePullBackOff](#) in [Images](#).

- Learn about [Go templates](#).
- Learn about [Pod status](#) and [Pod phase](#).
- Learn about [container states](#).

## Debug Init Containers

This page shows how to investigate problems related to the execution of Init Containers. The example command lines below refer to the Pod as `<pod-name>` and the Init Containers as `<init-container-1>` and `<init-container-2>`.

### Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

- You should be familiar with the basics of [Init Containers](#).

- You should have [Configured an Init Container](#).

## Checking the status of Init Containers

Display the status of your pod:

```
kubectl get pod <pod-name>
```

For example, a status of Init:1/2 indicates that one of two Init Containers has completed successfully:

NAME	READY	STATUS	RESTARTS	AGE
<pod-name>	0/1	Init:1/2	0	7s

See [Understanding Pod status](#) for more examples of status values and their meanings.

## Getting details about Init Containers

View more detailed information about Init Container execution:

```
kubectl describe pod <pod-name>
```

For example, a Pod with two Init Containers might show the following:

Init Containers:

<init-container-1>:

Container ID: ...

...

State: Terminated

Reason: Completed

Exit Code: 0

Started: ...

Finished: ...

Ready: True

Restart Count: 0

...

<init-container-2>:

Container ID: ...

...

State: Waiting

Reason: CrashLoopBackOff

Last State: Terminated

Reason: Error

Exit Code: 1

Started: ...

Finished: ...

Ready: False

Restart Count: 3

...

You can also access the Init Container statuses programmatically by reading the `status.initContainerStatuses` field on the Pod Spec:

```
kubectl get pod nginx --template '{{.status.initContainerStatuses}}'
```

This command will return the same information as above in raw JSON.

## Accessing logs from Init Containers

Pass the Init Container name along with the Pod name to access its logs.

```
kubectl logs <pod-name> -c <init-container-2>
```

Init Containers that run a shell script print commands as they're executed. For example, you can do this in Bash by running `set -x` at the beginning of the script.

## Understanding Pod status

A Pod status beginning with `Init:` summarizes the status of Init Container execution. The table below describes some example status values that you might see while debugging Init Containers.

Status	Meaning
Init:N/M	The Pod has M Init Containers, and N have completed so far.
Init:Error	An Init Container has failed to execute.
Init:CrashLoopBackOff	An Init Container has failed repeatedly.
Pending	The Pod has not yet begun executing Init Containers.
PodInitializing or Running	The Pod has already finished executing Init Containers.

## Debug Running Pods

This page explains how to debug Pods running (or crashing) on a Node.

### Before you begin

- Your [Pod](#) should already be scheduled and running. If your Pod is not yet running, start with [Debugging Pods](#).
- For some of the advanced debugging steps you need to know on which Node the Pod is running and have shell access to run commands on that Node. You don't need that access to run the standard debug steps that use `kubectl`.

## Using `kubectl describe pod` to fetch details about pods

For this example we'll use a Deployment to create two pods, similar to the earlier example.

[application/nginx-with-request.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
 name: nginx-deployment
```

```
spec:
 selector:
 matchLabels:
 app: nginx
 replicas: 2
 template:
 metadata:
 labels:
 app: nginx
 spec:
 containers:
 - name: nginx
 image: nginx
 resources:
 limits:
 memory: "128Mi"
 cpu: "500m"
 ports:
 - containerPort: 80
```

Create deployment by running following command:

```
kubectl apply -f https://k8s.io/examples/application/nginx-with-request.yaml
```

```
deployment.apps/nginx-deployment created
```

Check pod status by following command:

```
kubectl get pods
```

NAME	READY	STATUS	RESTARTS	AGE
nginx-deployment-67d4bdd6f5-cx2nz	1/1	Running	0	13s
nginx-deployment-67d4bdd6f5-w6kd7	1/1	Running	0	13s

We can retrieve a lot more information about each of these pods using `kubectl describe pod`. For example:

```
kubectl describe pod nginx-deployment-67d4bdd6f5-w6kd7
```

```
Name: nginx-deployment-67d4bdd6f5-w6kd7
Namespace: default
Priority: 0
Node: kube-worker-1/192.168.0.113
Start Time: Thu, 17 Feb 2022 16:51:01 -0500
Labels: app=nginx
 pod-template-hash=67d4bdd6f5
Annotations: <none>
Status: Running
IP: 10.88.0.3
IPs:
 IP: 10.88.0.3
 IP: 2001:db8::1
Controlled By: ReplicaSet/nginx-deployment-67d4bdd6f5
Containers:
```

```

nginx:

```

Here you can see configuration information about the container(s) and Pod (labels, resource requirements, etc.), as well as status information about the container(s) and Pod (state, readiness, restart count, events, etc.).

The container state is one of Waiting, Running, or Terminated. Depending on the state, additional information will be provided -- here you can see that for a container in Running state, the system tells you when the container started.

Ready tells you whether the container passed its last readiness probe. (In this case, the container does not have a readiness probe configured; the container is assumed to be ready if no readiness probe is configured.)

Restart Count tells you how many times the container has been restarted; this information can be useful for detecting crash loops in containers that are configured with a restart policy of 'always.'

Currently the only Condition associated with a Pod is the binary Ready condition, which indicates that the pod is able to service requests and should be added to the load balancing pools of all matching services.

Lastly, you see a log of recent events related to your Pod. "From" indicates the component that is logging the event. "Reason" and "Message" tell you what happened.

## Example: debugging Pending Pods

A common scenario that you can detect using events is when you've created a Pod that won't fit on any node. For example, the Pod might request more resources than are free on any node, or it might specify a label selector that doesn't match any nodes. Let's say we created the previous Deployment with 5 replicas (instead of 2) and requesting 600 millicores instead of 500, on a four-node cluster where each (virtual) machine has 1 CPU. In that case one of the Pods will not be able to schedule. (Note that because of the cluster add-on pods such as fluentd, skydns, etc., that run on each node, if we requested 1000 millicores then none of the Pods would be able to schedule.)

```
kubectl get pods
```

NAME	READY	STATUS	RESTARTS	AGE
nginx-deployment-1006230814-6winp	1/1	Running	0	7m
nginx-deployment-1006230814-fmgu3	1/1	Running	0	7m
nginx-deployment-1370807587-6ekbw	1/1	Running	0	1m
nginx-deployment-1370807587-fg172	0/1	Pending	0	1m
nginx-deployment-1370807587-fz9sd	0/1	Pending	0	1m

To find out why the nginx-deployment-1370807587-fz9sd pod is not running, we can use kubectl describe pod on the pending Pod and look at its events:

```
kubectl describe pod nginx-deployment-1370807587-fz9sd
```

```
Name: nginx-deployment-1370807587-fz9sd
Namespace: default
Node: /
Labels: app=nginx,pod-template-hash=1370807587
Status: Pending
IP:
Controllers: ReplicaSet/nginx-deployment-1370807587
Containers:
 nginx:
```

```

Image: nginx
Port: 80/TCP
QoS Tier:
 memory: Guaranteed
 cpu: Guaranteed
Limits:
 cpu: 1
 memory: 128Mi
Requests:
 cpu: 1
 memory: 128Mi
Environment Variables:
Volumes:
 default-token-4bcbi:
 Type: Secret (a volume populated by a Secret)
 SecretName: default-token-4bcbi
Events:
 FirstSeen LastSeen Count From SubobjectPath Type
Reason Message

1m 48s 7 {default-scheduler } Warning
FailedScheduling pod (nginx-deployment-1370807587-fz9sd) failed to fit in any node
fit failure on node (kubernetes-node-6ta5): Node didn't have enough resource: CPU, requested:
1000, used: 1420, capacity: 2000
fit failure on node (kubernetes-node-wul5): Node didn't have enough resource: CPU,
requested: 1000, used: 1100, capacity: 2000

```

Here you can see the event generated by the scheduler saying that the Pod failed to schedule for reason FailedScheduling (and possibly others). The message tells us that there were not enough resources for the Pod on any of the nodes.

To correct this situation, you can use `kubectl scale` to update your Deployment to specify four or fewer replicas. (Or you could leave the one Pod pending, which is harmless.)

Events such as the ones you saw at the end of `kubectl describe pod` are persisted in etcd and provide high-level information on what is happening in the cluster. To list all events you can use

```
kubectl get events
```

but you have to remember that events are namespaced. This means that if you're interested in events for some namespaced object (e.g. what happened with Pods in namespace my-namespace) you need to explicitly provide a namespace to the command:

```
kubectl get events --namespace=my-namespace
```

To see events from all namespaces, you can use the `--all-namespaces` argument.

In addition to `kubectl describe pod`, another way to get extra information about a pod (beyond what is provided by `kubectl get pod`) is to pass the `-o yaml` output format flag to `kubectl get pod`. This will give you, in YAML format, even more information than `kubectl describe pod`--essentially all of the information the system has about the Pod. Here you will see things like

annotations (which are key-value metadata without the label restrictions, that is used internally by Kubernetes system components), restart policy, ports, and volumes.

```
kubectl get pod nginx-deployment-1006230814-6winp -o yaml
```

## Examining pod logs

First, look at the logs of the affected container:

```
kubectl logs ${POD_NAME} ${CONTAINER_NAME}
```

If your container has previously crashed, you can access the previous container's crash log with:

```
kubectl logs --previous ${POD_NAME} ${CONTAINER_NAME}
```

## Debugging with container exec

If the [container image](#) includes debugging utilities, as is the case with images built from Linux and Windows OS base images, you can run commands inside a specific container with `kubectl exec`:

```
kubectl exec ${POD_NAME} -c ${CONTAINER_NAME} -- ${CMD} ${ARG1} ${ARG2} ... ${ARGN}
```

### Note:

`-c ${CONTAINER_NAME}` is optional. You can omit it for Pods that only contain a single container.

As an example, to look at the logs from a running Cassandra pod, you might run

```
kubectl exec cassandra -- cat /var/log/cassandra/system.log
```

You can run a shell that's connected to your terminal using the `-i` and `-t` arguments to `kubectl exec`, for example:

```
kubectl exec -it cassandra -- sh
```

For more details, see [Get a Shell to a Running Container](#).

## Debugging with an ephemeral debug container

FEATURE STATE: Kubernetes v1.25 [stable]

[Ephemeral containers](#) are useful for interactive troubleshooting when `kubectl exec` is insufficient because a container has crashed or a container image doesn't include debugging utilities, such as with [distroless images](#).

### Example debugging using ephemeral containers

You can use the `kubectl debug` command to add ephemeral containers to a running Pod. First, create a pod for the example:

```
kubectl run ephemeral-demo --image=registry.k8s.io/pause:3.1 --restart=Never
```

The examples in this section use the `pause` container image because it does not contain debugging utilities, but this method works with all container images.

If you attempt to use `kubectl exec` to create a shell you will see an error because there is no shell in this container image.

```
kubectl exec -it ephemeral-demo -- sh
```

```
OCI runtime exec failed: exec failed: container_linux.go:346: starting container process caused "exec: \"sh\": executable file not found in $PATH": unknown
```

You can instead add a debugging container using `kubectl debug`. If you specify the `-i/--interactive` argument, `kubectl` will automatically attach to the console of the Ephemeral Container.

```
kubectl debug -it ephemeral-demo --image=busybox:1.28 --target=ephemeral-demo
```

```
Defaulting debug container name to debugger-8xzrl.
If you don't see a command prompt, try pressing enter.
/ #
```

This command adds a new `busybox` container and attaches to it. The `--target` parameter targets the process namespace of another container. It's necessary here because `kubectl run` does not enable [process namespace sharing](#) in the pod it creates.

#### Note:

The `--target` parameter must be supported by the [Container Runtime](#). When not supported, the Ephemeral Container may not be started, or it may be started with an isolated process namespace so that `ps` does not reveal processes in other containers.

You can view the state of the newly created ephemeral container using `kubectl describe`:

```
kubectl describe pod ephemeral-demo
```

```
...
Ephemeral Containers:
 debugger-8xzrl:
 Container ID: docker://
b888f9adfd15bd5739fefa39e1df4dd3c617b9902082b1cfdc29c4028ffb2eb
 Image: busybox
 Image ID: docker-pullable://
busybox@sha256:1828edd60c5efd34b2bf5dd3282ec0cc04d47b2ff9caa0b6d4f07a21d1c08084
 Port: <none>
 Host Port: <none>
 State: Running
 Started: Wed, 12 Feb 2020 14:25:42 +0100
 Ready: False
 Restart Count: 0
 Environment: <none>
 Mounts: <none>
...
```

Use `kubectl delete` to remove the Pod when you're finished:

```
kubectl delete pod ephemeral-demo
```

## Debugging using a copy of the Pod

Sometimes Pod configuration options make it difficult to troubleshoot in certain situations. For example, you can't run `kubectl exec` to troubleshoot your container if your container image does not include a shell or if your application crashes on startup. In these situations you can use `kubectl debug` to create a copy of the Pod with configuration values changed to aid debugging.

### Copying a Pod while adding a new container

Adding a new container can be useful when your application is running but not behaving as you expect and you'd like to add additional troubleshooting utilities to the Pod.

For example, maybe your application's container images are built on busybox but you need debugging utilities not included in busybox. You can simulate this scenario using `kubectl run`:

```
kubectl run myapp --image=busybox:1.28 --restart=Never -- sleep 1d
```

Run this command to create a copy of `myapp` named `myapp-debug` that adds a new Ubuntu container for debugging:

```
kubectl debug myapp -it --image=ubuntu --share-processes --copy-to=myapp-debug
```

Defaulting debug container name to `debugger-w7xmf`.  
If you don't see a command prompt, try pressing enter.  
`root@myapp-debug:/#`

#### Note:

- `kubectl debug` automatically generates a container name if you don't choose one using the `--container` flag.

- The `-i` flag causes `kubectl debug` to attach to the new container by default. You can prevent this by specifying `--attach=false`. If your session becomes disconnected you can reattach using `kubectl attach`.
- The `--share-processes` allows the containers in this Pod to see processes from the other containers in the Pod. For more information about how this works, see [Share Process Namespace between Containers in a Pod](#).

Don't forget to clean up the debugging Pod when you're finished with it:

```
kubectl delete pod myapp myapp-debug
```

## Copying a Pod while changing its command

Sometimes it's useful to change the command for a container, for example to add a debugging flag or because the application is crashing.

To simulate a crashing application, use `kubectl run` to create a container that immediately exits:

```
kubectl run --image=busybox:1.28 myapp -- false
```

You can see using `kubectl describe pod myapp` that this container is crashing:

```
Containers:
 myapp:
 Image: busybox
 ...
 Args:
 false
 State: Waiting
 Reason: CrashLoopBackOff
 Last State: Terminated
 Reason: Error
 Exit Code: 1
```

You can use `kubectl debug` to create a copy of this Pod with the command changed to an interactive shell:

```
kubectl debug myapp -it --copy-to=myapp-debug --container=myapp -- sh
```

If you don't see a command prompt, try pressing enter.  
/ #

Now you have an interactive shell that you can use to perform tasks like checking filesystem paths or running the container command manually.

### Note:

- To change the command of a specific container you must specify its name using `--container` or `kubectl debug` will instead create a new container to run the command you specified.
- The `-i` flag causes `kubectl debug` to attach to the container by default. You can prevent this by specifying `--attach=false`. If your session becomes disconnected you can reattach using `kubectl attach`.

Don't forget to clean up the debugging Pod when you're finished with it:

```
kubectl delete pod myapp myapp-debug
```

## Copying a Pod while changing container images

In some situations you may want to change a misbehaving Pod from its normal production container images to an image containing a debugging build or additional utilities.

As an example, create a Pod using `kubectl run`:

```
kubectl run myapp --image=busybox:1.28 --restart=Never -- sleep 1d
```

Now use `kubectl debug` to make a copy and change its container image to `ubuntu`:

```
kubectl debug myapp --copy-to=myapp-debug --set-image *=ubuntu
```

The syntax of `--set-image` uses the same `container_name=image` syntax as `kubectl set image`. `*=ubuntu` means change the image of all containers to `ubuntu`.

Don't forget to clean up the debugging Pod when you're finished with it:

```
kubectl delete pod myapp myapp-debug
```

## Debugging via a shell on the node

If none of these approaches work, you can find the Node on which the Pod is running and create a Pod running on the Node. To create an interactive shell on a Node using `kubectl debug`, run:

```
kubectl debug node/mynode -it --image=ubuntu
```

Creating debugging pod `node-debugger-mynode-pdx84` with container debugger on node `mynode`.

If you don't see a command prompt, try pressing enter.

```
root@ek8s:/#
```

When creating a debugging session on a node, keep in mind that:

- `kubectl debug` automatically generates the name of the new Pod based on the name of the Node.
- The root filesystem of the Node will be mounted at `/host`.
- The container runs in the host IPC, Network, and PID namespaces, although the pod isn't privileged, so reading some process information may fail, and `chroot /host` may fail.
- If you need a privileged pod, create it manually.

Don't forget to clean up the debugging Pod when you're finished with it:

```
kubectl delete pod node-debugger-mynode-pdx84
```

# Get a Shell to a Running Container

This page shows how to use `kubectl exec` to get a shell to a running container.

## Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

## Getting a shell to a container

In this exercise, you create a Pod that has one container. The container runs the `nginx` image. Here is the configuration file for the Pod:

[application/shell-demo.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
 name: shell-demo
spec:
 volumes:
 - name: shared-data
 emptyDir: {}
 containers:
 - name: nginx
 image: nginx
 volumeMounts:
 - name: shared-data
 mountPath: /usr/share/nginx/html
 hostNetwork: true
 dnsPolicy: Default
```

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/application/shell-demo.yaml
```

Verify that the container is running:

```
kubectl get pod shell-demo
```

Get a shell to the running container:

```
kubectl exec --stdin --tty shell-demo -- /bin/bash
```

**Note:**

The double dash (--) separates the arguments you want to pass to the command from the kubectl arguments.

In your shell, list the root directory:

```
Run this inside the container
ls /
```

In your shell, experiment with other commands. Here are some examples:

```
You can run these example commands inside the container
ls /
cat /proc/mounts
cat /proc/1/maps
apt-get update
apt-get install -y tcpdump
tcpdump
apt-get install -y lsof
lsof
apt-get install -y procps
ps aux
ps aux | grep nginx
```

## Writing the root page for nginx

Look again at the configuration file for your Pod. The Pod has an `emptyDir` volume, and the container mounts the volume at `/usr/share/nginx/html`.

In your shell, create an `index.html` file in the `/usr/share/nginx/html` directory:

```
Run this inside the container
echo 'Hello shell demo' > /usr/share/nginx/html/index.html
```

In your shell, send a GET request to the nginx server:

```
Run this in the shell inside your container
apt-get update
apt-get install curl
curl http://localhost/
```

The output shows the text that you wrote to the `index.html` file:

```
Hello shell demo
```

When you are finished with your shell, enter `exit`.

```
exit # To quit the shell in the container
```

## Running individual commands in a container

In an ordinary command window, not your shell, list the environment variables in the running container:

```
kubectl exec shell-demo -- env
```

Experiment with running other commands. Here are some examples:

```
kubectl exec shell-demo -- ps aux
kubectl exec shell-demo -- ls /
kubectl exec shell-demo -- cat /proc/1/mounts
```

## Opening a shell when a Pod has more than one container

If a Pod has more than one container, use `--container` or `-c` to specify a container in the `kubectl exec` command. For example, suppose you have a Pod named `my-pod`, and the Pod has two containers named *main-app* and *helper-app*. The following command would open a shell to the *main-app* container.

```
kubectl exec -i -t my-pod --container main-app -- /bin/bash
```

**Note:**

The short options `-i` and `-t` are the same as the long options `--stdin` and `--tty`

## What's next

- Read about [kubectl exec](#)

## Troubleshooting Clusters

Debugging common cluster issues.

This doc is about cluster troubleshooting; we assume you have already ruled out your application as the root cause of the problem you are experiencing. See the [application troubleshooting guide](#) for tips on application debugging. You may also visit the [troubleshooting overview document](#) for more information.

For troubleshooting [kubectl](#), refer to [Troubleshooting kubectl](#).

## Listing your cluster

The first thing to debug in your cluster is if your nodes are all registered correctly.

Run the following command:

```
kubectl get nodes
```

And verify that all of the nodes you expect to see are present and that they are all in the Ready state.

To get detailed information about the overall health of your cluster, you can run:

```
kubectl cluster-info dump
```

## Example: debugging a down/unreachable node

Sometimes when debugging it can be useful to look at the status of a node -- for example, because you've noticed strange behavior of a Pod that's running on the node, or to find out why a Pod won't schedule onto the node. As with Pods, you can use `kubectl describe node` and `kubectl get node -o yaml` to retrieve detailed information about nodes. For example, here's what you'll see if a node is down (disconnected from the network, or kubelet dies and won't restart, etc.). Notice the events that show the node is NotReady, and also notice that the pods are no longer running (they are evicted after five minutes of NotReady status).

```
kubectl get nodes
```

NAME	STATUS	ROLES	AGE	VERSION
kube-worker-1	NotReady	<none>	1h	v1.23.3
kubernetes-node-bols	Ready	<none>	1h	v1.23.3

## Looking at logs

For now, digging deeper into the cluster requires logging into the relevant machines. Here are the locations of the relevant log files. On systemd-based systems, you may need to use `journalctl` instead of examining log files.

### Control Plane nodes

- `/var/log/kube-apiserver.log` - API Server, responsible for serving the API
- `/var/log/kube-scheduler.log` - Scheduler, responsible for making scheduling decisions
- `/var/log/kube-controller-manager.log` - a component that runs most Kubernetes built-in [controllers](#), with the notable exception of scheduling (the kube-scheduler handles scheduling).

### Worker Nodes

- `/var/log/kubelet.log` - logs from the kubelet, responsible for running containers on the node

- `/var/log/kube-proxy.log` - logs from kube-proxy, which is responsible for directing traffic to Service endpoints

## Cluster failure modes

This is an incomplete list of things that could go wrong, and how to adjust your cluster setup to mitigate the problems.

### Contributing causes

- VM(s) shutdown
- Network partition within cluster, or between cluster and users
- Crashes in Kubernetes software
- Data loss or unavailability of persistent storage (e.g. GCE PD or AWS EBS volume)
- Operator error, for example, misconfigured Kubernetes software or application software

### Specific scenarios

- API server VM shutdown or apiserver crashing
  - Results
    - unable to stop, update, or start new pods, services, replication controller
    - existing pods and services should continue to work normally unless they depend on the Kubernetes API
- API server backing storage lost
  - Results
    - the kube-apiserver component fails to start successfully and become healthy
    - kubelets will not be able to reach it but will continue to run the same pods and provide the same service proxying
    - manual recovery or recreation of apiserver state necessary before apiserver is restarted
- Supporting services (node controller, replication controller manager, scheduler, etc) VM shutdown or crashes
  - currently those are colocated with the apiserver, and their unavailability has similar consequences as apiserver
  - in future, these will be replicated as well and may not be co-located
  - they do not have their own persistent state
- Individual node (VM or physical machine) shuts down
  - Results
    - pods on that Node stop running
- Network partition
  - Results
    - partition A thinks the nodes in partition B are down; partition B thinks the apiserver is down. (Assuming the master VM ends up in partition A.)
- Kubelet software fault
  - Results
    - crashing kubelet cannot start new pods on the node
    - kubelet might delete the pods or not
    - node marked unhealthy
    - replication controllers start new pods elsewhere
- Cluster operator error
  - Results
    - loss of pods, services, etc

- lost of apiserver backing store
- users unable to read API
- etc.

## Mitigations

- Action: Use the IaaS provider's automatic VM restarting feature for IaaS VMs
  - Mitigates: Apiserver VM shutdown or apiserver crashing
  - Mitigates: Supporting services VM shutdown or crashes
- Action: Use IaaS providers reliable storage (e.g. GCE PD or AWS EBS volume) for VMs with apiserver+etcd
  - Mitigates: Apiserver backing storage lost
- Action: Use [high-availability](#) configuration
  - Mitigates: Control plane node shutdown or control plane components (scheduler, API server, controller-manager) crashing
    - Will tolerate one or more simultaneous node or component failures
  - Mitigates: API server backing storage (i.e., etcd's data directory) lost
    - Assumes HA (highly-available) etcd configuration
- Action: Snapshot apiserver PDs/EBS-volumes periodically
  - Mitigates: Apiserver backing storage lost
  - Mitigates: Some cases of operator error
  - Mitigates: Some cases of Kubernetes software fault
- Action: use replication controller and services in front of pods
  - Mitigates: Node shutdown
  - Mitigates: Kubelet software fault
- Action: applications (containers) designed to tolerate unexpected restarts
  - Mitigates: Node shutdown
  - Mitigates: Kubelet software fault

## What's next

- Learn about the metrics available in the [Resource Metrics Pipeline](#)
- Discover additional tools for [monitoring resource usage](#)
- Use Node Problem Detector to [monitor node health](#)
- Use kubectl debug node to [debug Kubernetes nodes](#)
- Use crictl to [debug Kubernetes nodes](#)
- Get more information about [Kubernetes auditing](#)
- Use telepresence to [develop and debug services locally](#)

# Troubleshooting kubectl

This documentation is about investigating and diagnosing [kubectl](#) related issues. If you encounter issues accessing kubectl or connecting to your cluster, this document outlines various common scenarios and potential solutions to help identify and address the likely cause.

## Before you begin

- You need to have a Kubernetes cluster.
- You also need to have kubectl installed - see [install tools](#)

## Verify kubectl setup

Make sure you have installed and configured kubectl correctly on your local machine. Check the kubectl version to ensure it is up-to-date and compatible with your cluster.

Check kubectl version:

```
kubectl version
```

You'll see a similar output:

```
Client Version: version.Info{Major:"1", Minor:"27",
GitVersion:"v1.27.4",GitCommit:"fa3d7990104d7c1f16943a67f11b154b71f6a132",
GitTreeState:"clean",BuildDate:"2023-07-19T12:20:54Z", GoVersion:"go1.20.6", Compiler:"gc",
Platform:"linux/amd64"}
Kustomize Version: v5.0.1
Server Version: version.Info{Major:"1", Minor:"27",
GitVersion:"v1.27.3",GitCommit:"25b4e43193bcda6c7328a6d147b1fb73a33f1598",
GitTreeState:"clean",BuildDate:"2023-06-14T09:47:40Z", GoVersion:"go1.20.5", Compiler:"gc",
Platform:"linux/amd64"}
```

If you see Unable to connect to the server: dial tcp <server-ip>:8443: i/o timeout, instead of Server Version, you need to troubleshoot kubectl connectivity with your cluster.

Make sure you have installed the kubectl by following the [official documentation for installing kubectl](#), and you have properly configured the \$PATH environment variable.

## Check kubeconfig

The kubectl requires a kubeconfig file to connect to a Kubernetes cluster. The kubeconfig file is usually located under the ~/.kube/config directory. Make sure that you have a valid kubeconfig file. If you don't have a kubeconfig file, you can obtain it from your Kubernetes administrator, or you can copy it from your Kubernetes control plane's /etc/kubernetes/admin.conf directory. If you have deployed your Kubernetes cluster on a cloud platform and lost your kubeconfig file, you can re-generate it using your cloud provider's tools. Refer the cloud provider's documentation for re-generating a kubeconfig file.

Check if the \$KUBECONFIG environment variable is configured correctly. You can set \$KUBECONFIGenvironment variable or use the --kubeconfig parameter with the kubectl to specify the directory of a kubeconfig file.

## Check VPN connectivity

If you are using a Virtual Private Network (VPN) to access your Kubernetes cluster, make sure that your VPN connection is active and stable. Sometimes, VPN disconnections can lead to connection issues with the cluster. Reconnect to the VPN and try accessing the cluster again.

## Authentication and authorization

If you are using the token based authentication and the kubectl is returning an error regarding the authentication token or authentication server address, validate the Kubernetes authentication token and the authentication server address are configured properly.

If kubectl is returning an error regarding the authorization, make sure that you are using the valid user credentials. And you have the permission to access the resource that you have requested.

## Verify contexts

Kubernetes supports [multiple clusters and contexts](#). Ensure that you are using the correct context to interact with your cluster.

List available contexts:

```
kubectl config get-contexts
```

Switch to the appropriate context:

```
kubectl config use-context <context-name>
```

## API server and load balancer

The [kube-apiserver](#) server is the central component of a Kubernetes cluster. If the API server or the load balancer that runs in front of your API servers is not reachable or not responding, you won't be able to interact with the cluster.

Check the if the API server's host is reachable by using ping command. Check cluster's network connectivity and firewall. If your are using a cloud provider for deploying the cluster, check your cloud provider's health check status for the cluster's API server.

Verify the status of the load balancer (if used) to ensure it is healthy and forwarding traffic to the API server.

## TLS problems

The Kubernetes API server only serves HTTPS requests by default. In that case TLS problems may occur due to various reasons, such as certificate expiry or chain of trust validity.

You can find the TLS certificate in the kubeconfig file, located in the `~/.kube/config` directory. The `certificate-authority` attribute contains the CA certificate and the `client-certificate` attribute contains the client certificate.

Verify the expiry of these certificates:

```
openssl x509 -noout -dates -in $(kubectl config view --minify --output 'jsonpath={.clusters[0].cluster.certificate-authority}')
```

output:

```
notBefore=Sep 2 08:34:12 2023 GMT
notAfter=Aug 31 08:34:12 2033 GMT
```

```
openssl x509 -noout -dates -in $(kubectl config view --minify --output 'jsonpath={.users[0].user.client-certificate}')
```

output:

```
notBefore=Sep 2 08:34:12 2023 GMT
notAfter=Sep 2 08:34:12 2026 GMT
```

## Verify kubectl helpers

Some kubectl authentication helpers provide easy access to Kubernetes clusters. If you have used such helpers and are facing connectivity issues, ensure that the necessary configurations are still present.

Check kubectl configuration for authentication details:

```
kubectl config view
```

If you previously used a helper tool (for example, `kubectl-oidc-login`), ensure that it is still installed and configured correctly.

## Resource metrics pipeline

For Kubernetes, the *Metrics API* offers a basic set of metrics to support automatic scaling and similar use cases. This API makes information available about resource usage for node and pod, including metrics for CPU and memory. If you deploy the Metrics API into your cluster, clients of the Kubernetes API can then query for this information, and you can use Kubernetes' access control mechanisms to manage permissions to do so.

The [HorizontalPodAutoscaler](#) (HPA) and [VerticalPodAutoscaler](#) (VPA) use data from the metrics API to adjust workload replicas and resources to meet customer demand.

You can also view the resource metrics using the [kubectl top](#) command.

### Note:

The Metrics API, and the metrics pipeline that it enables, only offers the minimum CPU and memory metrics to enable automatic scaling using HPA and / or VPA. If you would like to

provide a more complete set of metrics, you can complement the simpler Metrics API by deploying a second [metrics pipeline](#) that uses the *Custom Metrics API*.

Figure 1 illustrates the architecture of the resource metrics pipeline.

JavaScript must be [enabled](#) to view this content

Figure 1. Resource Metrics Pipeline

The architecture components, from right to left in the figure, consist of the following:

- [cAdvisor](#): Daemon for collecting, aggregating and exposing container metrics included in Kubelet.
- [kubelet](#): Node agent for managing container resources. Resource metrics are accessible using the `/metrics/resource` and `/stats kubelet` API endpoints.
- [node level resource metrics](#): API provided by the kubelet for discovering and retrieving per-node summarized stats available through the `/metrics/resource` endpoint.
- [metrics-server](#): Cluster addon component that collects and aggregates resource metrics pulled from each kubelet. The API server serves Metrics API for use by HPA, VPA, and by the `kubectl top` command. Metrics Server is a reference implementation of the Metrics API.
- [Metrics API](#): Kubernetes API supporting access to CPU and memory used for workload autoscaling. To make this work in your cluster, you need an API extension server that provides the Metrics API.

#### Note:

cAdvisor supports reading metrics from cgroups, which works with typical container runtimes on Linux. If you use a container runtime that uses another resource isolation mechanism, for example virtualization, then that container runtime must support [CRI Container Metrics](#) in order for metrics to be available to the kubelet.

## Metrics API

FEATURE STATE: Kubernetes 1.8 [beta]

The metrics-server implements the Metrics API. This API allows you to access CPU and memory usage for the nodes and pods in your cluster. Its primary role is to feed resource usage metrics to K8s autoscaler components.

Here is an example of the Metrics API request for a minikube node piped through jq for easier reading:

```
kubectl get --raw "/apis/metrics.k8s.io/v1beta1/nodes/minikube" | jq "
```

Here is the same API call using curl:

```
curl http://localhost:8080/apis/metrics.k8s.io/v1beta1/nodes/minikube
```

Sample response:

```
{
 "kind": "NodeMetrics",
 "apiVersion": "metrics.k8s.io/v1beta1",
 "metadata": {
 "name": "minikube",
 "selfLink": "/apis/metrics.k8s.io/v1beta1/nodes/minikube",
 "creationTimestamp": "2022-01-27T18:48:43Z"
 },
 "timestamp": "2022-01-27T18:48:33Z",
 "window": "30s",
 "usage": {
 "cpu": "487558164n",
 "memory": "732212Ki"
 }
}
```

Here is an example of the Metrics API request for a kube-scheduler-minikube pod contained in the kube-system namespace and piped through jq for easier reading:

```
kubectl get --raw "/apis/metrics.k8s.io/v1beta1/namespaces/kube-system/pods/kube-scheduler-minikube" | jq "
```

Here is the same API call using curl:

```
curl http://localhost:8080/apis/metrics.k8s.io/v1beta1/namespaces/kube-system/pods/kube-scheduler-minikube
```

Sample response:

```
{
 "kind": "PodMetrics",
 "apiVersion": "metrics.k8s.io/v1beta1",
 "metadata": {
 "name": "kube-scheduler-minikube",
 "namespace": "kube-system",
 "selfLink": "/apis/metrics.k8s.io/v1beta1/namespaces/kube-system/pods/kube-scheduler-minikube",
 "creationTimestamp": "2022-01-27T19:25:00Z"
 },
}
```

```
"timestamp": "2022-01-27T19:24:31Z",
"window": "30s",
"containers": [
 {
 "name": "kube-scheduler",
 "usage": {
 "cpu": "9559630n",
 "memory": "22244Ki"
 }
 }
]
```

The Metrics API is defined in the [k8s.io/metrics](https://github.com/kubernetes/k8s.io/tree/master/metrics) repository. You must enable the [API aggregation layer](#) and register an [APIService](#) for the metrics.k8s.io API.

To learn more about the Metrics API, see [resource metrics API design](#), the [metrics-server repository](#) and the [resource metrics API](#).

#### **Note:**

You must deploy the metrics-server or alternative adapter that serves the Metrics API to be able to access it.

## **Measuring resource usage**

### **CPU**

CPU is reported as the average core usage measured in cpu units. One cpu, in Kubernetes, is equivalent to 1 vCPU/Core for cloud providers, and 1 hyper-thread on bare-metal Intel processors.

This value is derived by taking a rate over a cumulative CPU counter provided by the kernel (in both Linux and Windows kernels). The time window used to calculate CPU is shown under window field in Metrics API.

To learn more about how Kubernetes allocates and measures CPU resources, see [meaning of CPU](#).

### **Memory**

Memory is reported as the working set, measured in bytes, at the instant the metric was collected.

In an ideal world, the "working set" is the amount of memory in-use that cannot be freed under memory pressure. However, calculation of the working set varies by host OS, and generally makes heavy use of heuristics to produce an estimate.

The Kubernetes model for a container's working set expects that the container runtime counts anonymous memory associated with the container in question. The working set metric typically also includes some cached (file-backed) memory, because the host OS cannot always reclaim pages.

To learn more about how Kubernetes allocates and measures memory resources, see [meaning of memory](#).

## Metrics Server

The metrics-server fetches resource metrics from the kubelets and exposes them in the Kubernetes API server through the Metrics API for use by the HPA and VPA. You can also view these metrics using the `kubectl top` command.

The metrics-server uses the Kubernetes API to track nodes and pods in your cluster. The metrics-server queries each node over HTTP to fetch metrics. The metrics-server also builds an internal view of pod metadata, and keeps a cache of pod health. That cached pod health information is available via the extension API that the metrics-server makes available.

For example with an HPA query, the metrics-server needs to identify which pods fulfill the label selectors in the deployment.

The metrics-server calls the [kubelet](#) API to collect metrics from each node. Depending on the metrics-server version it uses:

- Metrics resource endpoint `/metrics/resource` in version v0.6.0+ or
- Summary API endpoint `/stats/summary` in older versions

## What's next

To learn more about the metrics-server, see the [metrics-server repository](#).

You can also check out the following:

- [metrics-server design](#)
- [metrics-server FAQ](#)
- [metrics-server known issues](#)
- [metrics-server releases](#)
- [Horizontal Pod Autoscaling](#)

To learn about how the kubelet serves node metrics, and how you can access those via the Kubernetes API, read [Node Metrics Data](#).

## Tools for Monitoring Resources

To scale an application and provide a reliable service, you need to understand how the application behaves when it is deployed. You can examine application performance in a Kubernetes cluster by examining the containers, [pods](#), [services](#), and the characteristics of the overall cluster. Kubernetes provides detailed information about an application's resource usage at each of these levels. This information allows you to evaluate your application's performance and where bottlenecks can be removed to improve overall performance.

In Kubernetes, application monitoring does not depend on a single monitoring solution. On new clusters, you can use [resource metrics](#) or [full metrics](#) pipelines to collect monitoring statistics.

# Resource metrics pipeline

The resource metrics pipeline provides a limited set of metrics related to cluster components such as the [Horizontal Pod Autoscaler](#) controller, as well as the `kubectl top` utility. These metrics are collected by the lightweight, short-term, in-memory [metrics-server](#) and are exposed via the `metrics.k8s.io` API.

`metrics-server` discovers all nodes on the cluster and queries each node's [kubelet](#) for CPU and memory usage. The kubelet acts as a bridge between the Kubernetes master and the nodes, managing the pods and containers running on a machine. The kubelet translates each pod into its constituent containers and fetches individual container usage statistics from the container runtime through the container runtime interface. If you use a container runtime that uses Linux cgroups and namespaces to implement containers, and the container runtime does not publish usage statistics, then the kubelet can look up those statistics directly (using code from [cAdvisor](#)). No matter how those statistics arrive, the kubelet then exposes the aggregated pod resource usage statistics through the `metrics-server` Resource Metrics API. This API is served at `/metrics/resource/v1beta1` on the kubelet's authenticated and read-only ports.

## Full metrics pipeline

A full metrics pipeline gives you access to richer metrics. Kubernetes can respond to these metrics by automatically scaling or adapting the cluster based on its current state, using mechanisms such as the Horizontal Pod Autoscaler. The monitoring pipeline fetches metrics from the kubelet and then exposes them to Kubernetes via an adapter by implementing either the `custom.metrics.k8s.io` or `external.metrics.k8s.io` API.

Kubernetes is designed to work with [OpenMetrics](#), which is one of the [CNCF Observability and Analysis - Monitoring Projects](#), built upon and carefully extending [Prometheus exposition format](#) in almost 100% backwards-compatible ways.

If you glance over at the [CNCF Landscape](#), you can see a number of monitoring projects that can work with Kubernetes by *scraping* metric data and using that to help you observe your cluster. It is up to you to select the tool or tools that suit your needs. The CNCF landscape for observability and analytics includes a mix of open-source software, paid-for software-as-a-service, and other commercial products.

When you design and implement a full metrics pipeline you can make that monitoring data available back to Kubernetes. For example, a `HorizontalPodAutoscaler` can use the processed metrics to work out how many Pods to run for a component of your workload.

Integration of a full metrics pipeline into your Kubernetes implementation is outside the scope of Kubernetes documentation because of the very wide scope of possible solutions.

The choice of monitoring platform depends heavily on your needs, budget, and technical resources. Kubernetes does not recommend any specific metrics pipeline; [many options](#) are available. Your monitoring system should be capable of handling the [OpenMetrics](#) metrics transmission standard and needs to be chosen to best fit into your overall design and deployment of your infrastructure platform.

## What's next

Learn about additional debugging tools, including:

- [Logging](#)
- [Monitoring](#)
- [Getting into containers via exec](#)
- [Connecting to containers via proxies](#)
- [Connecting to containers via port forwarding](#)
- [Inspect Kubernetes node with crictl](#)

## Monitor Node Health

*Node Problem Detector* is a daemon for monitoring and reporting about a node's health. You can run Node Problem Detector as a DaemonSet or as a standalone daemon. Node Problem Detector collects information about node problems from various daemons and reports these conditions to the API server as Node [Conditions](#) or as [Events](#).

To learn how to install and use Node Problem Detector, see [Node Problem Detector project documentation](#).

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

## Limitations

- Node Problem Detector uses the kernel log format for reporting kernel issues. To learn how to extend the kernel log format, see [Add support for another log format](#).

## Enabling Node Problem Detector

Some cloud providers enable Node Problem Detector as an [Addon](#). You can also enable Node Problem Detector with kubectl or by creating an Addon DaemonSet.

### Using kubectl to enable Node Problem Detector

kubectl provides the most flexible management of Node Problem Detector. You can overwrite the default configuration to fit it into your environment or to detect customized node problems. For example:

1. Create a Node Problem Detector configuration similar to `node-problem-detector.yaml`:

[debug/node-problem-detector.yaml](#)

```
apiVersion: apps/v1
kind: DaemonSet
metadata:
 name: node-problem-detector-v0.1
 namespace: kube-system
 labels:
 k8s-app: node-problem-detector
 version: v0.1
 kubernetes.io/cluster-service: "true"
spec:
 selector:
 matchLabels:
 k8s-app: node-problem-detector
 version: v0.1
 kubernetes.io/cluster-service: "true"
 template:
 metadata:
 labels:
 k8s-app: node-problem-detector
 version: v0.1
 kubernetes.io/cluster-service: "true"
 spec:
 hostNetwork: true
 containers:
 - name: node-problem-detector
 image: registry.k8s.io/node-problem-detector:v0.1
 securityContext:
 privileged: true
 resources:
 limits:
 cpu: "200m"
 memory: "100Mi"
 requests:
 cpu: "20m"
 memory: "20Mi"
 volumeMounts:
 - name: log
 mountPath: /log
 readOnly: true
 volumes:
 - name: log
 hostPath:
 path: /var/log/
```

**Note:**

You should verify that the system log directory is right for your operating system distribution.

2. Start node problem detector with kubectl:

```
kubectly apply -f https://k8s.io/examples/debug/node-problem-detector.yaml
```

## Using an Addon pod to enable Node Problem Detector

If you are using a custom cluster bootstrap solution and don't need to overwrite the default configuration, you can leverage the Addon pod to further automate the deployment.

Create `node-problem-detector.yaml`, and save the configuration in the Addon pod's directory /`etc/kubernetes/addons/node-problem-detector` on a control plane node.

## Overwrite the configuration

The [default configuration](#) is embedded when building the Docker image of Node Problem Detector.

However, you can use a [ConfigMap](#) to overwrite the configuration:

1. Change the configuration files in `config/`
2. Create the ConfigMap `node-problem-detector-config`:

```
kubectly create configmap node-problem-detector-config --from-file=config/
```

3. Change the `node-problem-detector.yaml` to use the ConfigMap:

[debug/node-problem-detector-configmap.yaml](#)

```
apiVersion: apps/v1
kind: DaemonSet
metadata:
 name: node-problem-detector-v0.1
 namespace: kube-system
 labels:
 k8s-app: node-problem-detector
 version: v0.1
 kubernetes.io/cluster-service: "true"
spec:
 selector:
 matchLabels:
 k8s-app: node-problem-detector
 version: v0.1
 kubernetes.io/cluster-service: "true"
 template:
 metadata:
 labels:
 k8s-app: node-problem-detector
 version: v0.1
 kubernetes.io/cluster-service: "true"
 spec:
 hostNetwork: true
 containers:
 - name: node-problem-detector
 image: registry.k8s.io/node-problem-detector:v0.1
```

```

securityContext:
 privileged: true
resources:
 limits:
 cpu: "200m"
 memory: "100Mi"
 requests:
 cpu: "20m"
 memory: "20Mi"
volumeMounts:
- name: log
 mountPath: /log
 readOnly: true
- name: config # Overwrite the config/ directory with ConfigMap volume
 mountPath: /config
 readOnly: true
volumes:
- name: log
 hostPath:
 path: /var/log/
- name: config # Define ConfigMap volume
 configMap:
 name: node-problem-detector-config

```

4. Recreate the Node Problem Detector with the new configuration file:

```

If you have a node-problem-detector running, delete before recreating
kubectl delete -f https://k8s.io/examples/debug/node-problem-detector.yaml
kubectl apply -f https://k8s.io/examples/debug/node-problem-detector-configmap.yaml

```

### Note:

This approach only applies to a Node Problem Detector started with kubectl.

Overwriting a configuration is not supported if a Node Problem Detector runs as a cluster Addon. The Addon manager does not support ConfigMap.

## Problem Daemons

A problem daemon is a sub-daemon of the Node Problem Detector. It monitors specific kinds of node problems and reports them to the Node Problem Detector. There are several types of supported problem daemons.

- A `SystemLogMonitor` type of daemon monitors the system logs and reports problems and metrics according to predefined rules. You can customize the configurations for different log sources such as [filelog](#), [kmsg](#), [kernel](#), [abrt](#), and [systemd](#).
- A `SystemStatsMonitor` type of daemon collects various health-related system stats as metrics. You can customize its behavior by updating its [configuration file](#).
- A `CustomPluginMonitor` type of daemon invokes and checks various node problems by running user-defined scripts. You can use different custom plugin monitors to monitor different problems and customize the daemon behavior by updating the [configuration file](#).

- A HealthChecker type of daemon checks the health of the kubelet and container runtime on a node.

## Adding support for other log format

The system log monitor currently supports file-based logs, journald, and kmsg. Additional sources can be added by implementing a new [log watcher](#).

## Adding custom plugin monitors

You can extend the Node Problem Detector to execute any monitor scripts written in any language by developing a custom plugin. The monitor scripts must conform to the plugin protocol in exit code and standard output. For more information, please refer to the [plugin interface proposal](#).

## Exporter

An exporter reports the node problems and/or metrics to certain backends. The following exporters are supported:

- **Kubernetes exporter:** this exporter reports node problems to the Kubernetes API server. Temporary problems are reported as Events and permanent problems are reported as Node Conditions.
- **Prometheus exporter:** this exporter reports node problems and metrics locally as Prometheus (or OpenMetrics) metrics. You can specify the IP address and port for the exporter using command line arguments.
- **Stackdriver exporter:** this exporter reports node problems and metrics to the Stackdriver Monitoring API. The exporting behavior can be customized using a [configuration file](#).

## Recommendations and restrictions

It is recommended to run the Node Problem Detector in your cluster to monitor node health. When running the Node Problem Detector, you can expect extra resource overhead on each node. Usually this is fine, because:

- The kernel log grows relatively slowly.
- A resource limit is set for the Node Problem Detector.
- Even under high load, the resource usage is acceptable. For more information, see the Node Problem Detector [benchmark result](#).

## Debugging Kubernetes nodes with crictl

FEATURE STATE: Kubernetes v1.11 [stable]

crictl is a command-line interface for CRI-compatible container runtimes. You can use it to inspect and debug container runtimes and applications on a Kubernetes node. crictl and its source are hosted in the [cri-tools](#) repository.

# Before you begin

crictl requires a Linux operating system with a CRI runtime.

## Installing crictl

You can download a compressed archive crictl from the cri-tools [release page](#), for several different architectures. Download the version that corresponds to your version of Kubernetes. Extract it and move it to a location on your system path, such as `/usr/local/bin/`.

## General usage

The crictl command has several subcommands and runtime flags. Use `crictl help` or `crictl <subcommand> help` for more details.

You can set the endpoint for crictl by doing one of the following:

- Set the `--runtime-endpoint` and `--image-endpoint` flags.
- Set the `CONTAINER_RUNTIME_ENDPOINT` and `IMAGE_SERVICE_ENDPOINT` environment variables.
- Set the endpoint in the configuration file `/etc/crictl.yaml`. To specify a different file, use the `--config=PATH_TO_FILE` flag when you run crictl.

### Note:

If you don't set an endpoint, crictl attempts to connect to a list of known endpoints, which might result in an impact to performance.

You can also specify timeout values when connecting to the server and enable or disable debugging, by specifying timeout or debug values in the configuration file or using the `--timeout` and `--debug` command-line flags.

To view or edit the current configuration, view or edit the contents of `/etc/crictl.yaml`. For example, the configuration when using the containerd container runtime would be similar to this:

```
runtime-endpoint: unix:///var/run/containerd/containerd.sock
image-endpoint: unix:///var/run/containerd/containerd.sock
timeout: 10
debug: true
```

To learn more about crictl, refer to the [crictl documentation](#).

## Example crictl commands

The following examples show some crictl commands and example output.

## Warning:

If you use `crictl` to create pod sandboxes or containers on a running Kubernetes cluster, the Kubelet will eventually delete them. `crictl` is not a general purpose workflow tool, but a tool that is useful for debugging.

## List pods

List all pods:

```
crictl pods
```

The output is similar to this:

POD ID	CREATED	STATE	NAME	NAMESPACE
ATTEMPT				
926f1b5a1d33a	About a minute ago	Ready	sh-84d7dcf559-4r2gq	
default 0				
4dccb216c4adb	About a minute ago	Ready	nginx-65899c769f-wv2gp	
default 0				
a86316e96fa89	17 hours ago	Ready	kube-proxy-gblk4	kube-system
0				
919630b8f81f1	17 hours ago	Ready	nvidia-device-plugin-zgbbv	kube-
system 0				

List pods by name:

```
crictl pods --name nginx-65899c769f-wv2gp
```

The output is similar to this:

POD ID	CREATED	STATE	NAME	NAMESPACE
ATTEMPT				
4dccb216c4adb	2 minutes ago	Ready	nginx-65899c769f-wv2gp	default 0

List pods by label:

```
crictl pods --label run=nginx
```

The output is similar to this:

POD ID	CREATED	STATE	NAME	NAMESPACE
ATTEMPT				
4dccb216c4adb	2 minutes ago	Ready	nginx-65899c769f-wv2gp	default 0

## List images

List all images:

```
crictl images
```

The output is similar to this:

IMAGE	TAG	IMAGE ID	SIZE
busybox	latest	8c811b4aec35f	1.15MB
k8s-gcrio.azureedge.net/hyperkube-amd64	v1.10.3	e179bbfe5d238	665MB

## Execute a command in a running container

```
crictl exec -i -t 1f73f2d81bf98 ls
```

The output is similar to this:

```
bin dev etc home proc root sys tmp usr var
```

## Get a container's logs

Get all container logs:

```
crictl logs 87d3992f84f74
```

The output is similar to this:

```
10.240.0.96 - - [06/Jun/2018:02:45:49 +0000] "GET / HTTP/1.1" 200 612 "-" "curl/7.47.0" "-"
10.240.0.96 - - [06/Jun/2018:02:45:50 +0000] "GET / HTTP/1.1" 200 612 "-" "curl/7.47.0" "-"
10.240.0.96 - - [06/Jun/2018:02:45:51 +0000] "GET / HTTP/1.1" 200 612 "-" "curl/7.47.0" "-"
```

Get only the latest N lines of logs:

```
crictl logs --tail=1 87d3992f84f74
```

The output is similar to this:

```
10.240.0.96 - - [06/Jun/2018:02:45:51 +0000] "GET / HTTP/1.1" 200 612 "-" "curl/7.47.0" "-"
```

## Run a pod sandbox

Using crictl to run a pod sandbox is useful for debugging container runtimes. On a running Kubernetes cluster, the sandbox will eventually be stopped and deleted by the Kubelet.

1. Create a JSON file like the following:

```
{
 "metadata": {
 "name": "nginx-sandbox",
 "namespace": "default",
 "attempt": 1,
 "uid": "hdishd83djaidwnduwk28bcsb"
```

```
},
"log_directory": "/tmp",
"linux": {
}
}
```

2. Use the `crictl runp` command to apply the JSON and run the sandbox.

```
crictl runp pod-config.json
```

The ID of the sandbox is returned.

## Create a container

Using `crictl` to create a container is useful for debugging container runtimes. On a running Kubernetes cluster, the container will eventually be stopped and deleted by the Kubelet.

1. Pull a busybox image

```
crictl pull busybox
```

```
Image is up to date for
busybox@sha256:141c253bc4c3fd0a201d32dc1f493bcf3fff003b6df416dea4f41046e0f37d47
```

2. Create configs for the pod and the container:

### Pod config:

```
{
 "metadata": {
 "name": "busybox-sandbox",
 "namespace": "default",
 "attempt": 1,
 "uid": "aewi4aeThua7ooShohbo1phoj"
 },
 "log_directory": "/tmp",
 "linux": {
 }
}
```

### Container config:

```
{
 "metadata": {
 "name": "busybox"
 },
 "image": {
 "image": "busybox"
 },
 "command": [
 "top"
],
 "log_path": "busybox.log",
 "linux": {

```

```
}
}
```

3. Create the container, passing the ID of the previously-created pod, the container config file, and the pod config file. The ID of the container is returned.

```
crictl create f84dd361f8dc51518ed291fbadd6db537b0496536c1d2d6c05ff943ce8c9a54f
container-config.json pod-config.json
```

4. List all containers and verify that the newly-created container has its state set to Created.

```
crictl ps -a
```

The output is similar to this:

CONTAINER ID	IMAGE	CREATED	STATE	NAME	ATTEMPT
3e025dd50a72d	busybox	32 seconds ago	Created	busybox	0

## Start a container

To start a container, pass its ID to `crictl start`:

```
crictl start 3e025dd50a72d956c4f14881fbb5b1080c9275674e95fb67f965f6478a957d60
```

The output is similar to this:

```
3e025dd50a72d956c4f14881fbb5b1080c9275674e95fb67f965f6478a957d60
```

Check the container has its state set to Running.

```
crictl ps
```

The output is similar to this:

CONTAINER ID	IMAGE	CREATED	STATE	NAME	ATTEMPT
3e025dd50a72d	busybox	About a minute ago	Running	busybox	0

# Auditing

Kubernetes *auditing* provides a security-relevant, chronological set of records documenting the sequence of actions in a cluster. The cluster audits the activities generated by users, by applications that use the Kubernetes API, and by the control plane itself.

Auditing allows cluster administrators to answer the following questions:

- what happened?

- when did it happen?
- who initiated it?
- on what did it happen?
- where was it observed?
- from where was it initiated?
- to where was it going?

Audit records begin their lifecycle inside the [kube-apiserver](#) component. Each request on each stage of its execution generates an audit event, which is then pre-processed according to a certain policy and written to a backend. The policy determines what's recorded and the backends persist the records. The current backend implementations include logs files and webhooks.

Each request can be recorded with an associated *stage*. The defined stages are:

- RequestReceived - The stage for events generated as soon as the audit handler receives the request, and before it is delegated down the handler chain.
- ResponseStarted - Once the response headers are sent, but before the response body is sent. This stage is only generated for long-running requests (e.g. watch).
- ResponseComplete - The response body has been completed and no more bytes will be sent.
- Panic - Events generated when a panic occurred.

#### Note:

The configuration of an [Audit Event configuration](#) is different from the [Event](#) API object.

The audit logging feature increases the memory consumption of the API server because some context required for auditing is stored for each request. Memory consumption depends on the audit logging configuration.

## Audit policy

Audit policy defines rules about what events should be recorded and what data they should include. The audit policy object structure is defined in the [audit.k8s.io API group](#). When an event is processed, it's compared against the list of rules in order. The first matching rule sets the *audit level* of the event. The defined audit levels are:

- None - don't log events that match this rule.
- Metadata - log request metadata (requesting user, timestamp, resource, verb, etc.) but not request or response body.
- Request - log event metadata and request body but not response body. This does not apply for non-resource requests.
- RequestResponse - log event metadata, request and response bodies. This does not apply for non-resource requests.

You can pass a file with the policy to kube-apiserver using the `--audit-policy-file` flag. If the flag is omitted, no events are logged. Note that the rules field **must** be provided in the audit policy file. A policy with no (0) rules is treated as illegal.

Below is an example audit policy file:

[audit/audit-policy.yaml](#)

```

apiVersion: audit.k8s.io/v1 # This is required.
kind: Policy
Don't generate audit events for all requests in RequestReceived stage.
omitStages:
 - "RequestReceived"
rules:
 # Log pod changes at RequestResponse level
 - level: RequestResponse
 resources:
 - group: ""
 # Resource "pods" doesn't match requests to any subresource of pods,
 # which is consistent with the RBAC policy.
 resources: ["pods"]
 # Log "pods/log", "pods/status" at Metadata level
 - level: Metadata
 resources:
 - group: ""
 resources: ["pods/log", "pods/status"]

 # Don't log requests to a configmap called "controller-leader"
 - level: None
 resources:
 - group: ""
 resources: ["configmaps"]
 resourceNames: ["controller-leader"]

 # Don't log watch requests by the "system:kube-proxy" on endpoints or services
 - level: None
 users: ["system:kube-proxy"]
 verbs: ["watch"]
 resources:
 - group: "" # core API group
 resources: ["endpoints", "services"]

 # Don't log authenticated requests to certain non-resource URL paths.
 - level: None
 userGroups: ["system:authenticated"]
 nonResourceURLs:
 - "/api*" # Wildcard matching.
 - "/version"

 # Log the request body of configmap changes in kube-system.
 - level: Request
 resources:
 - group: "" # core API group
 resources: ["configmaps"]
 # This rule only applies to resources in the "kube-system" namespace.
 # The empty string "" can be used to select non-namespaced resources.
 namespaces: ["kube-system"]

 # Log configmap and secret changes in all other namespaces at the Metadata level.
 - level: Metadata
 resources:

```

```

- group: "" # core API group
 resources: ["secrets", "configmaps"]

Log all other resources in core and extensions at the Request level.
- level: Request
 resources:
 - group: "" # core API group
 - group: "extensions" # Version of group should NOT be included.

A catch-all rule to log all other requests at the Metadata level.
- level: Metadata
 # Long-running requests like watches that fall under this rule will not
 # generate an audit event in RequestReceived.
 omitStages:
 - "RequestReceived"

```

You can use a minimal audit policy file to log all requests at the Metadata level:

```

Log all requests at the Metadata level.
apiVersion: audit.k8s.io/v1
kind: Policy
rules:
- level: Metadata

```

If you're crafting your own audit profile, you can use the audit profile for Google Container-Optimized OS as a starting point. You can check the [configure-helper.sh](#) script, which generates an audit policy file. You can see most of the audit policy file by looking directly at the script.

You can also refer to the [Policy configuration reference](#) for details about the fields defined.

## Audit backends

Audit backends persist audit events to an external storage. Out of the box, the kube-apiserver provides two backends:

- Log backend, which writes events into the filesystem
- Webhook backend, which sends events to an external HTTP API

In all cases, audit events follow a structure defined by the Kubernetes API in the [audit.k8s.io API group](#).

### Note:

In case of patches, request body is a JSON array with patch operations, not a JSON object with an appropriate Kubernetes API object. For example, the following request body is a valid patch request to `/apis/batch/v1/namespaces/some-namespace/jobs/some-job-name`:

```

[
 {
 "op": "replace",
 "path": "/spec/parallelism",
 "value": 0
 },

```

```
{
 "op": "remove",
 "path": "/spec/template/spec/containers/0/terminationMessagePolicy"
}
]
```

## Log backend

The log backend writes audit events to a file in [JSONlines](#) format. You can configure the log audit backend using the following kube-apiserver flags:

- `--audit-log-path` specifies the log file path that log backend uses to write audit events. Not specifying this flag disables log backend. `-` means standard out
- `--audit-log-maxage` defines the maximum number of days to retain old audit log files
- `--audit-log-maxbackup` defines the maximum number of audit log files to retain
- `--audit-log-maxsize` defines the maximum size in megabytes of the audit log file before it gets rotated

If your cluster's control plane runs the kube-apiserver as a Pod, remember to mount the `hostPath` to the location of the policy file and log file, so that audit records are persisted. For example:

```
- --audit-policy-file=/etc/kubernetes/audit-policy.yaml
- --audit-log-path=/var/log/kubernetes/audit/audit.log
```

then mount the volumes:

```
...
volumeMounts:
- mountPath: /etc/kubernetes/audit-policy.yaml
 name: audit
 readOnly: true
- mountPath: /var/log/kubernetes/audit/
 name: audit-log
 readOnly: false
```

and finally configure the `hostPath`:

```
...
volumes:
- name: audit
 hostPath:
 path: /etc/kubernetes/audit-policy.yaml
 type: File
- name: audit-log
 hostPath:
 path: /var/log/kubernetes/audit/
 type: DirectoryOrCreate
```

## Webhook backend

The webhook audit backend sends audit events to a remote web API, which is assumed to be a form of the Kubernetes API, including means of authentication. You can configure a webhook audit backend using the following kube-apiserver flags:

- `--audit-webhook-config-file` specifies the path to a file with a webhook configuration. The webhook configuration is effectively a specialized [kubeconfig](#).
- `--audit-webhook-initial-backoff` specifies the amount of time to wait after the first failed request before retrying. Subsequent requests are retried with exponential backoff.

The webhook config file uses the kubeconfig format to specify the remote address of the service and credentials used to connect to it.

## Event batching

Both log and webhook backends support batching. Using webhook as an example, here's the list of available flags. To get the same flag for log backend, replace `webhook` with `log` in the flag name. By default, batching is enabled in webhook and disabled in log. Similarly, by default throttling is enabled in webhook and disabled in log.

- `--audit-webhook-mode` defines the buffering strategy. One of the following:
  - `batch` - buffer events and asynchronously process them in batches. This is the default.
  - `blocking` - block API server responses on processing each individual event.
  - `blocking-strict` - Same as `blocking`, but when there is a failure during audit logging at the `RequestReceived` stage, the whole request to the kube-apiserver fails.

The following flags are used only in the batch mode:

- `--audit-webhook-batch-buffer-size` defines the number of events to buffer before batching. If the rate of incoming events overflows the buffer, events are dropped.
- `--audit-webhook-batch-max-size` defines the maximum number of events in one batch.
- `--audit-webhook-batch-max-wait` defines the maximum amount of time to wait before unconditionally batching events in the queue.
- `--audit-webhook-batch-throttle-qps` defines the maximum average number of batches generated per second.
- `--audit-webhook-batch-throttle-burst` defines the maximum number of batches generated at the same moment if the allowed QPS was underutilized previously.

## Parameter tuning

Parameters should be set to accommodate the load on the API server.

For example, if kube-apiserver receives 100 requests each second, and each request is audited only on `ResponseStarted` and `ResponseComplete` stages, you should account for  $\approx 200$  audit events being generated each second. Assuming that there are up to 100 events in a batch, you should set throttling level at least 2 queries per second. Assuming that the backend can take up to 5 seconds to write events, you should set the buffer size to hold up to 5 seconds of events; that is: 10 batches, or 1000 events.

In most cases however, the default parameters should be sufficient and you don't have to worry about setting them manually. You can look at the following Prometheus metrics exposed by kube-apiserver and in the logs to monitor the state of the auditing subsystem.

- `apiserver_audit_event_total` metric contains the total number of audit events exported.
- `apiserver_audit_error_total` metric contains the total number of events dropped due to an error during exporting.

## Log entry truncation

Both log and webhook backends support limiting the size of events that are logged. As an example, the following is the list of flags available for the log backend:

- `audit-log-truncate-enabled` whether event and batch truncating is enabled.
- `audit-log-truncate-max-batch-size` maximum size in bytes of the batch sent to the underlying backend.
- `audit-log-truncate-max-event-size` maximum size in bytes of the audit event sent to the underlying backend.

By default truncate is disabled in both webhook and log, a cluster administrator should set `audit-log-truncate-enabled` or `audit-webhook-truncate-enabled` to enable the feature.

## What's next

- Learn more about [Event](#) and the [Policy](#) resource types by reading the Audit configuration reference.

# Debugging Kubernetes Nodes With Kubectl

This page shows how to debug a [node](#) running on the Kubernetes cluster using `kubectl debug` command.

## Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version 1.2. To check the version, enter `kubectl version`.

You need to have permission to create Pods and to assign those new Pods to arbitrary nodes. You also need to be authorized to create Pods that access filesystems from the host.

# Debugging a Node using kubectl debug node

Use the `kubectl debug node` command to deploy a Pod to a Node that you want to troubleshoot. This command is helpful in scenarios where you can't access your Node by using an SSH connection. When the Pod is created, the Pod opens an interactive shell on the Node. To create an interactive shell on a Node named “mynode”, run:

```
kubectl debug node/mynode -it --image=ubuntu
```

Creating debugging pod node-debugger-mynode-pdx84 with container debugger on node mynode.

If you don't see a command prompt, try pressing enter.

```
root@mynode:/#
```

The debug command helps to gather information and troubleshoot issues. Commands that you might use include `ip`, `ifconfig`, `nc`, `ping`, and `ps` and so on. You can also install other tools, such as `mtr`, `tcpdump`, and `curl`, from the respective package manager.

## Note:

The debug commands may differ based on the image the debugging pod is using and these commands might need to be installed.

The debugging Pod can access the root filesystem of the Node, mounted at `/host` in the Pod. If you run your kubelet in a filesystem namespace, the debugging Pod sees the root for that namespace, not for the entire node. For a typical Linux node, you can look at the following paths to find relevant logs:

```
/host/var/log/kubelet.log
```

Logs from the kubelet, responsible for running containers on the node.

```
/host/var/log/kube-proxy.log
```

Logs from kube-proxy, which is responsible for directing traffic to Service endpoints.

```
/host/var/log/containerd.log
```

Logs from the containerd process running on the node.

```
/host/var/log/syslog
```

Shows general messages and information regarding the system.

```
/host/var/log/kern.log
```

Shows kernel logs.

When creating a debugging session on a Node, keep in mind that:

- `kubectl debug` automatically generates the name of the new pod, based on the name of the node.
- The root filesystem of the Node will be mounted at `/host`.
- Although the container runs in the host IPC, Network, and PID namespaces, the pod isn't privileged. This means that reading some process information might fail because access to that information is restricted to superusers. For example, `chroot /host` will fail. If you need a privileged pod, create it manually.

## Cleaning up

When you finish using the debugging Pod, delete it:

```
kubectl get pods
```

NAME	READY	STATUS	RESTARTS	AGE
node-debugger-mynode-pdx84	0/1	Completed	0	8m1s

```
Change the pod name accordingly
kubectl delete pod node-debugger-mynode-pdx84 --now
```

```
pod "node-debugger-mynode-pdx84" deleted
```

#### Note:

The `kubectl debug node` command won't work if the Node is down (disconnected from the network, or kubelet dies and won't restart, etc.). Check [debugging a down/unreachable node](#) in that case.

## Developing and debugging services locally using telepresence

**Note:** This section links to third party projects that provide functionality required by Kubernetes. The Kubernetes project authors aren't responsible for these projects, which are listed alphabetically. To add a project to this list, read the [content guide](#) before submitting a change. [More information](#).

Kubernetes applications usually consist of multiple, separate services, each running in its own container. Developing and debugging these services on a remote Kubernetes cluster can be cumbersome, requiring you to [get a shell on a running container](#) in order to run debugging tools.

telepresence is a tool to ease the process of developing and debugging services locally while proxying the service to a remote Kubernetes cluster. Using telepresence allows you to use custom tools, such as a debugger and IDE, for a local service and provides the service full access to ConfigMap, secrets, and the services running on the remote cluster.

This document describes using telepresence to develop and debug services running on a remote cluster locally.

### Before you begin

- Kubernetes cluster is installed
- `kubectl` is configured to communicate with the cluster
- [Telepresence](#) is installed

## Connecting your local machine to a remote Kubernetes cluster

After installing telepresence, run `telepresence connect` to launch its Daemon and connect your local workstation to the cluster.

```
$ telepresence connect
```

```
Launching Telepresence Daemon
```

```
...
```

```
Connected to context default (https://<cluster public IP>)
```

You can curl services using the Kubernetes syntax e.g. `curl -ik https://kubernetes.default`

## Developing or debugging an existing service

When developing an application on Kubernetes, you typically program or debug a single service. The service might require access to other services for testing and debugging. One option is to use the continuous deployment pipeline, but even the fastest deployment pipeline introduces a delay in the program or debug cycle.

Use the `telepresence intercept $SERVICE_NAME --port $LOCAL_PORT:$REMOTE_PORT` command to create an "intercept" for rerouting remote service traffic.

Where:

- `$SERVICE_NAME` is the name of your local service
- `$LOCAL_PORT` is the port that your service is running on your local workstation
- And `$REMOTE_PORT` is the port your service listens to in the cluster

Running this command tells Telepresence to send remote traffic to your local service instead of the service in the remote Kubernetes cluster. Make edits to your service source code locally, save, and see the corresponding changes when accessing your remote application take effect immediately. You can also run your local service using a debugger or any other local development tool.

## How does Telepresence work?

Telepresence installs a traffic-agent sidecar next to your existing application's container running in the remote cluster. It then captures all traffic requests going into the Pod, and instead of forwarding this to the application in the remote cluster, it routes all traffic (when you create a [global intercept](#) or a subset of the traffic (when you create a [personal intercept](#)) to your local development environment.

## What's next

If you're interested in a hands-on tutorial, check out [this tutorial](#) that walks through locally developing the Guestbook application on Google Kubernetes Engine.

For further reading, visit the [Telepresence website](#).

## Windows debugging tips

### Node-level troubleshooting

1. My Pods are stuck at "Container Creating" or restarting over and over

Ensure that your pause image is compatible with your Windows OS version. See [Pause container](#) to see the latest / recommended pause image and/or get more information.

**Note:**

If using containerd as your container runtime the pause image is specified in the `plugins.plugins.cri.sandbox_image` field of the `config.toml` configuration file.

2. My pods show status as `ErrImagePull` or `ImagePullBackOff`

Ensure that your Pod is getting scheduled to a [compatible](#) Windows Node.

More information on how to specify a compatible node for your Pod can be found in [this guide](#).

## Network troubleshooting

1. My Windows Pods do not have network connectivity

If you are using virtual machines, ensure that MAC spoofing is **enabled** on all the VM network adapter(s).

2. My Windows Pods cannot ping external resources

Windows Pods do not have outbound rules programmed for the ICMP protocol. However, TCP/UDP is supported. When trying to demonstrate connectivity to resources outside of the cluster, substitute `ping <IP>` with corresponding `curl <IP>` commands.

If you are still facing problems, most likely your network configuration in [cni.conf](#) deserves some extra attention. You can always edit this static file. The configuration update will apply to any new Kubernetes resources.

One of the Kubernetes networking requirements (see [Kubernetes model](#)) is for cluster communication to occur without NAT internally. To honor this requirement, there is an [ExceptionList](#) for all the communication where you do not want outbound NAT to occur. However, this also means that you need to exclude the external IP you are trying to query from the `ExceptionList`. Only then will the traffic originating from your Windows pods be SNAT'ed correctly to receive a response from the outside world. In this regard, your `ExceptionList` in `cni.conf` should look as follows:

```
"ExceptionList": [
 "10.244.0.0/16", # Cluster subnet
 "10.96.0.0/12", # Service subnet
 "10.127.130.0/24" # Management (host) subnet
]
```

3. My Windows node cannot access NodePort type Services

Local NodePort access from the node itself fails. This is a known limitation. NodePort access works from other nodes or external clients.

4. vNICs and HNS endpoints of containers are being deleted

This issue can be caused when the `hostname-override` parameter is not passed to [kube-proxy](#). To resolve it, users need to pass the hostname to kube-proxy as follows:

```
C:\k\kube-proxy.exe --hostname-override=$(hostname)
```

#### 5. My Windows node cannot access my services using the service IP

This is a known limitation of the networking stack on Windows. However, Windows Pods can access the Service IP.

#### 6. No network adapter is found when starting the kubelet

The Windows networking stack needs a virtual adapter for Kubernetes networking to work. If the following commands return no results (in an admin shell), virtual network creation — a necessary prerequisite for the kubelet to work — has failed:

```
Get-HnsNetwork | ? Name -ieq "cbr0"
Get-NetAdapter | ? Name -Like "vEthernet (Ethernet*)"
```

Often it is worthwhile to modify the [InterfaceName](#) parameter of the `start.ps1` script, in cases where the host's network adapter isn't "Ethernet". Otherwise, consult the output of the `start-kubelet.ps1` script to see if there are errors during virtual network creation.

#### 7. DNS resolution is not properly working

Check the DNS limitations for Windows in this [section](#).

#### 8. `kubectl port-forward` fails with "unable to do port forwarding: wincat not found"

This was implemented in Kubernetes 1.15 by including `wincat.exe` in the pause infrastructure container `mcr.microsoft.com/oss/kubernetes/pause:3.6`. Be sure to use a supported version of Kubernetes. If you would like to build your own pause infrastructure container be sure to include [wincat](#).

#### 9. My Kubernetes installation is failing because my Windows Server node is behind a proxy

If you are behind a proxy, the following PowerShell environment variables must be defined:

```
[Environment]::SetEnvironmentVariable("HTTP_PROXY", "http://proxy.example.com:80/", [EnvironmentVariableTarget]::Machine)
[Environment]::SetEnvironmentVariable("HTTPS_PROXY", "http://proxy.example.com:443/", [EnvironmentVariableTarget]::Machine)
```

## Flannel troubleshooting

#### 1. With Flannel, my nodes are having issues after rejoining a cluster

Whenever a previously deleted node is being re-joined to the cluster, flannelD tries to assign a new pod subnet to the node. Users should remove the old pod subnet configuration files in the following paths:

```
Remove-Item C:\k\SourceVip.json
Remove-Item C:\k\SourceVipRequest.json
```

Flanneld is stuck in "Waiting for the Network to be created"

2.

There are numerous reports of this [issue](#); most likely it is a timing issue for when the management IP of the flannel network is set. A workaround is to relaunch start.ps1 or relaunch it manually as follows:

```
[Environment]::SetEnvironmentVariable("NODE_NAME", "<Windows_Worker_Hostname>")
C:\flannel\flanneld.exe --kubeconfig-file=c:\k\config --
iface=<Windows_Worker_Node_IP> --ip-masq=1 --kube-subnet-mgr=1
```

3. My Windows Pods cannot launch because of missing /run/flannel/subnet.env

This indicates that Flannel didn't launch correctly. You can either try to restart flanneld.exe or you can copy the files over manually from /run/flannel/subnet.env on the Kubernetes master to C:\run\flannel\subnet.env on the Windows worker node and modify the FLANNEL\_SUBNET row to a different number. For example, if node subnet 10.244.4.1/24 is desired:

```
FLANNEL_NETWORK=10.244.0.0/16
FLANNEL_SUBNET=10.244.4.1/24
FLANNEL_MTU=1500
FLANNEL_IPMASQ=true
```

## Further investigation

If these steps don't resolve your problem, you can get help running Windows containers on Windows nodes in Kubernetes through:

- StackOverflow [Windows Server Container](#) topic
- Kubernetes Official Forum [discuss.kubernetes.io](#)
- Kubernetes Slack [#SIG-Windows Channel](#)

# Manage Kubernetes Objects

Declarative and imperative paradigms for interacting with the Kubernetes API.

---

[Declarative Management of Kubernetes Objects Using Configuration Files](#)

[Declarative Management of Kubernetes Objects Using Kustomize](#)

[Managing Kubernetes Objects Using Imperative Commands](#)

[Imperative Management of Kubernetes Objects Using Configuration Files](#)

[Update API Objects in Place Using kubectl patch](#)

Use kubectl patch to update Kubernetes API objects in place. Do a strategic merge patch or a JSON merge patch.

[Migrate Kubernetes Objects Using Storage Version Migration](#)

# Declarative Management of Kubernetes Objects Using Configuration Files

Kubernetes objects can be created, updated, and deleted by storing multiple object configuration files in a directory and using `kubectl` apply to recursively create and update those objects as needed. This method retains writes made to live objects without merging the changes back into the object configuration files. `kubectl diff` also gives you a preview of what changes apply will make.

## Before you begin

Install [kubectl](#).

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

## Trade-offs

The `kubectl` tool supports three kinds of object management:

- Imperative commands
- Imperative object configuration
- Declarative object configuration

See [Kubernetes Object Management](#) for a discussion of the advantages and disadvantage of each kind of object management.

## Overview

Declarative object configuration requires a firm understanding of the Kubernetes object definitions and configuration. Read and complete the following documents if you have not already:

- [Managing Kubernetes Objects Using Imperative Commands](#)
- [Imperative Management of Kubernetes Objects Using Configuration Files](#)

Following are definitions for terms used in this document:

- *object configuration file / configuration file*: A file that defines the configuration for a Kubernetes object. This topic shows how to pass configuration files to `kubectl` apply. Configuration files are typically stored in source control, such as Git.

- *live object configuration / live configuration*: The live configuration values of an object, as observed by the Kubernetes cluster. These are kept in the Kubernetes cluster storage, typically etcd.
- *declarative configuration writer / declarative writer*: A person or software component that makes updates to a live object. The live writers referred to in this topic make changes to object configuration files and run `kubectl apply` to write the changes.

## How to create objects

Use `kubectl apply` to create all objects, except those that already exist, defined by configuration files in a specified directory:

```
kubectl apply -f <directory>
```

This sets the `kubectl.kubernetes.io/last-applied-configuration: '{...}'` annotation on each object. The annotation contains the contents of the object configuration file that was used to create the object.

### Note:

Add the `-R` flag to recursively process directories.

Here's an example of an object configuration file:

[application/simple\\_deployment.yaml](https://k8s.io/examples/application/simple_deployment.yaml)

```
apiVersion: apps/v1
kind: Deployment
metadata:
 name: nginx-deployment
spec:
 selector:
 matchLabels:
 app: nginx
 minReadySeconds: 5
 template:
 metadata:
 labels:
 app: nginx
 spec:
 containers:
 - name: nginx
 image: nginx:1.14.2
 ports:
 - containerPort: 80
```

Run `kubectl diff` to print the object that will be created:

```
kubectl diff -f https://k8s.io/examples/application/simple_deployment.yaml
```

**Note:**

diff uses [server-side dry-run](#), which needs to be enabled on kube-apiserver.

Since diff performs a server-side apply request in dry-run mode, it requires granting PATCH, CREATE, and UPDATE permissions. See [Dry-Run Authorization](#) for details.

Create the object using kubectl apply:

```
kubectl apply -f https://k8s.io/examples/application/simple_deployment.yaml
```

Print the live configuration using kubectl get:

```
kubectl get -f https://k8s.io/examples/application/simple_deployment.yaml -o yaml
```

The output shows that the kubectl.kubernetes.io/last-applied-configuration annotation was written to the live configuration, and it matches the configuration file:

```
kind: Deployment
metadata:
 annotations:
 # ...
 # This is the json representation of simple_deployment.yaml
 # It was written by kubectl apply when the object was created
 kubectl.kubernetes.io/last-applied-configuration: |
 {"apiVersion":"apps/v1","kind":"Deployment",
 "metadata":{"annotations":{},"name":"nginx-deployment","namespace":"default"},
 "spec":{"minReadySeconds":5,"selector":{"matchLabels":{"app":"nginx"}},
 "template":{"metadata":
{"labels":{"app":"nginx"}},
 "spec":{"containers":[{"image":"nginx:1.14.2","name":"nginx",
 "ports":[{"containerPort":80}]}}}}}}
 # ...
spec:
 # ...
 minReadySeconds: 5
 selector:
 matchLabels:
 # ...
 app: nginx
 template:
 metadata:
 # ...
 labels:
 app: nginx
 spec:
 containers:
 - image: nginx:1.14.2
 # ...
 name: nginx
 ports:
 - containerPort: 80
 # ...
 # ...
```

```
...
...
```

## How to update objects

You can also use `kubect apply` to update all objects defined in a directory, even if those objects already exist. This approach accomplishes the following:

1. Sets fields that appear in the configuration file in the live configuration.
2. Clears fields removed from the configuration file in the live configuration.

```
kubect diff -f <directory>
kubect apply -f <directory>
```

### Note:

Add the `-R` flag to recursively process directories.

Here's an example configuration file:

[application/simple\\_deployment.yaml](https://k8s.io/examples/application/simple_deployment.yaml)

```
apiVersion: apps/v1
kind: Deployment
metadata:
 name: nginx-deployment
spec:
 selector:
 matchLabels:
 app: nginx
 minReadySeconds: 5
 template:
 metadata:
 labels:
 app: nginx
 spec:
 containers:
 - name: nginx
 image: nginx:1.14.2
 ports:
 - containerPort: 80
```

Create the object using `kubect apply`:

```
kubect apply -f https://k8s.io/examples/application/simple_deployment.yaml
```

### Note:

For purposes of illustration, the preceding command refers to a single configuration file instead of a directory.

Print the live configuration using `kubect get`:

```
kubectl get -f https://k8s.io/examples/application/simple_deployment.yaml -o yaml
```

The output shows that the `kubectl.kubernetes.io/last-applied-configuration` annotation was written to the live configuration, and it matches the configuration file:

```
kind: Deployment
metadata:
 annotations:
 # ...
 # This is the json representation of simple_deployment.yaml
 # It was written by kubectl apply when the object was created
 kubectl.kubernetes.io/last-applied-configuration: |
 {"apiVersion":"apps/v1","kind":"Deployment",
 "metadata":{"annotations":{"name":"nginx-deployment","namespace":"default"},
 "spec":{"minReadySeconds":5,"selector":{"matchLabels":{"app":"nginx"},"template":{"metadata":
{"labels":{"app":"nginx"},
 "spec":{"containers":[{"image":"nginx:1.14.2","name":"nginx",
 "ports":[{"containerPort":80}]}}}}}}}}
 # ...
spec:
 # ...
 minReadySeconds: 5
 selector:
 matchLabels:
 # ...
 app: nginx
 template:
 metadata:
 # ...
 labels:
 app: nginx
 spec:
 containers:
 - image: nginx:1.14.2
 # ...
 name: nginx
 ports:
 - containerPort: 80
 # ...
 # ...
 # ...
 # ...
```

Directly update the `replicas` field in the live configuration by using `kubectl scale`. This does not use `kubectl apply`:

```
kubectl scale deployment/nginx-deployment --replicas=2
```

Print the live configuration using `kubectl get`:

```
kubectl get deployment nginx-deployment -o yaml
```

The output shows that the `replicas` field has been set to 2, and the `last-applied-configuration` annotation does not contain a `replicas` field:

```

apiVersion: apps/v1
kind: Deployment
metadata:
 annotations:
 # ...
 # note that the annotation does not contain replicas
 # because it was not updated through apply
 kubectl.kubernetes.io/last-applied-configuration: |
 {"apiVersion":"apps/v1","kind":"Deployment",
 "metadata":{"annotations":{},"name":"nginx-deployment","namespace":"default"},
 "spec":{"minReadySeconds":5,"selector":{"matchLabels":{"app":"nginx"},"template":{"metadata":
{"labels":{"app":"nginx"}},
 "spec":{"containers":[{"image":"nginx:1.14.2","name":"nginx",
 "ports":[{"containerPort":80}]}]}}}}
 # ...
spec:
 replicas: 2 # written by scale
 # ...
 minReadySeconds: 5
 selector:
 matchLabels:
 # ...
 app: nginx
 template:
 metadata:
 # ...
 labels:
 app: nginx
 spec:
 containers:
 - image: nginx:1.14.2
 # ...
 name: nginx
 ports:
 - containerPort: 80
 # ...

```

Update the `simple_deployment.yaml` configuration file to change the image from `nginx:1.14.2` to `nginx:1.16.1`, and delete the `minReadySeconds` field:

[application/update\\_deployment.yaml](#)

```

apiVersion: apps/v1
kind: Deployment
metadata:
 name: nginx-deployment
spec:
 selector:
 matchLabels:
 app: nginx
 template:
 metadata:
 labels:

```

```
 app: nginx
spec:
 containers:
 - name: nginx
 image: nginx:1.16.1 # update the image
 ports:
 - containerPort: 80
```

Apply the changes made to the configuration file:

```
kubectl diff -f https://k8s.io/examples/application/update_deployment.yaml
kubectl apply -f https://k8s.io/examples/application/update_deployment.yaml
```

Print the live configuration using kubectl get:

```
kubectl get -f https://k8s.io/examples/application/update_deployment.yaml -o yaml
```

The output shows the following changes to the live configuration:

- The replicas field retains the value of 2 set by kubectl scale. This is possible because it is omitted from the configuration file.
- The image field has been updated to nginx:1.16.1 from nginx:1.14.2.
- The last-applied-configuration annotation has been updated with the new image.
- The minReadySeconds field has been cleared.
- The last-applied-configuration annotation no longer contains the minReadySeconds field.

```
apiVersion: apps/v1
kind: Deployment
metadata:
 annotations:
 # ...
 # The annotation contains the updated image to nginx 1.16.1,
 # but does not contain the updated replicas to 2
 kubectl.kubernetes.io/last-applied-configuration: |
 {"apiVersion":"apps/v1","kind":"Deployment",
 "metadata":{"annotations":{},"name":"nginx-deployment","namespace":"default"},
 "spec":{"selector":{"matchLabels":{"app":"nginx"},"template":{"metadata":{"labels":
{"app":"nginx"},
 "spec":{"containers":[{"image":"nginx:1.16.1","name":"nginx",
 "ports":[{"containerPort":80}]}}]]}}}}
 # ...
spec:
 replicas: 2 # Set by `kubectl scale`. Ignored by `kubectl apply`.
 # minReadySeconds cleared by `kubectl apply`
 # ...
 selector:
 matchLabels:
 # ...
 app: nginx
 template:
 metadata:
 # ...
 labels:
 app: nginx
```

```
spec:
 containers:
 - image: nginx:1.16.1 # Set by `kubectl apply`
 # ...
 name: nginx
 ports:
 - containerPort: 80
 # ...
 # ...
 # ...
...
```

### Warning:

Mixing `kubectl apply` with the imperative object configuration commands `create` and `replace` is not supported. This is because `create` and `replace` do not retain the `kubectl.kubernetes.io/last-applied-configuration` that `kubectl apply` uses to compute updates.

## How to delete objects

There are two approaches to delete objects managed by `kubectl apply`.

### Recommended: `kubectl delete -f <filename>`

Manually deleting objects using the imperative command is the recommended approach, as it is more explicit about what is being deleted, and less likely to result in the user deleting something unintentionally:

```
kubectl delete -f <filename>
```

### Alternative: `kubectl apply -f <directory> --prune`

As an alternative to `kubectl delete`, you can use `kubectl apply` to identify objects to be deleted after their manifests have been removed from a directory in the local filesystem.

In Kubernetes 1.30, there are two pruning modes available in `kubectl apply`:

- Allowlist-based pruning: This mode has existed since `kubectl` v1.5 but is still in alpha due to usability, correctness and performance issues with its design. The `ApplySet`-based mode is designed to replace it.
  - `ApplySet`-based pruning: An *apply set* is a server-side object (by default, a `Secret`) that `kubectl` can use to accurately and efficiently track set membership across **apply** operations. This mode was introduced in alpha in `kubectl` v1.27 as a replacement for allowlist-based pruning.
- [Allow list](#)
  - [Apply set](#)

FEATURE STATE: Kubernetes v1.5 [alpha]

## Warning:

Take care when using `--prune` with `kubectl apply` in allow list mode. Which objects are pruned depends on the values of the `--prune-allowlist`, `--selector` and `--namespace` flags, and relies on dynamic discovery of the objects in scope. Especially if flag values are changed between invocations, this can lead to objects being unexpectedly deleted or retained.

To use allowlist-based pruning, add the following flags to your `kubectl apply` invocation:

- `--prune`: Delete previously applied objects that are not in the set passed to the current invocation.
- `--prune-allowlist`: A list of group-version-kinds (GVKs) to consider for pruning. This flag is optional but strongly encouraged, as its default value is a partial list of both namespaced and cluster-scoped types, which can lead to surprising results.
- `--selector/-l`: Use a label selector to constrain the set of objects selected for pruning. This flag is optional but strongly encouraged.
- `--all`: use instead of `--selector/-l` to explicitly select all previously applied objects of the allowlisted types.

Allowlist-based pruning queries the API server for all objects of the allowlisted GVKs that match the given labels (if any), and attempts to match the returned live object configurations against the object manifest files. If an object matches the query, and it does not have a manifest in the directory, and it has a `kubectl.kubernetes.io/last-applied-configuration` annotation, it is deleted.

```
kubectl apply -f <directory> --prune -l <labels> --prune-allowlist=<gvk-list>
```

## Warning:

Apply with prune should only be run against the root directory containing the object manifests. Running against sub-directories can cause objects to be unintentionally deleted if they were previously applied, have the labels given (if any), and do not appear in the subdirectory.

FEATURE STATE: Kubernetes v1.27 [alpha]

## Caution:

`kubectl apply --prune --applyset` is in alpha, and backwards incompatible changes might be introduced in subsequent releases.

To use ApplySet-based pruning, set the `KUBECTL_APPLYSET=true` environment variable, and add the following flags to your `kubectl apply` invocation:

- `--prune`: Delete previously applied objects that are not in the set passed to the current invocation.
- `--applyset`: The name of an object that `kubectl` can use to accurately and efficiently track set membership across apply operations.

```
KUBECTL_APPLYSET=true kubectl apply -f <directory> --prune --applyset=<name>
```

By default, the type of the ApplySet parent object used is a Secret. However, ConfigMaps can also be used in the format: `--applyset=configmaps/<name>`. When using a Secret or ConfigMap, `kubectl` will create the object if it does not already exist.

It is also possible to use custom resources as ApplySet parent objects. To enable this, label the Custom Resource Definition (CRD) that defines the resource you want to use with the following: `applyset.kubernetes.io/is-parent-type: true`. Then, create the object you want to use as an ApplySet parent (kubectl does not do this automatically for custom resources). Finally, refer to that object in the applyset flag as follows: `--applyset=<resource>.<group>/<name>` (for example, `widgets.custom.example.com/widget-name`).

With ApplySet-based pruning, kubectl adds the `applyset.kubernetes.io/part-of=<parentID>` label to each object in the set before they are sent to the server. For performance reasons, it also collects the list of resource types and namespaces that the set contains and adds these in annotations on the live parent object. Finally, at the end of the apply operation, it queries the API server for objects of those types in those namespaces (or in the cluster scope, as applicable) that belong to the set, as defined by the `applyset.kubernetes.io/part-of=<parentID>` label.

Caveats and restrictions:

- Each object may be a member of at most one set.
- The `--namespace` flag is required when using any namespaced parent, including the default Secret. This means that ApplySets spanning multiple namespaces must use a cluster-scoped custom resource as the parent object.
- To safely use ApplySet-based pruning with multiple directories, use a unique ApplySet name for each.

## How to view an object

You can use `kubectl get` with `-o yaml` to view the configuration of a live object:

```
kubectl get -f <filename|url> -o yaml
```

## How apply calculates differences and merges changes

**Caution:**

A *patch* is an update operation that is scoped to specific fields of an object instead of the entire object. This enables updating only a specific set of fields on an object without reading the object first.

When `kubectl apply` updates the live configuration for an object, it does so by sending a patch request to the API server. The patch defines updates scoped to specific fields of the live object configuration. The `kubectl apply` command calculates this patch request using the configuration file, the live configuration, and the last-applied-configuration annotation stored in the live configuration.

### Merge patch calculation

The `kubectl apply` command writes the contents of the configuration file to the `kubectl.kubernetes.io/last-applied-configuration` annotation. This is used to identify fields that have been removed from the configuration file and need to be cleared from the live configuration. Here are the steps used to calculate which fields should be deleted or set:

1. Calculate the fields to delete. These are the fields present in last-applied-configuration and missing from the configuration file.

2. Calculate the fields to add or set. These are the fields present in the configuration file whose values don't match the live configuration.

Here's an example. Suppose this is the configuration file for a Deployment object:

[application/update\\_deployment.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
 name: nginx-deployment
spec:
 selector:
 matchLabels:
 app: nginx
 template:
 metadata:
 labels:
 app: nginx
 spec:
 containers:
 - name: nginx
 image: nginx:1.16.1 # update the image
 ports:
 - containerPort: 80
```

Also, suppose this is the live configuration for the same Deployment object:

```
apiVersion: apps/v1
kind: Deployment
metadata:
 annotations:
 # ...
 # note that the annotation does not contain replicas
 # because it was not updated through apply
 kubectl.kubernetes.io/last-applied-configuration: |
 {"apiVersion":"apps/v1","kind":"Deployment",
 "metadata":{"annotations":{},"name":"nginx-deployment","namespace":"default"},
 "spec":{"minReadySeconds":5,"selector":{"matchLabels":{"app":"nginx"},"template":{"metadata":
{"labels":{"app":"nginx"},
"spec":{"containers":[{"image":"nginx:1.14.2","name":"nginx",
"ports":[{"containerPort":80}]}}]}}}}
 # ...
spec:
 replicas: 2 # written by scale
 # ...
 minReadySeconds: 5
 selector:
 matchLabels:
 # ...
 app: nginx
 template:
 metadata:
```

```
...
labels:
 app: nginx
spec:
 containers:
 - image: nginx:1.14.2
 # ...
 name: nginx
 ports:
 - containerPort: 80
 # ...
```

Here are the merge calculations that would be performed by `kubect apply`:

1. Calculate the fields to delete by reading values from last-applied-configuration and comparing them to values in the configuration file. Clear fields explicitly set to null in the local object configuration file regardless of whether they appear in the last-applied-configuration. In this example, `minReadySeconds` appears in the last-applied-configuration annotation, but does not appear in the configuration file. **Action:** Clear `minReadySeconds` from the live configuration.
2. Calculate the fields to set by reading values from the configuration file and comparing them to values in the live configuration. In this example, the value of `image` in the configuration file does not match the value in the live configuration. **Action:** Set the value of `image` in the live configuration.
3. Set the last-applied-configuration annotation to match the value of the configuration file.
4. Merge the results from 1, 2, 3 into a single patch request to the API server.

Here is the live configuration that is the result of the merge:

```
apiVersion: apps/v1
kind: Deployment
metadata:
 annotations:
 # ...
 # The annotation contains the updated image to nginx 1.16.1,
 # but does not contain the updated replicas to 2
 kubectl.kubernetes.io/last-applied-configuration: |
 {"apiVersion":"apps/v1","kind":"Deployment",
 "metadata":{"annotations":{},"name":"nginx-deployment","namespace":"default"},
 "spec":{"selector":{"matchLabels":{"app":"nginx"},"template":{"metadata":{"labels":
{"app":"nginx"},"spec":{"containers":[{"image":"nginx:1.16.1","name":"nginx",
"ports":[{"containerPort":80}]}}}}}}}
 # ...
 spec:
 selector:
 matchLabels:
 # ...
 app: nginx
 replicas: 2 # Set by `kubectl scale`. Ignored by `kubectl apply`.
 # minReadySeconds cleared by `kubectl apply`
 # ...
 template:
```

```

metadata:
 # ...
 labels:
 app: nginx
spec:
 containers:
 - image: nginx:1.16.1 # Set by `kubectl apply`
 # ...
 name: nginx
 ports:
 - containerPort: 80
 # ...
 # ...
 # ...
 # ...

```

## How different types of fields are merged

How a particular field in a configuration file is merged with the live configuration depends on the type of the field. There are several types of fields:

- *primitive*: A field of type string, integer, or boolean. For example, `image` and `replicas` are primitive fields. **Action**: Replace.
- *map*, also called *object*: A field of type map or a complex type that contains subfields. For example, `labels`, `annotations`, `spec` and `metadata` are all maps. **Action**: Merge elements or subfields.
- *list*: A field containing a list of items that can be either primitive types or maps. For example, `containers`, `ports`, and `args` are lists. **Action**: Varies.

When `kubectl apply` updates a map or list field, it typically does not replace the entire field, but instead updates the individual subelements. For instance, when merging the `spec` on a `Deployment`, the entire `spec` is not replaced. Instead the subfields of `spec`, such as `replicas`, are compared and merged.

## Merging changes to primitive fields

Primitive fields are replaced or cleared.

**Note:**

- is used for "not applicable" because the value is not used.

Field in object configuration file	Field in live object configuration	Field in last-applied-configuration	Action
Yes	Yes	-	Set live to configuration file value.
Yes	No	-	Set live to local configuration.
No	-	Yes	Clear from live configuration.

Field in object configuration file	Field in live object configuration	Field in last-applied-configuration	Action
No	-	No	Do nothing. Keep live value.

## Merging changes to map fields

Fields that represent maps are merged by comparing each of the subfields or elements of the map:

### Note:

- is used for "not applicable" because the value is not used.

Key in object configuration file	Key in live object configuration	Field in last-applied-configuration	Action
Yes	Yes	-	Compare sub fields values.
Yes	No	-	Set live to local configuration.
No	-	Yes	Delete from live configuration.
No	-	No	Do nothing. Keep live value.

## Merging changes for fields of type list

Merging changes to a list uses one of three strategies:

- Replace the list if all its elements are primitives.
- Merge individual elements in a list of complex elements.
- Merge a list of primitive elements.

The choice of strategy is made on a per-field basis.

### Replace the list if all its elements are primitives

Treat the list the same as a primitive field. Replace or delete the entire list. This preserves ordering.

**Example:** Use `kubectl apply` to update the `args` field of a `Container` in a `Pod`. This sets the value of `args` in the live configuration to the value in the configuration file. Any `args` elements that had previously been added to the live configuration are lost. The order of the `args` elements defined in the configuration file is retained in the live configuration.

```
last-applied-configuration value
args: ["a", "b"]
```

```
configuration file value
args: ["a", "c"]
```

```
live configuration
```

```
args: ["a", "b", "d"]
```

```
result after merge
args: ["a", "c"]
```

**Explanation:** The merge used the configuration file value as the new list value.

### Merge individual elements of a list of complex elements:

Treat the list as a map, and treat a specific field of each element as a key. Add, delete, or update individual elements. This does not preserve ordering.

This merge strategy uses a special tag on each field called a `patchMergeKey`. The `patchMergeKey` is defined for each field in the Kubernetes source code: [types.go](https://types.go) When merging a list of maps, the field specified as the `patchMergeKey` for a given element is used like a map key for that element.

**Example:** Use `kubectl apply` to update the `containers` field of a `PodSpec`. This merges the list as though it was a map where each element is keyed by `name`.

```
last-applied-configuration value
containers:
- name: nginx
 image: nginx:1.16
- name: nginx-helper-a # key: nginx-helper-a; will be deleted in result
 image: helper:1.3
- name: nginx-helper-b # key: nginx-helper-b; will be retained
 image: helper:1.3

configuration file value
containers:
- name: nginx
 image: nginx:1.16
- name: nginx-helper-b
 image: helper:1.3
- name: nginx-helper-c # key: nginx-helper-c; will be added in result
 image: helper:1.3

live configuration
containers:
- name: nginx
 image: nginx:1.16
- name: nginx-helper-a
 image: helper:1.3
- name: nginx-helper-b
 image: helper:1.3
 args: ["run"] # Field will be retained
- name: nginx-helper-d # key: nginx-helper-d; will be retained
 image: helper:1.3

result after merge
containers:
- name: nginx
```

```
image: nginx:1.16
Element nginx-helper-a was deleted
- name: nginx-helper-b
 image: helper:1.3
 args: ["run"] # Field was retained
- name: nginx-helper-c # Element was added
 image: helper:1.3
- name: nginx-helper-d # Element was ignored
 image: helper:1.3
```

### Explanation:

- The container named "nginx-helper-a" was deleted because no container named "nginx-helper-a" appeared in the configuration file.
- The container named "nginx-helper-b" retained the changes to args in the live configuration. kubectl apply was able to identify that "nginx-helper-b" in the live configuration was the same "nginx-helper-b" as in the configuration file, even though their fields had different values (no args in the configuration file). This is because the patchMergeKey field value (name) was identical in both.
- The container named "nginx-helper-c" was added because no container with that name appeared in the live configuration, but one with that name appeared in the configuration file.
- The container named "nginx-helper-d" was retained because no element with that name appeared in the last-applied-configuration.

### Merge a list of primitive elements

As of Kubernetes 1.5, merging lists of primitive elements is not supported.

### Note:

Which of the above strategies is chosen for a given field is controlled by the patchStrategy tag in [types.go](https://kubernetes.io/docs/reference/generated/kubernetes-api/v1.10/#listmeta-1.10). If no patchStrategy is specified for a field of type list, then the list is replaced.

## Default field values

The API server sets certain fields to default values in the live configuration if they are not specified when the object is created.

Here's a configuration file for a Deployment. The file does not specify strategy:

[application/simple\\_deployment.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
 name: nginx-deployment
spec:
 selector:
 matchLabels:
 app: nginx
 minReadySeconds: 5
```

```
template:
 metadata:
 labels:
 app: nginx
 spec:
 containers:
 - name: nginx
 image: nginx:1.14.2
 ports:
 - containerPort: 80
```

Create the object using kubectl apply:

```
kubectl apply -f https://k8s.io/examples/application/simple_deployment.yaml
```

Print the live configuration using kubectl get:

```
kubectl get -f https://k8s.io/examples/application/simple_deployment.yaml -o yaml
```

The output shows that the API server set several fields to default values in the live configuration. These fields were not specified in the configuration file.

```
apiVersion: apps/v1
kind: Deployment
...
spec:
 selector:
 matchLabels:
 app: nginx
 minReadySeconds: 5
 replicas: 1 # defaulted by apiserver
 strategy:
 rollingUpdate: # defaulted by apiserver - derived from strategy.type
 maxSurge: 1
 maxUnavailable: 1
 type: RollingUpdate # defaulted by apiserver
 template:
 metadata:
 creationTimestamp: null
 labels:
 app: nginx
 spec:
 containers:
 - image: nginx:1.14.2
 imagePullPolicy: IfNotPresent # defaulted by apiserver
 name: nginx
 ports:
 - containerPort: 80
 protocol: TCP # defaulted by apiserver
 resources: {} # defaulted by apiserver
 terminationMessagePath: /dev/termination-log # defaulted by apiserver
 dnsPolicy: ClusterFirst # defaulted by apiserver
 restartPolicy: Always # defaulted by apiserver
 securityContext: {} # defaulted by apiserver
```

```
terminationGracePeriodSeconds: 30 # defaulted by apiserver
...
```

In a patch request, defaulted fields are not re-defaulted unless they are explicitly cleared as part of a patch request. This can cause unexpected behavior for fields that are defaulted based on the values of other fields. When the other fields are later changed, the values defaulted from them will not be updated unless they are explicitly cleared.

For this reason, it is recommended that certain fields defaulted by the server are explicitly defined in the configuration file, even if the desired values match the server defaults. This makes it easier to recognize conflicting values that will not be re-defaulted by the server.

### Example:

```
last-applied-configuration
spec:
 template:
 metadata:
 labels:
 app: nginx
 spec:
 containers:

### Explanation:

1. The user creates a Deployment without defining `strategy.type`.
2. The server defaults `strategy.type` to `RollingUpdate` and defaults the `strategy.rollingUpdate` values.
3. The user changes `strategy.type` to `Recreate`. The `strategy.rollingUpdate` values remain at their defaulted values, though the server expects them to be cleared. If the `strategy.rollingUpdate` values had been defined initially in the configuration file, it would have been more clear that they needed to be deleted.
4. Apply fails because `strategy.rollingUpdate` is not cleared. The `strategy.rollingupdate` field cannot be defined with a `strategy.type` of `Recreate`.

Recommendation: These fields should be explicitly defined in the object configuration file:

- Selectors and PodTemplate labels on workloads, such as Deployment, StatefulSet, Job, DaemonSet, ReplicaSet, and ReplicationController
- Deployment rollout strategy

### How to clear server-defaulted fields or fields set by other writers

Fields that do not appear in the configuration file can be cleared by setting their values to null and then applying the configuration file. For fields defaulted by the server, this triggers re-defaulting the values.

# How to change ownership of a field between the configuration file and direct imperative writers

These are the only methods you should use to change an individual object field:

- Use `kubectl apply`.
- Write directly to the live configuration without modifying the configuration file: for example, use `kubectl scale`.

## Changing the owner from a direct imperative writer to a configuration file

Add the field to the configuration file. For the field, discontinue direct updates to the live configuration that do not go through `kubectl apply`.

## Changing the owner from a configuration file to a direct imperative writer

As of Kubernetes 1.5, changing ownership of a field from a configuration file to an imperative writer requires manual steps:

- Remove the field from the configuration file.
- Remove the field from the `kubectl.kubernetes.io/last-applied-configuration` annotation on the live object.

## Changing management methods

Kubernetes objects should be managed using only one method at a time. Switching from one method to another is possible, but is a manual process.

### Note:

It is OK to use imperative deletion with declarative management.

## Migrating from imperative command management to declarative object configuration

Migrating from imperative command management to declarative object configuration involves several manual steps:

1. Export the live object to a local configuration file:

```
kubectl get <kind>/<name> -o yaml > <kind>_<name>.yaml
```

2. Manually remove the `status` field from the configuration file.

### Note:

This step is optional, as `kubectl apply` does not update the `status` field even if it is present in the configuration file.

- Set the `kubectl.kubernetes.io/last-applied-configuration` annotation on the object:
3. 

```
kubectl replace --save-config -f <kind>_<name>.yaml
```
  4. Change processes to use `kubectl apply` for managing the object exclusively.

## Migrating from imperative object configuration to declarative object configuration

1. Set the `kubectl.kubernetes.io/last-applied-configuration` annotation on the object:  

```
kubectl replace --save-config -f <kind>_<name>.yaml
```
2. Change processes to use `kubectl apply` for managing the object exclusively.

## Defining controller selectors and PodTemplate labels

### Warning:

Updating selectors on controllers is strongly discouraged.

The recommended approach is to define a single, immutable PodTemplate label used only by the controller selector with no other semantic meaning.

### Example:

```
selector:
 matchLabels:
 controller-selector: "apps/v1/deployment/nginx"
template:
 metadata:
 labels:
 controller-selector: "apps/v1/deployment/nginx"
```

## What's next

- [Managing Kubernetes Objects Using Imperative Commands](#)
- [Imperative Management of Kubernetes Objects Using Configuration Files](#)
- [Kubectl Command Reference](#)
- [Kubernetes API Reference](#)

## Declarative Management of Kubernetes Objects Using Kustomize

[Kustomize](#) is a standalone tool to customize Kubernetes objects through a [kustomization file](#).

Since 1.14, Kubectl also supports the management of Kubernetes objects using a kustomization file. To view Resources found in a directory containing a kustomization file, run the following command:

```
kubectl kustomize <kustomization_directory>
```

To apply those Resources, run kubectl apply with --kustomize or -k flag:

```
kubectl apply -k <kustomization_directory>
```

## Before you begin

Install [kubectl](#).

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter kubectl version.

## Overview of Kustomize

Kustomize is a tool for customizing Kubernetes configurations. It has the following features to manage application configuration files:

- generating resources from other sources
- setting cross-cutting fields for resources
- composing and customizing collections of resources

## Generating Resources

ConfigMaps and Secrets hold configuration or sensitive data that are used by other Kubernetes objects, such as Pods. The source of truth of ConfigMaps or Secrets are usually external to a cluster, such as a .properties file or an SSH keyfile. Kustomize has secretGenerator and configMapGenerator, which generate Secret and ConfigMap from files or literals.

### configMapGenerator

To generate a ConfigMap from a file, add an entry to the files list in configMapGenerator. Here is an example of generating a ConfigMap with a data item from a .properties file:

```
Create a application.properties file
cat <<EOF >application.properties
FOO=Bar
EOF

cat <<EOF >./kustomization.yaml
configMapGenerator:
- name: example-configmap-1
 files:
 - application.properties
EOF
```

The generated ConfigMap can be examined with the following command:

```
kubectl kustomize ./
```

The generated ConfigMap is:

```
apiVersion: v1
data:
 application.properties: |
 FOO=Bar
kind: ConfigMap
metadata:
 name: example-configmap-1-8mbdf7882g
```

To generate a ConfigMap from an env file, add an entry to the envs list in configMapGenerator. Here is an example of generating a ConfigMap with a data item from a .env file:

```
Create a .env file
cat <<EOF >.env
FOO=Bar
EOF

cat <<EOF >./kustomization.yaml
configMapGenerator:
- name: example-configmap-1
 envs:
 - .env
EOF
```

The generated ConfigMap can be examined with the following command:

```
kubectl kustomize ./
```

The generated ConfigMap is:

```
apiVersion: v1
data:
 FOO: Bar
kind: ConfigMap
metadata:
 name: example-configmap-1-42cbbf598f
```

**Note:**

Each variable in the .env file becomes a separate key in the ConfigMap that you generate. This is different from the previous example which embeds a file named application.properties (and all its entries) as the value for a single key.

ConfigMaps can also be generated from literal key-value pairs. To generate a ConfigMap from a literal key-value pair, add an entry to the literals list in configMapGenerator. Here is an example of generating a ConfigMap with a data item from a key-value pair:

```
cat <<EOF >./kustomization.yaml
configMapGenerator:
```

```
- name: example-configmap-2
 literals:
 - FOO=Bar
EOF
```

The generated ConfigMap can be checked by the following command:

```
kubectl kustomize ./
```

The generated ConfigMap is:

```
apiVersion: v1
data:
 FOO: Bar
kind: ConfigMap
metadata:
 name: example-configmap-2-g2hdhfc6tk
```

To use a generated ConfigMap in a Deployment, reference it by the name of the configMapGenerator. Kustomize will automatically replace this name with the generated name.

This is an example deployment that uses a generated ConfigMap:

```
Create a application.properties file
cat <<EOF >application.properties
FOO=Bar
EOF
```

```
cat <<EOF >deployment.yaml
```

```
apiVersion: apps/v1
kind: Deployment
metadata:
 name: my-app
 labels:
 app: my-app
spec:
 selector:
 matchLabels:
 app: my-app
 template:
 metadata:
 labels:
 app: my-app
 spec:
 containers:
 - name: app
 image: my-app
 volumeMounts:
 - name: config
 mountPath: /config
 volumes:
 - name: config
 configMap:
 name: example-configmap-1
```

EOF

```
cat <<EOF >./kustomization.yaml
resources:
- deployment.yaml
configMapGenerator:
- name: example-configmap-1
 files:
 - application.properties
EOF
```

Generate the ConfigMap and Deployment:

```
kubectl kustomize ./
```

The generated Deployment will refer to the generated ConfigMap by name:

```
apiVersion: v1
data:
 application.properties: |
 FOO=Bar
kind: ConfigMap
metadata:
 name: example-configmap-1-g4hk9g2ff8

apiVersion: apps/v1
kind: Deployment
metadata:
 labels:
 app: my-app
 name: my-app
spec:
 selector:
 matchLabels:
 app: my-app
 template:
 metadata:
 labels:
 app: my-app
 spec:
 containers:
 - image: my-app
 name: app
 volumeMounts:
 - mountPath: /config
 name: config
 volumes:
 - configMap:
 name: example-configmap-1-g4hk9g2ff8
 name: config
```

## secretGenerator

You can generate Secrets from files or literal key-value pairs. To generate a Secret from a file, add an entry to the files list in secretGenerator. Here is an example of generating a Secret with a data item from a file:

```
Create a password.txt file
cat <<EOF >./password.txt
username=admin
password=secret
EOF

cat <<EOF >./kustomization.yaml
secretGenerator:
- name: example-secret-1
 files:
 - password.txt
EOF
```

The generated Secret is as follows:

```
apiVersion: v1
data:
 password.txt: dXNlcm5hbWU9YWRTaW4KcGFzc3dvcmQ9c2VjcmV0Cg==
kind: Secret
metadata:
 name: example-secret-1-t2kt65hgtb
type: Opaque
```

To generate a Secret from a literal key-value pair, add an entry to literals list in secretGenerator. Here is an example of generating a Secret with a data item from a key-value pair:

```
cat <<EOF >./kustomization.yaml
secretGenerator:
- name: example-secret-2
 literals:
 - username=admin
 - password=secret
EOF
```

The generated Secret is as follows:

```
apiVersion: v1
data:
 password: c2VjcmV0
 username: YWRtaW4=
kind: Secret
metadata:
 name: example-secret-2-t52t6g96d8
type: Opaque
```

Like ConfigMaps, generated Secrets can be used in Deployments by referring to the name of the secretGenerator:

```
Create a password.txt file
cat <<EOF >./password.txt
username=admin
password=secret
EOF

cat <<EOF >deployment.yaml
apiVersion: apps/v1
kind: Deployment
metadata:
 name: my-app
 labels:
 app: my-app
spec:
 selector:
 matchLabels:
 app: my-app
 template:
 metadata:
 labels:
 app: my-app
 spec:
 containers:
 - name: app
 image: my-app
 volumeMounts:
 - name: password
 mountPath: /secrets
 volumes:
 - name: password
 secret:
 secretName: example-secret-1
EOF

cat <<EOF >./kustomization.yaml
resources:
- deployment.yaml
secretGenerator:
- name: example-secret-1
 files:
 - password.txt
EOF
```

## generatorOptions

The generated ConfigMaps and Secrets have a content hash suffix appended. This ensures that a new ConfigMap or Secret is generated when the contents are changed. To disable the behavior of appending a suffix, one can use generatorOptions. Besides that, it is also possible to specify cross-cutting options for generated ConfigMaps and Secrets.

```
cat <<EOF >./kustomization.yaml
configMapGenerator:
- name: example-configmap-3
```

```
literals:
- FOO=Bar
generatorOptions:
 disableNameSuffixHash: true
labels:
 type: generated
annotations:
 note: generated
EOF
```

Runkubectl kustomize ./ to view the generated ConfigMap:

```
apiVersion: v1
data:
 FOO: Bar
kind: ConfigMap
metadata:
 annotations:
 note: generated
 labels:
 type: generated
 name: example-configmap-3
```

## Setting cross-cutting fields

It is quite common to set cross-cutting fields for all Kubernetes resources in a project. Some use cases for setting cross-cutting fields:

- setting the same namespace for all Resources
- adding the same name prefix or suffix
- adding the same set of labels
- adding the same set of annotations

Here is an example:

```
Create a deployment.yaml
cat <<EOF >./deployment.yaml
apiVersion: apps/v1
kind: Deployment
metadata:
 name: nginx-deployment
 labels:
 app: nginx
spec:
 selector:
 matchLabels:
 app: nginx
 template:
 metadata:
 labels:
 app: nginx
 spec:
 containers:
```

```
- name: nginx
 image: nginx
EOF

cat <<EOF >./kustomization.yaml
namespace: my-namespace
namePrefix: dev-
nameSuffix: "-001"
commonLabels:
 app: bingo
commonAnnotations:
 oncallPager: 800-555-1212
resources:
- deployment.yaml
EOF
```

Run `kubectl kustomize ./` to view those fields are all set in the Deployment Resource:

```
apiVersion: apps/v1
kind: Deployment
metadata:
 annotations:
 oncallPager: 800-555-1212
 labels:
 app: bingo
 name: dev-nginx-deployment-001
 namespace: my-namespace
spec:
 selector:
 matchLabels:
 app: bingo
 template:
 metadata:
 annotations:
 oncallPager: 800-555-1212
 labels:
 app: bingo
 spec:
 containers:
 - image: nginx
 name: nginx
```

## Composing and Customizing Resources

It is common to compose a set of Resources in a project and manage them inside the same file or directory. Kustomize offers composing Resources from different files and applying patches or other customization to them.

### Composing

Kustomize supports composition of different resources. The `resources` field, in the `kustomization.yaml` file, defines the list of resources to include in a configuration. Set the path

to a resource's configuration file in the resources list. Here is an example of an NGINX application comprised of a Deployment and a Service:

```
Create a deployment.yaml file
```

```
cat <<EOF > deployment.yaml
```

```
apiVersion: apps/v1
```

```
kind: Deployment
```

```
metadata:
```

```
 name: my-nginx
```

```
spec:
```

```
 selector:
```

```
 matchLabels:
```

```
 run: my-nginx
```

```
 replicas: 2
```

```
 template:
```

```
 metadata:
```

```
 labels:
```

```
 run: my-nginx
```

```
 spec:
```

```
 containers:
```

```
 - name: my-nginx
```

```
 image: nginx
```

```
 ports:
```

```
 - containerPort: 80
```

```
EOF
```

```
Create a service.yaml file
```

```
cat <<EOF > service.yaml
```

```
apiVersion: v1
```

```
kind: Service
```

```
metadata:
```

```
 name: my-nginx
```

```
 labels:
```

```
 run: my-nginx
```

```
spec:
```

```
 ports:
```

```
 - port: 80
```

```
 protocol: TCP
```

```
 selector:
```

```
 run: my-nginx
```

```
EOF
```

```
Create a kustomization.yaml composing them
```

```
cat <<EOF > ./kustomization.yaml
```

```
resources:
```

```
- deployment.yaml
```

```
- service.yaml
```

```
EOF
```

The Resources from `kubectl kustomize ./` contain both the Deployment and the Service objects.

## Customizing

Patches can be used to apply different customizations to Resources. Kustomize supports different patching mechanisms through `patchesStrategicMerge` and `patchesJson6902`. `patchesStrategicMerge` is a list of file paths. Each file should be resolved to a [strategic merge patch](#). The names inside the patches must match Resource names that are already loaded. Small patches that do one thing are recommended. For example, create one patch for increasing the deployment replica number and another patch for setting the memory limit.

```
Create a deployment.yaml file
cat <<EOF > deployment.yaml
apiVersion: apps/v1
kind: Deployment
metadata:
 name: my-nginx
spec:
 selector:
 matchLabels:
 run: my-nginx
 replicas: 2
 template:
 metadata:
 labels:
 run: my-nginx
 spec:
 containers:
 - name: my-nginx
 image: nginx
 ports:
 - containerPort: 80
EOF

Create a patch increase_replicas.yaml
cat <<EOF > increase_replicas.yaml
apiVersion: apps/v1
kind: Deployment
metadata:
 name: my-nginx
spec:
 replicas: 3
EOF

Create another patch set_memory.yaml
cat <<EOF > set_memory.yaml
apiVersion: apps/v1
kind: Deployment
metadata:
 name: my-nginx
spec:
 template:
 spec:
 containers:
 - name: my-nginx
```

```
resources:
 limits:
 memory: 512Mi
EOF
```

```
cat <<EOF >./kustomization.yaml
resources:
- deployment.yaml
patchesStrategicMerge:
- increase_replicas.yaml
- set_memory.yaml
EOF
```

Run `kubectl kustomize ./` to view the Deployment:

```
apiVersion: apps/v1
kind: Deployment
metadata:
 name: my-nginx
spec:
 replicas: 3
 selector:
 matchLabels:
 run: my-nginx
 template:
 metadata:
 labels:
 run: my-nginx
 spec:
 containers:
 - image: nginx
 name: my-nginx
 ports:
 - containerPort: 80
 resources:
 limits:
 memory: 512Mi
```

Not all Resources or fields support strategic merge patches. To support modifying arbitrary fields in arbitrary Resources, Kustomize offers applying [JSON patch](#) through `patchesJson6902`. To find the correct Resource for a Json patch, the group, version, kind and name of that Resource need to be specified in `kustomization.yaml`. For example, increasing the replica number of a Deployment object can also be done through `patchesJson6902`.

```
Create a deployment.yaml file
cat <<EOF > deployment.yaml
apiVersion: apps/v1
kind: Deployment
metadata:
 name: my-nginx
spec:
 selector:
 matchLabels:
```

```
 run: my-nginx
replicas: 2
template:
 metadata:
 labels:
 run: my-nginx
 spec:
 containers:
 - name: my-nginx
 image: nginx
 ports:
 - containerPort: 80
EOF
```

```
Create a json patch
cat <<EOF > patch.yaml
- op: replace
 path: /spec/replicas
 value: 3
EOF
```

```
Create a kustomization.yaml
cat <<EOF > ./kustomization.yaml
resources:
- deployment.yaml

patchesJson6902:
- target:
 group: apps
 version: v1
 kind: Deployment
 name: my-nginx
 path: patch.yaml
EOF
```

Run `kubectl kustomize ./` to see the `replicas` field is updated:

```
apiVersion: apps/v1
kind: Deployment
metadata:
 name: my-nginx
spec:
 replicas: 3
 selector:
 matchLabels:
 run: my-nginx
 template:
 metadata:
 labels:
 run: my-nginx
 spec:
 containers:
 - image: nginx
```

```
name: my-nginx
ports:
- containerPort: 80
```

In addition to patches, Kustomize also offers customizing container images or injecting field values from other objects into containers without creating patches. For example, you can change the image used inside containers by specifying the new image in images field in kustomization.yaml.

```
cat <<EOF > deployment.yaml
```

```
apiVersion: apps/v1
```

```
kind: Deployment
```

```
metadata:
```

```
 name: my-nginx
```

```
spec:
```

```
 selector:
```

```
 matchLabels:
```

```
 run: my-nginx
```

```
 replicas: 2
```

```
 template:
```

```
 metadata:
```

```
 labels:
```

```
 run: my-nginx
```

```
 spec:
```

```
 containers:
```

```
 - name: my-nginx
```

```
 image: nginx
```

```
 ports:
```

```
 - containerPort: 80
```

```
EOF
```

```
cat <<EOF > ./kustomization.yaml
```

```
resources:
```

```
- deployment.yaml
```

```
images:
```

```
- name: nginx
```

```
 newName: my.image.registry/nginx
```

```
 newTag: 1.4.0
```

```
EOF
```

Run `kubectl kustomize ./` to see that the image being used is updated:

```
apiVersion: apps/v1
```

```
kind: Deployment
```

```
metadata:
```

```
 name: my-nginx
```

```
spec:
```

```
 replicas: 2
```

```
 selector:
```

```
 matchLabels:
```

```
 run: my-nginx
```

```
 template:
```

```
 metadata:
```

```
labels:
 run: my-nginx
spec:
 containers:
 - image: my.image.registry/nginx:1.4.0
 name: my-nginx
 ports:
 - containerPort: 80
```

Sometimes, the application running in a Pod may need to use configuration values from other objects. For example, a Pod from a Deployment object need to read the corresponding Service name from Env or as a command argument. Since the Service name may change as namePrefix or nameSuffix is added in the kustomization.yaml file. It is not recommended to hard code the Service name in the command argument. For this usage, Kustomize can inject the Service name into containers through vars.

```
Create a deployment.yaml file (quoting the here doc delimiter)
```

```
cat <<'EOF' > deployment.yaml
```

```
apiVersion: apps/v1
```

```
kind: Deployment
```

```
metadata:
```

```
 name: my-nginx
```

```
spec:
```

```
 selector:
```

```
 matchLabels:
```

```
 run: my-nginx
```

```
 replicas: 2
```

```
 template:
```

```
 metadata:
```

```
 labels:
```

```
 run: my-nginx
```

```
 spec:
```

```
 containers:
```

```
 - name: my-nginx
```

```
 image: nginx
```

```
 command: ["start", "--host", "$(MY_SERVICE_NAME)"]
```

```
EOF
```

```
Create a service.yaml file
```

```
cat <<EOF > service.yaml
```

```
apiVersion: v1
```

```
kind: Service
```

```
metadata:
```

```
 name: my-nginx
```

```
 labels:
```

```
 run: my-nginx
```

```
spec:
```

```
 ports:
```

```
 - port: 80
```

```
 protocol: TCP
```

```
 selector:
```

```
 run: my-nginx
```

```
EOF
```

```

cat <<EOF >./kustomization.yaml
namePrefix: dev-
nameSuffix: "-001"

resources:
- deployment.yaml
- service.yaml

vars:
- name: MY_SERVICE_NAME
 objref:
 kind: Service
 name: my-nginx
 apiVersion: v1
EOF

```

Run `kubectl kustomize ./` to see that the Service name injected into containers is `dev-my-nginx-001`:

```

apiVersion: apps/v1
kind: Deployment
metadata:
 name: dev-my-nginx-001
spec:
 replicas: 2
 selector:
 matchLabels:
 run: my-nginx
 template:
 metadata:
 labels:
 run: my-nginx
 spec:
 containers:
 - command:
 - start
 - --host
 - dev-my-nginx-001
 image: nginx
 name: my-nginx

```

## Bases and Overlays

Kustomize has the concepts of **bases** and **overlays**. A **base** is a directory with a `kustomization.yaml`, which contains a set of resources and associated customization. A base could be either a local directory or a directory from a remote repo, as long as a `kustomization.yaml` is present inside. An **overlay** is a directory with a `kustomization.yaml` that refers to other kustomization directories as its bases. A **base** has no knowledge of an overlay and can be used in multiple overlays. An overlay may have multiple bases and it composes all resources from bases and may also have customization on top of them.

Here is an example of a base:

```
Create a directory to hold the base
mkdir base
Create a base/deployment.yaml
cat <<EOF > base/deployment.yaml
apiVersion: apps/v1
kind: Deployment
metadata:
 name: my-nginx
spec:
 selector:
 matchLabels:
 run: my-nginx
 replicas: 2
 template:
 metadata:
 labels:
 run: my-nginx
 spec:
 containers:
 - name: my-nginx
 image: nginx
EOF

Create a base/service.yaml file
cat <<EOF > base/service.yaml
apiVersion: v1
kind: Service
metadata:
 name: my-nginx
 labels:
 run: my-nginx
spec:
 ports:
 - port: 80
 protocol: TCP
 selector:
 run: my-nginx
EOF

Create a base/kustomization.yaml
cat <<EOF > base/kustomization.yaml
resources:
- deployment.yaml
- service.yaml
EOF
```

This base can be used in multiple overlays. You can add different `namePrefix` or other cross-cutting fields in different overlays. Here are two overlays using the same base.

```
mkdir dev
cat <<EOF > dev/kustomization.yaml
resources:
```

```
- ../base
namePrefix: dev-
EOF

mkdir prod
cat <<EOF > prod/kustomization.yaml
resources:
- ../base
namePrefix: prod-
EOF
```

## How to apply/view/delete objects using Kustomize

Use `--kustomize` or `-k` in `kubectl` commands to recognize Resources managed by `kustomization.yaml`. Note that `-k` should point to a `kustomization` directory, such as

```
kubectl apply -k <kustomization directory>/
```

Given the following `kustomization.yaml`,

```
Create a deployment.yaml file
cat <<EOF > deployment.yaml
apiVersion: apps/v1
kind: Deployment
metadata:
 name: my-nginx
spec:
 selector:
 matchLabels:
 run: my-nginx
 replicas: 2
 template:
 metadata:
 labels:
 run: my-nginx
 spec:
 containers:
 - name: my-nginx
 image: nginx
 ports:
 - containerPort: 80
EOF

Create a kustomization.yaml
cat <<EOF > ./kustomization.yaml
namePrefix: dev-
commonLabels:
 app: my-nginx
resources:
- deployment.yaml
EOF
```

Run the following command to apply the Deployment object `dev-my-nginx`:

```
> kubectl apply -k ./
deployment.apps/dev-my-nginx created
```

Run one of the following commands to view the Deployment object dev-my-nginx:

```
kubectl get -k ./
```

```
kubectl describe -k ./
```

Run the following command to compare the Deployment object dev-my-nginx against the state that the cluster would be in if the manifest was applied:

```
kubectl diff -k ./
```

Run the following command to delete the Deployment object dev-my-nginx:

```
> kubectl delete -k ./
deployment.apps "dev-my-nginx" deleted
```

## Kustomize Feature List

Field	Type	Explanation
namespace	string	add namespace to all resources
namePrefix	string	value of this field is prepended to the names of all resources
nameSuffix	string	value of this field is appended to the names of all resources
commonLabels	map[string]string	labels to add to all resources and selectors
commonAnnotations	map[string]string	annotations to add to all resources
resources	[]string	each entry in this list must resolve to an existing resource configuration file
configMapGenerator	[] <a href="#">ConfigMapArgs</a>	Each entry in this list generates a ConfigMap
secretGenerator	[] <a href="#">SecretArgs</a>	Each entry in this list generates a Secret
generatorOptions	<a href="#">GeneratorOptions</a>	Modify behaviors of all ConfigMap and Secret generator
bases	[]string	Each entry in this list should resolve to a directory containing a kustomization.yaml file
patchesStrategicMerge	[]string	Each entry in this list should resolve a strategic merge patch of a Kubernetes object
patchesJson6902	[] <a href="#">Patch</a>	Each entry in this list should resolve to a Kubernetes object and a Json Patch
vars	[] <a href="#">Var</a>	Each entry is to capture text from one resource's field
images	[] <a href="#">Image</a>	Each entry is to modify the name, tags and/or digest for one image without creating patches
configurations	[]string	Each entry in this list should resolve to a file containing <a href="#">Kustomize transformer configurations</a>
crds	[]string	Each entry in this list should resolve to an OpenAPI definition file for Kubernetes types

# Managing Kubernetes Objects Using Imperative Commands

Kubernetes objects can quickly be created, updated, and deleted directly using imperative commands built into the kubectl command-line tool. This document explains how those commands are organized and how to use them to manage live objects.

## Before you begin

Install [kubectl](#).

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter kubectl version.

## Trade-offs

The kubectl tool supports three kinds of object management:

- Imperative commands
- Imperative object configuration
- Declarative object configuration

See [Kubernetes Object Management](#) for a discussion of the advantages and disadvantage of each kind of object management.

## How to create objects

The kubectl tool supports verb-driven commands for creating some of the most common object types. The commands are named to be recognizable to users unfamiliar with the Kubernetes object types.

- `run`: Create a new Pod to run a Container.
- `expose`: Create a new Service object to load balance traffic across Pods.
- `autoscale`: Create a new Autoscaler object to automatically horizontally scale a controller, such as a Deployment.

The `kubectl` tool also supports creation commands driven by object type. These commands support more object types and are more explicit about their intent, but require users to know the type of objects they intend to create.

- `create <objecttype> [<subtype>] <instancename>`

Some objects types have subtypes that you can specify in the `create` command. For example, the `Service` object has several subtypes including `ClusterIP`, `LoadBalancer`, and `NodePort`. Here's an example that creates a `Service` with subtype `NodePort`:

```
kubectl create service nodeport <myservicename>
```

In the preceding example, the `create service nodeport` command is called a subcommand of the `create service` command.

You can use the `-h` flag to find the arguments and flags supported by a subcommand:

```
kubectl create service nodeport -h
```

## How to update objects

The `kubectl` command supports verb-driven commands for some common update operations. These commands are named to enable users unfamiliar with Kubernetes objects to perform updates without knowing the specific fields that must be set:

- `scale`: Horizontally scale a controller to add or remove Pods by updating the replica count of the controller.
- `annotate`: Add or remove an annotation from an object.
- `label`: Add or remove a label from an object.

The `kubectl` command also supports update commands driven by an aspect of the object. Setting this aspect may set different fields for different object types:

- `set <field>`: Set an aspect of an object.

### Note:

In Kubernetes version 1.5, not every verb-driven command has an associated aspect-driven command.

The `kubectl` tool supports these additional ways to update a live object directly, however they require a better understanding of the Kubernetes object schema.

- `edit`: Directly edit the raw configuration of a live object by opening its configuration in an editor.
- `patch`: Directly modify specific fields of a live object by using a patch string. For more details on patch strings, see the patch section in [API Conventions](#).

## How to delete objects

You can use the `delete` command to delete an object from a cluster:

- `delete <type>/<name>`

## Note:

You can use `kubectl delete` for both imperative commands and imperative object configuration. The difference is in the arguments passed to the command. To use `kubectl delete` as an imperative command, pass the object to be deleted as an argument. Here's an example that passes a Deployment object named `nginx`:

```
kubectl delete deployment/nginx
```

## How to view an object

There are several commands for printing information about an object:

- `get`: Prints basic information about matching objects. Use `get -h` to see a list of options.
- `describe`: Prints aggregated detailed information about matching objects.
- `logs`: Prints the stdout and stderr for a container running in a Pod.

## Using set commands to modify objects before creation

There are some object fields that don't have a flag you can use in a `create` command. In some of those cases, you can use a combination of `set` and `create` to specify a value for the field before object creation. This is done by piping the output of the `create` command to the `set` command, and then back to the `create` command. Here's an example:

```
kubectl create service clusterip my-svc --clusterip="None" -o yaml --dry-run=client | kubectl set selector --local -f - 'environment=qa' -o yaml | kubectl create -f -
```

1. The `kubectl create service -o yaml --dry-run=client` command creates the configuration for the Service, but prints it to stdout as YAML instead of sending it to the Kubernetes API server.
2. The `kubectl set selector --local -f - -o yaml` command reads the configuration from stdin, and writes the updated configuration to stdout as YAML.
3. The `kubectl create -f -` command creates the object using the configuration provided via stdin.

## Using --edit to modify objects before creation

You can use `kubectl create --edit` to make arbitrary changes to an object before it is created. Here's an example:

```
kubectl create service clusterip my-svc --clusterip="None" -o yaml --dry-run=client > /tmp/srv.yaml
kubectl create --edit -f /tmp/srv.yaml
```

1. The `kubectl create service` command creates the configuration for the Service and saves it to `/tmp/srv.yaml`.
2. The `kubectl create --edit` command opens the configuration file for editing before it creates the object.

# Imperative Management of Kubernetes Objects Using Configuration Files

Kubernetes objects can be created, updated, and deleted by using the `kubectl` command-line tool along with an object configuration file written in YAML or JSON. This document explains how to define and manage objects using configuration files.

## Before you begin

Install [kubectl](#).

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

## Trade-offs

The `kubectl` tool supports three kinds of object management:

- Imperative commands
- Imperative object configuration
- Declarative object configuration

See [Kubernetes Object Management](#) for a discussion of the advantages and disadvantage of each kind of object management.

## How to create objects

You can use `kubectl create -f` to create an object from a configuration file. Refer to the [kubernetes API reference](#) for details.

- `kubectl create -f <filename|url>`

# How to update objects

## Warning:

Updating objects with the `replace` command drops all parts of the spec not specified in the configuration file. This should not be used with objects whose specs are partially managed by the cluster, such as Services of type LoadBalancer, where the `externalIPs` field is managed independently from the configuration file. Independently managed fields must be copied to the configuration file to prevent `replace` from dropping them.

You can use `kubectl replace -f` to update a live object according to a configuration file.

- `kubectl replace -f <filename|url>`

# How to delete objects

You can use `kubectl delete -f` to delete an object that is described in a configuration file.

- `kubectl delete -f <filename|url>`

## Note:

If configuration file has specified the `generateName` field in the metadata section instead of the `name` field, you cannot delete the object using `kubectl delete -f <filename|url>`. You will have to use other flags for deleting the object. For example:

```
kubectl delete <type> <name>
kubectl delete <type> -l <label>
```

# How to view an object

You can use `kubectl get -f` to view information about an object that is described in a configuration file.

- `kubectl get -f <filename|url> -o yaml`

The `-o yaml` flag specifies that the full object configuration is printed. Use `kubectl get -h` to see a list of options.

# Limitations

The `create`, `replace`, and `delete` commands work well when each object's configuration is fully defined and recorded in its configuration file. However when a live object is updated, and the updates are not merged into its configuration file, the updates will be lost the next time a `replace` is executed. This can happen if a controller, such as a HorizontalPodAutoscaler, makes updates directly to a live object. Here's an example:

1. You create an object from a configuration file.
2. Another source updates the object by changing some field.

3. You replace the object from the configuration file. Changes made by the other source in step 2 are lost.

If you need to support multiple writers to the same object, you can use `kubectl apply` to manage the object.

## Creating and editing an object from a URL without saving the configuration

Suppose you have the URL of an object configuration file. You can use `kubectl create --edit` to make changes to the configuration before the object is created. This is particularly useful for tutorials and tasks that point to a configuration file that could be modified by the reader.

```
kubectl create -f <url> --edit
```

## Migrating from imperative commands to imperative object configuration

Migrating from imperative commands to imperative object configuration involves several manual steps.

1. Export the live object to a local object configuration file:

```
kubectl get <kind>/<name> -o yaml > <kind>_<name>.yaml
```

2. Manually remove the status field from the object configuration file.
3. For subsequent object management, use `replace` exclusively.

```
kubectl replace -f <kind>_<name>.yaml
```

## Defining controller selectors and PodTemplate labels

### Warning:

Updating selectors on controllers is strongly discouraged.

The recommended approach is to define a single, immutable PodTemplate label used only by the controller selector with no other semantic meaning.

Example label:

```
selector:
 matchLabels:
 controller-selector: "apps/v1/deployment/nginx"
template:
 metadata:
 labels:
 controller-selector: "apps/v1/deployment/nginx"
```

## What's next

- [Kubernetes API Reference](#)

# Update API Objects in Place Using kubectl patch

Use kubectl patch to update Kubernetes API objects in place. Do a strategic merge patch or a JSON merge patch.

This task shows how to use kubectl patch to update an API object in place. The exercises in this task demonstrate a strategic merge patch and a JSON merge patch.

## Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter kubectl version.

## Use a strategic merge patch to update a Deployment

Here's the configuration file for a Deployment that has two replicas. Each replica is a Pod that has one container:

[application/deployment-patch.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
 name: patch-demo
spec:
 replicas: 2
 selector:
 matchLabels:
 app: nginx
 template:
 metadata:
 labels:
 app: nginx
 spec:
```

```
containers:
- name: patch-demo-ctr
 image: nginx
tolerations:
- effect: NoSchedule
 key: dedicated
 value: test-team
```

Create the Deployment:

```
kubectl apply -f https://k8s.io/examples/application/deployment-patch.yaml
```

View the Pods associated with your Deployment:

```
kubectl get pods
```

The output shows that the Deployment has two Pods. The 1/1 indicates that each Pod has one container:

NAME	READY	STATUS	RESTARTS	AGE
patch-demo-28633765-670qr	1/1	Running	0	23s
patch-demo-28633765-j5qs3	1/1	Running	0	23s

Make a note of the names of the running Pods. Later, you will see that these Pods get terminated and replaced by new ones.

At this point, each Pod has one Container that runs the nginx image. Now suppose you want each Pod to have two containers: one that runs nginx and one that runs redis.

Create a file named patch-file.yaml that has this content:

```
spec:
 template:
 spec:
 containers:
 - name: patch-demo-ctr-2
 image: redis
```

Patch your Deployment:

```
kubectl patch deployment patch-demo --patch-file patch-file.yaml
```

View the patched Deployment:

```
kubectl get deployment patch-demo --output yaml
```

The output shows that the PodSpec in the Deployment has two Containers:

```
containers:
- image: redis
 imagePullPolicy: Always
 name: patch-demo-ctr-2
...
- image: nginx
 imagePullPolicy: Always
```

```
name: patch-demo-ctr
...
```

View the Pods associated with your patched Deployment:

```
kubectl get pods
```

The output shows that the running Pods have different names from the Pods that were running previously. The Deployment terminated the old Pods and created two new Pods that comply with the updated Deployment spec. The 2/2 indicates that each Pod has two Containers:

NAME	READY	STATUS	RESTARTS	AGE
patch-demo-1081991389-2wrn5	2/2	Running	0	1m
patch-demo-1081991389-jmg7b	2/2	Running	0	1m

Take a closer look at one of the patch-demo Pods:

```
kubectl get pod <your-pod-name> --output yaml
```

The output shows that the Pod has two Containers: one running nginx and one running redis:

```
containers:
- image: redis
...
- image: nginx
...
```

## Notes on the strategic merge patch

The patch you did in the preceding exercise is called a *strategic merge patch*. Notice that the patch did not replace the containers list. Instead it added a new Container to the list. In other words, the list in the patch was merged with the existing list. This is not always what happens when you use a strategic merge patch on a list. In some cases, the list is replaced, not merged.

With a strategic merge patch, a list is either replaced or merged depending on its patch strategy. The patch strategy is specified by the value of the patchStrategy key in a field tag in the Kubernetes source code. For example, the Containers field of PodSpec struct has a patchStrategy of merge:

```
type PodSpec struct {
...
Containers []Container `json:"containers" patchStrategy:"merge" patchMergeKey:"name" ...`
...
}
```

You can also see the patch strategy in the [OpenApi spec](#):

```
"io.k8s.api.core.v1.PodSpec": {
 ...,
 "containers": {
 "description": "List of containers belonging to the pod.",
 },
 "x-kubernetes-patch-merge-key": "name",
}
```

```
"x-kubernetes-patch-strategy": "merge"
}
```

And you can see the patch strategy in the [Kubernetes API documentation](#).

Create a file named patch-file-tolerations.yaml that has this content:

```
spec:
 template:
 spec:
 tolerations:
 - effect: NoSchedule
 key: disktype
 value: ssd
```

Patch your Deployment:

```
kubectl patch deployment patch-demo --patch-file patch-file-tolerations.yaml
```

View the patched Deployment:

```
kubectl get deployment patch-demo --output yaml
```

The output shows that the PodSpec in the Deployment has only one Tolerations:

```
tolerations:
- effect: NoSchedule
 key: disktype
 value: ssd
```

Notice that the tolerations list in the PodSpec was replaced, not merged. This is because the Tolerations field of PodSpec does not have a patchStrategy key in its field tag. So the strategic merge patch uses the default patch strategy, which is replace.

```
type PodSpec struct {
 ...
 Tolerations []Toleration `json:"tolerations,omitempty" protobuf:"bytes,
22,opt,name=tolerations"`
 ...
}
```

## Use a JSON merge patch to update a Deployment

A strategic merge patch is different from a [JSON merge patch](#). With a JSON merge patch, if you want to update a list, you have to specify the entire new list. And the new list completely replaces the existing list.

The kubectl patch command has a type parameter that you can set to one of these values:

Parameter value	Merge type
json	<a href="#">JSON Patch, RFC 6902</a>
merge	<a href="#">JSON Merge Patch, RFC 7386</a>
strategic	Strategic merge patch

For a comparison of JSON patch and JSON merge patch, see [JSON Patch and JSON Merge Patch](#).

The default value for the type parameter is strategic. So in the preceding exercise, you did a strategic merge patch.

Next, do a JSON merge patch on your same Deployment. Create a file named patch-file-2.yaml that has this content:

```
spec:
 template:
 spec:
 containers:
 - name: patch-demo-ctr-3
 image: gcr.io/google-samples/node-hello:1.0
```

In your patch command, set type to merge:

```
kubectl patch deployment patch-demo --type merge --patch-file patch-file-2.yaml
```

View the patched Deployment:

```
kubectl get deployment patch-demo --output yaml
```

The containers list that you specified in the patch has only one Container. The output shows that your list of one Container replaced the existing containers list.

```
spec:
 containers:
 - image: gcr.io/google-samples/node-hello:1.0
 ...
 name: patch-demo-ctr-3
```

List the running Pods:

```
kubectl get pods
```

In the output, you can see that the existing Pods were terminated, and new Pods were created. The 1/1 indicates that each new Pod is running only one Container.

NAME	READY	STATUS	RESTARTS	AGE
patch-demo-1307768864-69308	1/1	Running	0	1m
patch-demo-1307768864-c86dc	1/1	Running	0	1m

## Use strategic merge patch to update a Deployment using the retainKeys strategy

Here's the configuration file for a Deployment that uses the RollingUpdate strategy:

[application/deployment-retainkeys.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
```

```
name: retainkeys-demo
spec:
 selector:
 matchLabels:
 app: nginx
 strategy:
 rollingUpdate:
 maxSurge: 30%
 template:
 metadata:
 labels:
 app: nginx
 spec:
 containers:
 - name: retainkeys-demo-ctr
 image: nginx
```

Create the deployment:

```
kubectl apply -f https://k8s.io/examples/application/deployment-retainkeys.yaml
```

At this point, the deployment is created and is using the RollingUpdate strategy.

Create a file named patch-file-no-retainkeys.yaml that has this content:

```
spec:
 strategy:
 type: Recreate
```

Patch your Deployment:

```
kubectl patch deployment retainkeys-demo --type strategic --patch-file patch-file-no-retainkeys.yaml
```

In the output, you can see that it is not possible to set type as Recreate when a value is defined for spec.strategy.rollingUpdate:

The Deployment "retainkeys-demo" is invalid: spec.strategy.rollingUpdate: Forbidden: may not be specified when strategy `type` is 'Recreate'

The way to remove the value for spec.strategy.rollingUpdate when updating the value for type is to use the retainKeys strategy for the strategic merge.

Create another file named patch-file-retainkeys.yaml that has this content:

```
spec:
 strategy:
 $retainKeys:
 - type
 type: Recreate
```

With this patch, we indicate that we want to retain only the type key of the strategy object. Thus, the rollingUpdate will be removed during the patch operation.

Patch your Deployment again with this new patch:

```
kubectl patch deployment retainkeys-demo --type strategic --patch-file patch-file-retainkeys.yaml
```

Examine the content of the Deployment:

```
kubectl get deployment retainkeys-demo --output yaml
```

The output shows that the strategy object in the Deployment does not contain the rollingUpdate key anymore:

```
spec:
 strategy:
 type: Recreate
 template:
```

## Notes on the strategic merge patch using the retainKeys strategy

The patch you did in the preceding exercise is called a *strategic merge patch with retainKeys strategy*. This method introduces a new directive \$retainKeys that has the following strategies:

- It contains a list of strings.
- All fields needing to be preserved must be present in the \$retainKeys list.
- The fields that are present will be merged with live object.
- All of the missing fields will be cleared when patching.
- All fields in the \$retainKeys list must be a superset or the same as the fields present in the patch.

The retainKeys strategy does not work for all objects. It only works when the value of the patchStrategy key in a field tag in the Kubernetes source code contains retainKeys. For example, the Strategy field of the DeploymentSpec struct has a patchStrategy of retainKeys:

```
type DeploymentSpec struct {
 ...
 // +patchStrategy=retainKeys
 Strategy DeploymentStrategy `json:"strategy,omitempty" patchStrategy:"retainKeys" ...`
 ...
}
```

You can also see the retainKeys strategy in the [OpenApi spec](#):

```
"io.k8s.api.apps.v1.DeploymentSpec": {
 ...,
 "strategy": {
 "$ref": "#/definitions/io.k8s.api.apps.v1.DeploymentStrategy",
 "description": "The deployment strategy to use to replace existing pods with new ones.",
 "x-kubernetes-patch-strategy": "retainKeys"
 },

}
```

And you can see the retainKeys strategy in the [Kubernetes API documentation](#).

## Alternate forms of the kubectl patch command

The `kubectl patch` command takes YAML or JSON. It can take the patch as a file or directly on the command line.

Create a file named `patch-file.json` that has this content:

```
{
 "spec": {
 "template": {
 "spec": {
 "containers": [
 {
 "name": "patch-demo-ctr-2",
 "image": "redis"
 }
]
 }
 }
 }
}
```

The following commands are equivalent:

```
kubectl patch deployment patch-demo --patch-file patch-file.yaml
kubectl patch deployment patch-demo --patch 'spec:\n template:\n spec:\n containers:\n -\n name: patch-demo-ctr-2\n image: redis'

kubectl patch deployment patch-demo --patch-file patch-file.json
kubectl patch deployment patch-demo --patch '{"spec": {"template": {"spec": {"containers": [{"name": "patch-demo-ctr-2", "image": "redis"}]}}}'
```

## Update an object's replica count using kubectl patch with --subresource

FEATURE STATE: Kubernetes v1.24 [alpha]

The flag `--subresource=[subresource-name]` is used with `kubectl` commands like `get`, `patch`, `edit` and `replace` to fetch and update status and scale subresources of the resources (applicable for `kubectl` version v1.24 or more). This flag is used with all the API resources (built-in and CRs) that have status or scale subresource. Deployment is one of the examples which supports these subresources.

Here's a manifest for a Deployment that has two replicas:

[application/deployment.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
 name: nginx-deployment
spec:
 selector:
 matchLabels:
```

```
 app: nginx
replicas: 2 # tells deployment to run 2 pods matching the template
template:
 metadata:
 labels:
 app: nginx
 spec:
 containers:
 - name: nginx
 image: nginx:1.14.2
 ports:
 - containerPort: 80
```

Create the Deployment:

```
kubectl apply -f https://k8s.io/examples/application/deployment.yaml
```

View the Pods associated with your Deployment:

```
kubectl get pods -l app=nginx
```

In the output, you can see that Deployment has two Pods. For example:

NAME	READY	STATUS	RESTARTS	AGE
nginx-deployment-7fb96c846b-22567	1/1	Running	0	47s
nginx-deployment-7fb96c846b-mlgns	1/1	Running	0	47s

Now, patch that Deployment with `--subresource=[subresource-name]` flag:

```
kubectl patch deployment nginx-deployment --subresource='scale' --type='merge' -p '{"spec": {"replicas":3}}'
```

The output is:

```
scale.autoscaling/nginx-deployment patched
```

View the Pods associated with your patched Deployment:

```
kubectl get pods -l app=nginx
```

In the output, you can see one new pod is created, so now you have 3 running pods.

NAME	READY	STATUS	RESTARTS	AGE
nginx-deployment-7fb96c846b-22567	1/1	Running	0	107s
nginx-deployment-7fb96c846b-lxfr2	1/1	Running	0	14s
nginx-deployment-7fb96c846b-mlgns	1/1	Running	0	107s

View the patched Deployment:

```
kubectl get deployment nginx-deployment -o yaml
```

```
...
spec:
 replicas: 3
...
```

```
status:
...
availableReplicas: 3
readyReplicas: 3
replicas: 3
```

**Note:**

If you run `kubectl patch` and specify `--subresource` flag for resource that doesn't support that particular subresource, the API server returns a 404 Not Found error.

## Summary

In this exercise, you used `kubectl patch` to change the live configuration of a Deployment object. You did not change the configuration file that you originally used to create the Deployment object. Other commands for updating API objects include [kubectl annotate](#), [kubectl edit](#), [kubectl replace](#), [kubectl scale](#), and [kubectl apply](#).

**Note:**

Strategic merge patch is not supported for custom resources.

## What's next

- [Kubernetes Object Management](#)

- [Imperative Management of Kubernetes Objects Using Configuration Files](#)
- [Declarative Management of Kubernetes Objects Using Configuration Files](#)

# Migrate Kubernetes Objects Using Storage Version Migration

FEATURE STATE: Kubernetes v1.30 [alpha]

Kubernetes relies on API data being actively re-written, to support some maintenance activities related to at rest storage. Two prominent examples are the versioned schema of stored resources (that is, the preferred storage schema changing from v1 to v2 for a given resource) and encryption at rest (that is, rewriting stale data based on a change in how the data should be encrypted).

## Before you begin

Install [kubectl](#).

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at

least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be version v1.30. To check the version, enter `kubectl version`.

## Re-encrypt Kubernetes secrets using storage version migration

- To begin with, [configure KMS provider](#) to encrypt data at rest in etcd using following encryption configuration.

```
kind: EncryptionConfiguration
apiVersion: apiserver.config.k8s.io/v1
resources:
- resources:
 - secrets
providers:
- aescbc:
 keys:
 - name: key1
 secret: c2VjcmV0IGlzIHNIY3VyZQ==
```

Make sure to enable automatic reload of encryption configuration file by setting `--encryption-provider-config-automatic-reload` to true.

- Create a Secret using `kubectl`.

```
kubectl create secret generic my-secret --from-literal=key1=supersecret
```

- [Verify](#) the serialized data for that Secret object is prefixed with `k8s:enc:aescbc:v1:key1`.
- Update the encryption configuration file as follows to rotate the encryption key.

```
kind: EncryptionConfiguration
apiVersion: apiserver.config.k8s.io/v1
resources:
- resources:
 - secrets
providers:
- aescbc:
 keys:
 - name: key2
 secret: c2VjcmV0IGlzIHNIY3VyZSwgaXMgaXQ/
 - aescbc:
 keys:
 - name: key1
 secret: c2VjcmV0IGlzIHNIY3VyZQ==
```

- To ensure that previously created secret `my-secret` is re-encrypted with new key `key2`, you will use *Storage Version Migration*.

Create a StorageVersionMigration manifest named `migrate-secret.yaml` as follows:

- ```
kind: StorageVersionMigration
apiVersion: storagemigration.k8s.io/v1alpha1
metadata:
  name: secrets-migration
spec:
  resource:
    group: ""
    version: v1
    resource: secrets
```

Create the object using *kubectl* as follows:

```
kubectl apply -f migrate-secret.yaml
```

- Monitor migration of Secrets by checking the `.status` of the StorageVersionMigration. A successful migration should have its Succeeded condition set to true. Get the StorageVersionMigration object as follows:

```
kubectl get storageversionmigration.storagemigration.k8s.io/secrets-migration -o yaml
```

The output is similar to:

```
kind: StorageVersionMigration
apiVersion: storagemigration.k8s.io/v1alpha1
metadata:
  name: secrets-migration
  uid: 628f6922-a9cb-4514-b076-12d3c178967c
  resourceVersion: "90"
  creationTimestamp: "2024-03-12T20:29:45Z"
spec:
  resource:
    group: ""
    version: v1
    resource: secrets
status:
  conditions:
  - type: Running
    status: "False"
    lastUpdateTime: "2024-03-12T20:29:46Z"
    reason: StorageVersionMigrationInProgress
  - type: Succeeded
    status: "True"
    lastUpdateTime: "2024-03-12T20:29:46Z"
    reason: StorageVersionMigrationSucceeded
  resourceVersion: "84"
```

- [Verify](#) the stored secret is now prefixed with `k8s:enc:aescbc:v1:key2`.

Update the preferred storage schema of a CRD

Consider a scenario where a [CustomResourceDefinition](#) (CRD) is created to serve custom resources (CRs) and is set as the preferred storage schema. When it's time to introduce v2 of the CRD, it can be added for serving only with a conversion webhook. This enables a smoother transition where users can create CRs using either the v1 or v2 schema, with the webhook in place to perform the necessary schema conversion between them. Before setting v2 as the preferred storage schema version, it's important to ensure that all existing CRs stored as v1 are migrated to v2. This migration can be achieved through *Storage Version Migration* to migrate all CRs from v1 to v2.

- Create a manifest for the CRD, named test-crd.yaml, as follows:

```
apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
metadata:
  name: selfierequests.stable.example.com
spec:
  group: stable.example.com
  names:
    plural: SelfieRequests
    singular: SelfieRequest
    kind: SelfieRequest
    listKind: SelfieRequestList
  scope: Namespaced
  versions:
  - name: v1
    served: true
    storage: true
    schema:
      openAPIV3Schema:
        type: object
        properties:
          hostPort:
            type: string
  conversion:
    strategy: Webhook
    webhook:
      clientConfig:
        url: "https://127.0.0.1:9443/crdconvert"
        caBundle: <CABundle info>
    conversionReviewVersions:
    - v1
    - v2
```

Create CRD using kubectl:

```
kubectl apply -f test-crd.yaml
```

- Create a manifest for an example testcrd. Name the manifest cr1.yaml and use these contents:

```
apiVersion: stable.example.com/v1
kind: SelfieRequest
metadata:
  name: cr1
  namespace: default
```

Create CR using kubectl:

```
kubectl apply -f cr1.yaml
```

- Verify that CR is written and stored as v1 by getting the object from etcd.

```
ETCDCTL_API=3 etcdctl get /kubernetes.io/stable.example.com/testcrds/default/cr1 [...] |
hexdump -C
```

where [...] contains the additional arguments for connecting to the etcd server.

- Update the CRD test-crd.yaml to include v2 version for serving and storage and v1 as serving only, as follows:

```
apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
metadata:
  name: selfierequests.stable.example.com
spec:
  group: stable.example.com
  names:
    plural: SelfieRequests
    singular: SelfieRequest
    kind: SelfieRequest
    listKind: SelfieRequestList
    scope: Namespaced
  versions:
    - name: v2
      served: true
      storage: true
      schema:
        openAPIV3Schema:
          type: object
          properties:
            host:
              type: string
            port:
              type: string
    - name: v1
      served: true
      storage: false
      schema:
        openAPIV3Schema:
          type: object
          properties:
            hostPort:
              type: string
  conversion:
```

```
strategy: Webhook
webhook:
  clientConfig:
    url: "https://127.0.0.1:9443/crdconvert"
    caBundle: <CABundle info>
  conversionReviewVersions:
    - v1
    - v2
```

Update CRD using kubectl:

```
kubectl apply -f test-crd.yaml
```

- Create CR resource file with name cr2.yaml as follows:

```
apiVersion: stable.example.com/v2
kind: SelfieRequest
metadata:
  name: cr2
  namespace: default
```

- Create CR using kubectl:

```
kubectl apply -f cr2.yaml
```

- Verify that CR is written and stored as v2 by getting the object from etcd.

```
ETCDCTL_API=3 etcdctl get /kubernetes.io/stable.example.com/testcrds/default/cr2 [...] |
hexdump -C
```

where [...] contains the additional arguments for connecting to the etcd server.

- Create a StorageVersionMigration manifest named migrate-crd.yaml, with the contents as follows:

```
kind: StorageVersionMigration
apiVersion: storagemigration.k8s.io/v1alpha1
metadata:
  name: crdsvm
spec:
  resource:
    group: stable.example.com
    version: v1
  resource: SelfieRequest
```

Create the object using *kubectl* as follows:

```
kubectl apply -f migrate-crd.yaml
```

- Monitor migration of secrets using status. Successful migration should have Succeeded condition set to "True" in the status field. Get the migration resource as follows:

```
kubectl get storageversionmigration.storagemigration.k8s.io/crdsvm -o yaml
```

The output is similar to:

```
kind: StorageVersionMigration
apiVersion: storagemigration.k8s.io/v1alpha1
metadata:
  name: crdsvm
  uid: 13062fe4-32d7-47cc-9528-5067fa0c6ac8
  resourceVersion: "111"
  creationTimestamp: "2024-03-12T22:40:01Z"
spec:
  resource:
    group: stable.example.com
    version: v1
    resource: testcrds
status:
  conditions:
    - type: Running
      status: "False"
      lastUpdateTime: "2024-03-12T22:40:03Z"
      reason: StorageVersionMigrationInProgress
    - type: Succeeded
      status: "True"
      lastUpdateTime: "2024-03-12T22:40:03Z"
      reason: StorageVersionMigrationSucceeded
  resourceVersion: "106"
```

- Verify that previously created cr1 is now written and stored as v2 by getting the object from etcd.

```
ETCDCTL_API=3 etcdctl get /kubernetes.io/stable.example.com/testcrds/default/cr1 [...] | hexdump -C
```

where [...] contains the additional arguments for connecting to the etcd server.

Managing Secrets

Managing confidential settings data using Secrets.

[Managing Secrets using kubectl](#)

Creating Secret objects using kubectl command line.

[Managing Secrets using Configuration File](#)

Creating Secret objects using resource configuration file.

[Managing Secrets using Kustomize](#)

Creating Secret objects using kustomization.yaml file.

Managing Secrets using kubectl

Creating Secret objects using kubectl command line.

This page shows you how to create, edit, manage, and delete Kubernetes [Secrets](#) using the kubectl command-line tool.

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Create a Secret

A Secret object stores sensitive data such as credentials used by Pods to access services. For example, you might need a Secret to store the username and password needed to access a database.

You can create the Secret by passing the raw data in the command, or by storing the credentials in files that you pass in the command. The following commands create a Secret that stores the username admin and the password S!B*d\$zDsb=.

Use raw data

Run the following command:

```
kubectl create secret generic db-user-pass \
  --from-literal=username=admin \
  --from-literal=password='S!B\*d$zDsb='
```

You must use single quotes " to escape special characters such as \$, \, *, =, and ! in your strings. If you don't, your shell will interpret these characters.

Note:

The stringData field for a Secret does not work well with server-side apply.

Use source files

1. Store the credentials in files:

```
echo -n 'admin' > ./username.txt
echo -n 'S!B\*d$zDsb=' > ./password.txt
```

The `-n` flag ensures that the generated files do not have an extra newline character at the end of the text. This is important because when `kubectl` reads a file and encodes the content into a base64 string, the extra newline character gets encoded too. You do not need to escape special characters in strings that you include in a file.

2. Pass the file paths in the `kubectl` command:

```
kubectl create secret generic db-user-pass \  
  --from-file=./username.txt \  
  --from-file=./password.txt
```

The default key name is the file name. You can optionally set the key name using `--from-file=[key=]source`. For example:

```
kubectl create secret generic db-user-pass \  
  --from-file=username=./username.txt \  
  --from-file=password=./password.txt
```

With either method, the output is similar to:

```
secret/db-user-pass created
```

Verify the Secret

Check that the Secret was created:

```
kubectl get secrets
```

The output is similar to:

| NAME | TYPE | DATA | AGE |
|--------------|--------|------|-----|
| db-user-pass | Opaque | 2 | 51s |

View the details of the Secret:

```
kubectl describe secret db-user-pass
```

The output is similar to:

```
Name:      db-user-pass  
Namespace: default  
Labels:    <none>  
Annotations: <none>  
  
Type:      Opaque  
  
Data  
====  
password:  12 bytes  
username:  5 bytes
```

The commands `kubectl get` and `kubectl describe` avoid showing the contents of a Secret by default. This is to protect the Secret from being exposed accidentally, or from being stored in a terminal log.

Decode the Secret

1. View the contents of the Secret you created:

```
kubectl get secret db-user-pass -o jsonpath='{.data}'
```

The output is similar to:

```
{ "password": "UyFCXCpkJHpEc2I9", "username": "YWRtaW4=" }
```

2. Decode the password data:

```
echo 'UyFCXCpkJHpEc2I9' | base64 --decode
```

The output is similar to:

```
S!B\*d$zDsb=
```

Caution:

This is an example for documentation purposes. In practice, this method could cause the command with the encoded data to be stored in your shell history. Anyone with access to your computer could find the command and decode the secret. A better approach is to combine the view and decode commands.

```
kubectl get secret db-user-pass -o jsonpath='{.data.password}' | base64 --decode
```

Edit a Secret

You can edit an existing Secret object unless it is [immutable](#). To edit a Secret, run the following command:

```
kubectl edit secrets <secret-name>
```

This opens your default editor and allows you to update the base64 encoded Secret values in the data field, such as in the following example:

```
# Please edit the object below. Lines beginning with a '#' will be ignored,
# and an empty file will abort the edit. If an error occurs while saving this file, it will be
# reopened with the relevant failures.
#
apiVersion: v1
data:
  password: UyFCXCpkJHpEc2I9
  username: YWRtaW4=
kind: Secret
metadata:
  creationTimestamp: "2022-06-28T17:44:13Z"
  name: db-user-pass
  namespace: default
  resourceVersion: "12708504"
  uid: 91becd59-78fa-4c85-823f-6d44436242ac
type: Opaque
```

Clean up

To delete a Secret, run the following command:

```
kubectl delete secret db-user-pass
```

What's next

- Read more about the [Secret concept](#)
- Learn how to [manage Secrets using config file](#)
- Learn how to [manage Secrets using kustomize](#)

Managing Secrets using Configuration File

Creating Secret objects using resource configuration file.

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Create the Secret

You can define the Secret object in a manifest first, in JSON or YAML format, and then create that object. The [Secret](#) resource contains two maps: data and stringData. The data field is used to store arbitrary data, encoded using base64. The stringData field is provided for convenience, and it allows you to provide the same data as unencoded strings. The keys of data and stringData must consist of alphanumeric characters, -, _ or ..

The following example stores two strings in a Secret using the data field.

1. Convert the strings to base64:

```
echo -n 'admin' | base64  
echo -n '1f2d1e2e67df' | base64
```

Note:

The serialized JSON and YAML values of Secret data are encoded as base64 strings. Newlines are not valid within these strings and must be omitted. When using the base64 utility on Darwin/macOS, users should avoid using the -b option to split long lines. Conversely, Linux users *should* add the option -w 0 to base64 commands or the pipeline `base64 | tr -d '\n'` if the -w option is not available.

The output is similar to:

```
YWRtaW4=  
MWYyZDFlMmU2N2Rm
```

2. Create the manifest:

```
apiVersion: v1  
kind: Secret  
metadata:  
  name: mysecret  
type: Opaque  
data:  
  username: YWRtaW4=  
  password: MWYyZDFlMmU2N2Rm
```

Note that the name of a Secret object must be a valid [DNS subdomain name](#).

3. Create the Secret using [kubectl apply](#):

```
kubectl apply -f ./secret.yaml
```

The output is similar to:

```
secret/mysecret created
```

To verify that the Secret was created and to decode the Secret data, refer to [Managing Secrets using kubectl](#).

Specify unencoded data when creating a Secret

For certain scenarios, you may wish to use the `stringData` field instead. This field allows you to put a non-base64 encoded string directly into the Secret, and the string will be encoded for you when the Secret is created or updated.

A practical example of this might be where you are deploying an application that uses a Secret to store a configuration file, and you want to populate parts of that configuration file during your deployment process.

For example, if your application uses the following configuration file:

```
apiUrl: "https://my.api.com/api/v1"  
username: "<user>"  
password: "<password>"
```

You could store this in a Secret using the following definition:

```
apiVersion: v1  
kind: Secret  
metadata:  
  name: mysecret  
type: Opaque  
stringData:  
  config.yaml: |
```

```
apiUrl: "https://my.api.com/api/v1"
username: <user>
password: <password>
```

Note:

The `stringData` field for a Secret does not work well with server-side apply.

When you retrieve the Secret data, the command returns the encoded values, and not the plaintext values you provided in `stringData`.

For example, if you run the following command:

```
kubectl get secret mysecret -o yaml
```

The output is similar to:

```
apiVersion: v1
data:
  config.yaml: YXBpVXJsOiAiaHR0cHM6Ly9teS5hcGkuY29tL2FwaS92MSIKdXNlcm5hbWU6IHt7dXNlcm5hbWV9fQpwYXNzd29yZDoge3twYXNzd29yZHU19
kind: Secret
metadata:
  creationTimestamp: 2018-11-15T20:40:59Z
  name: mysecret
  namespace: default
  resourceVersion: "7225"
  uid: c280ad2e-e916-11e8-98f2-025000000001
type: Opaque
```

Specify both data and stringData

If you specify a field in both `data` and `stringData`, the value from `stringData` is used.

For example, if you define the following Secret:

```
apiVersion: v1
kind: Secret
metadata:
  name: mysecret
type: Opaque
data:
  username: YWRtaW4=
stringData:
  username: administrator
```

Note:

The `stringData` field for a Secret does not work well with server-side apply.

The Secret object is created as follows:

```
apiVersion: v1
data:
  username: YWRtaW5pc3RyYXRvcg==
kind: Secret
metadata:
  creationTimestamp: 2018-11-15T20:46:46Z
  name: mysecret
  namespace: default
  resourceVersion: "7579"
  uid: 91460ecb-e917-11e8-98f2-025000000001
type: Opaque
```

YWRtaW5pc3RyYXRvcg== decodes to administrator.

Edit a Secret

To edit the data in the Secret you created using a manifest, modify the data or stringData field in your manifest and apply the file to your cluster. You can edit an existing Secret object unless it is [immutable](#).

For example, if you want to change the password from the previous example to birdsarentreal, do the following:

1. Encode the new password string:

```
echo -n 'birdsarentreal' | base64
```

The output is similar to:

```
YmlyZHNhcmVudHJlYWw=
```

2. Update the data field with your new password string:

```
apiVersion: v1
kind: Secret
metadata:
  name: mysecret
type: Opaque
data:
  username: YWRtaW4=
  password: YmlyZHNhcmVudHJlYWw=
```

3. Apply the manifest to your cluster:

```
kubectl apply -f ./secret.yaml
```

The output is similar to:

```
secret/mysecret configured
```

Kubernetes updates the existing Secret object. In detail, the kubectl tool notices that there is an existing Secret object with the same name. kubectl fetches the existing object, plans changes to it, and submits the changed Secret object to your cluster control plane.

If you specified `kubectl apply --server-side` instead, `kubectl` uses [Server Side Apply](#) instead.

Clean up

To delete the Secret you have created:

```
kubectl delete secret mysecret
```

What's next

- Learn how to [manage Secrets using kubectl](#)
- Learn how to [manage Secrets using kustomize](#)

Managing Secrets using Kustomize

Creating Secret objects using `kustomization.yaml` file.

`kubectl` supports using the [Kustomize object management tool](#) to manage Secrets and ConfigMaps. You create a *resource generator* using Kustomize, which generates a Secret that you can apply to the API server using `kubectl`.

Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Create a Secret

You can generate a Secret by defining a `secretGenerator` in a `kustomization.yaml` file that references other existing files, `.env` files, or literal values. For example, the following instructions create a Kustomization file for the username `admin` and the password `1f2d1e2e67df`.

Note:

The `stringData` field for a Secret does not work well with server-side apply.

Create the Kustomization file

- [Literals](#)
- [Files](#)
- [.env files](#)

```
secretGenerator:
- name: database-creds
  literals:
  - username=admin
  - password=1f2d1e2e67df
```

1. Store the credentials in files. The filenames are the keys of the secret:

```
echo -n 'admin' > ./username.txt
echo -n '1f2d1e2e67df' > ./password.txt
```

The `-n` flag ensures that there's no newline character at the end of your files.

2. Create the `kustomization.yaml` file:

```
secretGenerator:
- name: database-creds
  files:
  - username.txt
  - password.txt
```

You can also define the `secretGenerator` in the `kustomization.yaml` file by providing `.env` files. For example, the following `kustomization.yaml` file pulls in data from an `.env.secret` file:

```
secretGenerator:
- name: db-user-pass
  envs:
  - .env.secret
```

In all cases, you don't need to base64 encode the values. The name of the YAML file **must** be `kustomization.yaml` or `kustomization.yml`.

Apply the kustomization file

To create the Secret, apply the directory that contains the kustomization file:

```
kubectl apply -k <directory-path>
```

The output is similar to:

```
secret/database-creds-5hdk7hhgfk created
```

When a Secret is generated, the Secret name is created by hashing the Secret data and appending the hash value to the name. This ensures that a new Secret is generated each time the data is modified.

To verify that the Secret was created and to decode the Secret data,

```
kubectl get -k <directory-path> -o jsonpath='{.data}'
```

The output is similar to:

```
{ "password": "UyFCXCpkJHpEc2I9", "username": "YWRtaW4=" }
```

```
echo 'UyFCXCpkJHpEc2I9' | base64 --decode
```

The output is similar to:

```
S!B\*d$zDsb=
```

For more information, refer to [Managing Secrets using kubectl](#) and [Declarative Management of Kubernetes Objects Using Kustomize](#).

Edit a Secret

1. In your kustomization.yaml file, modify the data, such as the password.
2. Apply the directory that contains the kustomization file:

```
kubectl apply -k <directory-path>
```

The output is similar to:

```
secret/db-user-pass-6f24b56cc8 created
```

The edited Secret is created as a new Secret object, instead of updating the existing Secret object. You might need to update references to the Secret in your Pods.

Clean up

To delete a Secret, use kubectl:

```
kubectl delete secret db-user-pass
```

What's next

- Read more about the [Secret concept](#)
- Learn how to [manage Secrets using kubectl](#)
- Learn how to [manage Secrets using config file](#)

Inject Data Into Applications

Specify configuration and other data for the Pods that run your workload.

[Define a Command and Arguments for a Container](#)

[Define Dependent Environment Variables](#)

[Define Environment Variables for a Container](#)

[Expose Pod Information to Containers Through Environment Variables](#)

[Expose Pod Information to Containers Through Files](#)

Define a Command and Arguments for a Container

This page shows how to define commands and arguments when you run a container in a [Pod](#).

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter kubectl version.

Define a command and arguments when you create a Pod

When you create a Pod, you can define a command and arguments for the containers that run in the Pod. To define a command, include the command field in the configuration file. To define arguments for the command, include the args field in the configuration file. The command and arguments that you define cannot be changed after the Pod is created.

The command and arguments that you define in the configuration file override the default command and arguments provided by the container image. If you define args, but do not define a command, the default command is used with your new arguments.

Note:

The command field corresponds to ENTRYPOINT, and the args field corresponds to CMD in some container runtimes.

In this exercise, you create a Pod that runs one container. The configuration file for the Pod defines a command and two arguments:

[pods/commands.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
  name: command-demo
  labels:
    purpose: demonstrate-command
spec:
  containers:
  - name: command-demo-container
    image: debian
```

```
command: ["printenv"]
args: ["HOSTNAME", "KUBERNETES_PORT"]
restartPolicy: OnFailure
```

1. Create a Pod based on the YAML configuration file:

```
kubectl apply -f https://k8s.io/examples/pods/commands.yaml
```

2. List the running Pods:

```
kubectl get pods
```

The output shows that the container that ran in the command-demo Pod has completed.

3. To see the output of the command that ran in the container, view the logs from the Pod:

```
kubectl logs command-demo
```

The output shows the values of the HOSTNAME and KUBERNETES_PORT environment variables:

```
command-demo
tcp://10.3.240.1:443
```

Use environment variables to define arguments

In the preceding example, you defined the arguments directly by providing strings. As an alternative to providing strings directly, you can define arguments by using environment variables:

```
env:
- name: MESSAGE
  value: "hello world"
command: ["/bin/echo"]
args: ["$(MESSAGE)"]
```

This means you can define an argument for a Pod using any of the techniques available for defining environment variables, including [ConfigMaps](#) and [Secrets](#).

Note:

The environment variable appears in parentheses, "\$(VAR)". This is required for the variable to be expanded in the command or args field.

Run a command in a shell

In some cases, you need your command to run in a shell. For example, your command might consist of several commands piped together, or it might be a shell script. To run your command in a shell, wrap it like this:

```
command: ["/bin/sh"]
args: ["-c", "while true; do echo hello; sleep 10;done"]
```

What's next

- Learn more about [configuring pods and containers](#).
- Learn more about [running commands in a container](#).
- See [Container](#).

Define Dependent Environment Variables

This page shows how to define dependent environment variables for a container in a Kubernetes Pod.

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

Define an environment dependent variable for a container

When you create a Pod, you can set dependent environment variables for the containers that run in the Pod. To set dependent environment variables, you can use `$(VAR_NAME)` in the value of `env` in the configuration file.

In this exercise, you create a Pod that runs one container. The configuration file for the Pod defines a dependent environment variable with common usage defined. Here is the configuration manifest for the Pod:

[pods/inject/dependent-envvars.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
  name: dependent-envvars-demo
spec:
  containers:
    - name: dependent-envvars-demo
      args:
        - while true; do echo -en '\n'; printf
UNCHANGED_REFERENCE=$UNCHANGED_REFERENCE'\n'; printf
SERVICE_ADDRESS=$SERVICE_ADDRESS'\n';printf
ESCAPED_REFERENCE=$ESCAPED_REFERENCE'\n'; sleep 30; done;
      command:
        - sh
        - -c
```

```
image: busybox:1.28
env:
- name: SERVICE_PORT
  value: "80"
- name: SERVICE_IP
  value: "172.17.0.1"
- name: UNCHANGED_REFERENCE
  value: "${(PROTOCOL)}://${(SERVICE_IP)}:${(SERVICE_PORT)}"
- name: PROTOCOL
  value: "https"
- name: SERVICE_ADDRESS
  value: "${(PROTOCOL)}://${(SERVICE_IP)}:${(SERVICE_PORT)}"
- name: ESCAPED_REFERENCE
  value: "${$(PROTOCOL)}://${(SERVICE_IP)}:${(SERVICE_PORT)}"
```

1. Create a Pod based on that manifest:

```
kubectl apply -f https://k8s.io/examples/pods/inject/dependent-envvars.yaml
```

```
pod/dependent-envvars-demo created
```

2. List the running Pods:

```
kubectl get pods dependent-envvars-demo
```

| NAME | READY | STATUS | RESTARTS | AGE |
|------------------------|-------|---------|----------|-----|
| dependent-envvars-demo | 1/1 | Running | 0 | 9s |

3. Check the logs for the container running in your Pod:

```
kubectl logs pod/dependent-envvars-demo
```

```
UNCHANGED_REFERENCE=${(PROTOCOL)}://172.17.0.1:80
SERVICE_ADDRESS=https://172.17.0.1:80
ESCAPED_REFERENCE=${$(PROTOCOL)}://172.17.0.1:80
```

As shown above, you have defined the correct dependency reference of `SERVICE_ADDRESS`, bad dependency reference of `UNCHANGED_REFERENCE` and skip dependent references of `ESCAPED_REFERENCE`.

When an environment variable is already defined when being referenced, the reference can be correctly resolved, such as in the `SERVICE_ADDRESS` case.

Note that order matters in the `env` list. An environment variable is not considered "defined" if it is specified further down the list. That is why `UNCHANGED_REFERENCE` fails to resolve `$(PROTOCOL)` in the example above.

When the environment variable is undefined or only includes some variables, the undefined environment variable is treated as a normal string, such as `UNCHANGED_REFERENCE`. Note that incorrectly parsed environment variables, in general, will not block the container from starting.

The `$(VAR_NAME)` syntax can be escaped with a double `$`, ie: `$$ (VAR_NAME)`. Escaped references are never expanded, regardless of whether the referenced variable is defined or not. This can be seen from the `ESCAPED_REFERENCE` case above.

What's next

- Learn more about [environment variables](#).
- See [EnvVarSource](#).

Define Environment Variables for a Container

This page shows how to define environment variables for a container in a Kubernetes Pod.

Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

Define an environment variable for a container

When you create a Pod, you can set environment variables for the containers that run in the Pod. To set environment variables, include the `env` or `envFrom` field in the configuration file.

The `env` and `envFrom` fields have different effects.

`env`

allows you to set environment variables for a container, specifying a value directly for each variable that you name.

`envFrom`

allows you to set environment variables for a container by referencing either a `ConfigMap` or a `Secret`. When you use `envFrom`, all the key-value pairs in the referenced `ConfigMap` or `Secret` are set as environment variables for the container. You can also specify a common prefix string.

You can read more about [ConfigMap](#) and [Secret](#).

This page explains how to use `env`.

In this exercise, you create a Pod that runs one container. The configuration file for the Pod defines an environment variable with name `DEMO_GREETING` and value "Hello from the environment". Here is the configuration manifest for the Pod:

[pods/inject/envvars.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
  name: envar-demo
  labels:
    purpose: demonstrate-envvars
spec:
  containers:
  - name: envar-demo-container
    image: gcr.io/google-samples/node-hello:1.0
    env:
    - name: DEMO_GREETING
      value: "Hello from the environment"
    - name: DEMO_FAREWELL
      value: "Such a sweet sorrow"
```

1. Create a Pod based on that manifest:

```
kubectl apply -f https://k8s.io/examples/pods/inject/envvars.yaml
```

2. List the running Pods:

```
kubectl get pods -l purpose=demonstrate-envvars
```

The output is similar to:

| NAME | READY | STATUS | RESTARTS | AGE |
|------------|-------|---------|----------|-----|
| envar-demo | 1/1 | Running | 0 | 9s |

3. List the Pod's container environment variables:

```
kubectl exec envar-demo -- printenv
```

The output is similar to this:

```
NODE_VERSION=4.4.2
EXAMPLE_SERVICE_PORT_8080_TCP_ADDR=10.3.245.237
HOSTNAME=envar-demo
...
DEMO_GREETING=Hello from the environment
DEMO_FAREWELL=Such a sweet sorrow
```

Note:

The environment variables set using the `env` or `envFrom` field override any environment variables specified in the container image.

Note:

Environment variables may reference each other, however ordering is important. Variables making use of others defined in the same context must come later in the list. Similarly, avoid circular references.

Using environment variables inside of your config

Environment variables that you define in a Pod's configuration under `.spec.containers[*].env[*]` can be used elsewhere in the configuration, for example in commands and arguments that you set for the Pod's containers. In the example configuration below, the `GREETING`, `HONORIFIC`, and `NAME` environment variables are set to Warm greetings to, The Most Honorable, and Kubernetes, respectively. The environment variable `MESSAGE` combines the set of all these environment variables and then uses it as a CLI argument passed to the `env-print-demo` container.

Environment variable names consist of letters, numbers, underscores, dots, or hyphens, but the first character cannot be a digit. If the `RelaxedEnvironmentVariableValidation` [feature gate](#) is enabled, all [printable ASCII characters](#) except `"=`" may be used for environment variable names.

```
apiVersion: v1
kind: Pod
metadata:
  name: print-greeting
spec:
  containers:
  - name: env-print-demo
    image: bash
    env:
    - name: GREETING
      value: "Warm greetings to"
    - name: HONORIFIC
      value: "The Most Honorable"
    - name: NAME
      value: "Kubernetes"
    - name: MESSAGE
      value: "${GREETING} ${HONORIFIC} ${NAME}"
    command: ["echo"]
    args: ["${MESSAGE}"]
```

Upon creation, the command `echo Warm greetings to The Most Honorable Kubernetes` is run on the container.

Expose Pod Information to Containers Through Environment Variables

This page shows how a Pod can use environment variables to expose information about itself to containers running in the Pod, using the *downward API*. You can use environment variables to expose Pod fields, container fields, or both.

In Kubernetes, there are two ways to expose Pod and container fields to a running container:

- *Environment variables*, as explained in this task
- [Volume files](#)

Together, these two ways of exposing Pod and container fields are called the downward API.

As Services are the primary mode of communication between containerized applications managed by Kubernetes, it is helpful to be able to discover them at runtime.

Read more about accessing Services [here](#).

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Use Pod fields as values for environment variables

In this part of exercise, you create a Pod that has one container, and you project Pod-level fields into the running container as environment variables.

[pods/inject/dapi-envvars-pod.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
  name: dapi-envvars-fieldref
spec:
  containers:
    - name: test-container
      image: registry.k8s.io/busybox
      command: [ "sh", "-c" ]
      args:
        - while true; do
          echo -en '\n';
          printenv MY_NODE_NAME MY_POD_NAME MY_POD_NAMESPACE;
          printenv MY_POD_IP MY_POD_SERVICE_ACCOUNT;
          sleep 10;
        done;
      env:
        - name: MY_NODE_NAME
          valueFrom:
            fieldRef:
              fieldPath: spec.nodeName
        - name: MY_POD_NAME
          valueFrom:
```

```
    fieldRef:
      fieldPath: metadata.name
- name: MY_POD_NAMESPACE
valueFrom:
  fieldRef:
    fieldPath: metadata.namespace
- name: MY_POD_IP
valueFrom:
  fieldRef:
    fieldPath: status.podIP
- name: MY_POD_SERVICE_ACCOUNT
valueFrom:
  fieldRef:
    fieldPath: spec.serviceAccountName
restartPolicy: Never
```

In that manifest, you can see five environment variables. The `env` field is an array of environment variable definitions. The first element in the array specifies that the `MY_NODE_NAME` environment variable gets its value from the Pod's `spec.nodeName` field. Similarly, the other environment variables get their names from Pod fields.

Note:

The fields in this example are Pod fields. They are not fields of the container in the Pod.

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/inject/dapi-envvars-pod.yaml
```

Verify that the container in the Pod is running:

```
# If the new Pod isn't yet healthy, rerun this command a few times.
kubectl get pods
```

View the container's logs:

```
kubectl logs dapi-envvars-fieldref
```

The output shows the values of selected environment variables:

```
minikube
dapi-envvars-fieldref
default
172.17.0.4
default
```

To see why these values are in the log, look at the `command` and `args` fields in the configuration file. When the container starts, it writes the values of five environment variables to stdout. It repeats this every ten seconds.

Next, get a shell into the container that is running in your Pod:

```
kubectl exec -it dapi-envvars-fieldref -- sh
```

In your shell, view the environment variables:

```
# Run this in a shell inside the container
printenv
```

The output shows that certain environment variables have been assigned the values of Pod fields:

```
MY_POD_SERVICE_ACCOUNT=default
...
MY_POD_NAMESPACE=default
MY_POD_IP=172.17.0.4
...
MY_NODE_NAME=minikube
...
MY_POD_NAME=dapi-envvars-fieldref
```

Use container fields as values for environment variables

In the preceding exercise, you used information from Pod-level fields as the values for environment variables. In this next exercise, you are going to pass fields that are part of the Pod definition, but taken from the specific [container](#) rather than from the Pod overall.

Here is a manifest for another Pod that again has just one container:

[pods/inject/dapi-envvars-container.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
  name: dapi-envvars-resourcefieldref
spec:
  containers:
    - name: test-container
      image: registry.k8s.io/busybox:1.24
      command: [ "sh", "-c" ]
      args:
        - while true; do
          echo -en '\n';
          printenv MY_CPU_REQUEST MY_CPU_LIMIT;
          printenv MY_MEM_REQUEST MY_MEM_LIMIT;
          sleep 10;
        done;
      resources:
        requests:
          memory: "32Mi"
          cpu: "125m"
        limits:
          memory: "64Mi"
          cpu: "250m"
      env:
        - name: MY_CPU_REQUEST
          valueFrom:
```

```

    resourceFieldRef:
      containerName: test-container
      resource: requests.cpu
- name: MY_CPU_LIMIT
valueFrom:
  resourceFieldRef:
    containerName: test-container
    resource: limits.cpu
- name: MY_MEM_REQUEST
valueFrom:
  resourceFieldRef:
    containerName: test-container
    resource: requests.memory
- name: MY_MEM_LIMIT
valueFrom:
  resourceFieldRef:
    containerName: test-container
    resource: limits.memory
restartPolicy: Never

```

In this manifest, you can see four environment variables. The `env` field is an array of environment variable definitions. The first element in the array specifies that the `MY_CPU_REQUEST` environment variable gets its value from the `requests.cpu` field of a container named `test-container`. Similarly, the other environment variables get their values from fields that are specific to this container.

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/inject/dapi-envvars-container.yaml
```

Verify that the container in the Pod is running:

```
# If the new Pod isn't yet healthy, rerun this command a few times.
kubectl get pods
```

View the container's logs:

```
kubectl logs dapi-envvars-resourcefieldref
```

The output shows the values of selected environment variables:

```

1
1
33554432
67108864

```

What's next

- Read [Defining Environment Variables for a Container](#)
- Read the [spec](#) API definition for Pod. This includes the definition of Container (part of Pod).
- Read the list of [available fields](#) that you can expose using the downward API.

Read about Pods, containers and environment variables in the legacy API reference:

- [PodSpec](#)
- [Container](#)
- [EnvVar](#)
- [EnvVarSource](#)
- [ObjectFieldSelector](#)
- [ResourceFieldSelector](#)

Expose Pod Information to Containers Through Files

This page shows how a Pod can use a [downwardAPI volume](#), to expose information about itself to containers running in the Pod. A downwardAPI volume can expose Pod fields and container fields.

In Kubernetes, there are two ways to expose Pod and container fields to a running container:

- [Environment variables](#)
- Volume files, as explained in this task

Together, these two ways of exposing Pod and container fields are called the *downward API*.

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

Store Pod fields

In this part of exercise, you create a Pod that has one container, and you project Pod-level fields into the running container as files. Here is the manifest for the Pod:

[pods/inject/dapi-volume.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
  name: kubernetes-downwardapi-volume-example
  labels:
    zone: us-est-coast
    cluster: test-cluster1
    rack: rack-22
  annotations:
    build: two
```

```

  builder: john-doe
spec:
  containers:
  - name: client-container
    image: registry.k8s.io/busybox
    command: ["sh", "-c"]
    args:
    - while true; do
      if [[ -e /etc/podinfo/labels ]]; then
        echo -en '\n\n'; cat /etc/podinfo/labels; fi;
      if [[ -e /etc/podinfo/annotations ]]; then
        echo -en '\n\n'; cat /etc/podinfo/annotations; fi;
      sleep 5;
    done;
  volumeMounts:
  - name: podinfo
    mountPath: /etc/podinfo
  volumes:
  - name: podinfo
    downwardAPI:
      items:
      - path: "labels"
        fieldRef:
          fieldPath: metadata.labels
      - path: "annotations"
        fieldRef:
          fieldPath: metadata.annotations

```

In the manifest, you can see that the Pod has a downwardAPI Volume, and the container mounts the volume at /etc/podinfo.

Look at the items array under downwardAPI. Each element of the array defines a downwardAPI volume. The first element specifies that the value of the Pod's metadata.labels field should be stored in a file named labels. The second element specifies that the value of the Pod's annotations field should be stored in a file named annotations.

Note:

The fields in this example are Pod fields. They are not fields of the container in the Pod.

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/inject/dapi-volume.yaml
```

Verify that the container in the Pod is running:

```
kubectl get pods
```

View the container's logs:

```
kubectl logs kubernetes-downwardapi-volume-example
```

The output shows the contents of the labels file and the annotations file:

```
cluster="test-cluster1"
rack="rack-22"
zone="us-est-coast"

build="two"
builder="john-doe"
```

Get a shell into the container that is running in your Pod:

```
kubectl exec -it kubernetes-downwardapi-volume-example -- sh
```

In your shell, view the labels file:

```
/# cat /etc/podinfo/labels
```

The output shows that all of the Pod's labels have been written to the labels file:

```
cluster="test-cluster1"
rack="rack-22"
zone="us-est-coast"
```

Similarly, view the annotations file:

```
/# cat /etc/podinfo/annotations
```

View the files in the /etc/podinfo directory:

```
/# ls -laR /etc/podinfo
```

In the output, you can see that the labels and annotations files are in a temporary subdirectory: in this example, `..2982_06_02_21_47_53.299460680`. In the `/etc/podinfo` directory, `..data` is a symbolic link to the temporary subdirectory. Also in the `/etc/podinfo` directory, `labels` and `annotations` are symbolic links.

```
drwxr-xr-x ... Feb 6 21:47 ..2982_06_02_21_47_53.299460680
lrwxrwxrwx ... Feb 6 21:47 ..data -> ..2982_06_02_21_47_53.299460680
lrwxrwxrwx ... Feb 6 21:47 annotations -> ..data/annotations
lrwxrwxrwx ... Feb 6 21:47 labels -> ..data/labels
```

```
/etc/..2982_06_02_21_47_53.299460680:
total 8
-rw-r--r-- ... Feb 6 21:47 annotations
-rw-r--r-- ... Feb 6 21:47 labels
```

Using symbolic links enables dynamic atomic refresh of the metadata; updates are written to a new temporary directory, and the `..data` symlink is updated atomically using [rename\(2\)](#).

Note:

A container using Downward API as a [subPath](#) volume mount will not receive Downward API updates.

Exit the shell:

```
/# exit
```

Store container fields

The preceding exercise, you made Pod-level fields accessible using the downward API. In this next exercise, you are going to pass fields that are part of the Pod definition, but taken from the specific [container](#) rather than from the Pod overall. Here is a manifest for a Pod that again has just one container:

[pods/inject/dapi-volume-resources.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
  name: kubernetes-downwardapi-volume-example-2
spec:
  containers:
    - name: client-container
      image: registry.k8s.io/busybox:1.24
      command: ["sh", "-c"]
      args:
        - while true; do
          echo -en '\n';
          if [[ -e /etc/podinfo/cpu_limit ]]; then
            echo -en '\n'; cat /etc/podinfo/cpu_limit; fi;
          if [[ -e /etc/podinfo/cpu_request ]]; then
            echo -en '\n'; cat /etc/podinfo/cpu_request; fi;
          if [[ -e /etc/podinfo/mem_limit ]]; then
            echo -en '\n'; cat /etc/podinfo/mem_limit; fi;
          if [[ -e /etc/podinfo/mem_request ]]; then
            echo -en '\n'; cat /etc/podinfo/mem_request; fi;
          sleep 5;
        done;
      resources:
        requests:
          memory: "32Mi"
          cpu: "125m"
        limits:
          memory: "64Mi"
          cpu: "250m"
      volumeMounts:
        - name: podinfo
          mountPath: /etc/podinfo
  volumes:
    - name: podinfo
      downwardAPI:
        items:
          - path: "cpu_limit"
            resourceFieldRef:
              containerName: client-container
              resource: limits.cpu
              divisor: 1m
```

```
- path: "cpu_request"
  resourceFieldRef:
    containerName: client-container
    resource: requests.cpu
    divisor: 1m
- path: "mem_limit"
  resourceFieldRef:
    containerName: client-container
    resource: limits.memory
    divisor: 1Mi
- path: "mem_request"
  resourceFieldRef:
    containerName: client-container
    resource: requests.memory
    divisor: 1Mi
```

In the manifest, you can see that the Pod has a [downwardAPI volume](#), and that the single container in that Pod mounts the volume at `/etc/podinfo`.

Look at the `items` array under `downwardAPI`. Each element of the array defines a file in the downward API volume.

The first element specifies that in the container named `client-container`, the value of the `limits.cpu` field in the format specified by `1m` should be published as a file named `cpu_limit`. The `divisor` field is optional and has the default value of 1. A divisor of 1 means cores for cpu resources, or bytes for memory resources.

Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/inject/dapi-volume-resources.yaml
```

Get a shell into the container that is running in your Pod:

```
kubectl exec -it kubernetes-downwardapi-volume-example-2 -- sh
```

In your shell, view the `cpu_limit` file:

```
# Run this in a shell inside the container
cat /etc/podinfo/cpu_limit
```

You can use similar commands to view the `cpu_request`, `mem_limit` and `mem_request` files.

Project keys to specific paths and file permissions

You can project keys to specific paths and specific permissions on a per-file basis. For more information, see [Secrets](#).

What's next

- Read the [spec](#) API definition for Pod. This includes the definition of Container (part of Pod).
- Read the list of [available fields](#) that you can expose using the downward API.

Read about volumes in the legacy API reference:

- Check the [Volume](#) API definition which defines a generic volume in a Pod for containers to access.
- Check the [DownwardAPIVolumeSource](#) API definition which defines a volume that contains Downward API information.
- Check the [DownwardAPIVolumeFile](#) API definition which contains references to object or resource fields for populating a file in the Downward API volume.
- Check the [ResourceFieldSelector](#) API definition which specifies the container resources and their output format.

Distribute Credentials Securely Using Secrets

This page shows how to securely inject sensitive data, such as passwords and encryption keys, into Pods.

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Convert your secret data to a base-64 representation

Suppose you want to have two pieces of secret data: a username `my-app` and a password `39528$vdg7Jb`. First, use a base64 encoding tool to convert your username and password to a base64 representation. Here's an example using the commonly available base64 program:

```
echo -n 'my-app' | base64
echo -n '39528$vdg7Jb' | base64
```

The output shows that the base-64 representation of your username is `bXktYXBw`, and the base-64 representation of your password is `Mzk1MjgkdmRnN0pi`.

Caution:

Use a local tool trusted by your OS to decrease the security risks of external tools.

Create a Secret

Here is a configuration file you can use to create a Secret that holds your username and password:

[pods/inject/secret.yaml](#)

```
apiVersion: v1
kind: Secret
metadata:
  name: test-secret
data:
  username: bXktYXBw
  password: Mzk1MjgkdmRnN0pi
```

1. Create the Secret

```
kubectl apply -f https://k8s.io/examples/pods/inject/secret.yaml
```

2. View information about the Secret:

```
kubectl get secret test-secret
```

Output:

| NAME | TYPE | DATA | AGE |
|-------------|--------|------|-----|
| test-secret | Opaque | 2 | 1m |

3. View more detailed information about the Secret:

```
kubectl describe secret test-secret
```

Output:

```
Name:      test-secret
Namespace: default
Labels:    <none>
Annotations: <none>
```

```
Type: Opaque
```

```
Data
```

```
====
```

```
password: 13 bytes
```

```
username: 7 bytes
```

Create a Secret directly with kubectl

If you want to skip the Base64 encoding step, you can create the same Secret using the `kubectl create secret` command. For example:

```
kubectl create secret generic test-secret --from-literal=username=my-app --from-literal=password=39528$vdg7Jb'
```

This is more convenient. The detailed approach shown earlier runs through each step explicitly to demonstrate what is happening.

Create a Pod that has access to the secret data through a Volume

Here is a configuration file you can use to create a Pod:

[pods/inject/secret-pod.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
  name: secret-test-pod
spec:
  containers:
    - name: test-container
      image: nginx
      volumeMounts:
        # name must match the volume name below
        - name: secret-volume
          mountPath: /etc/secret-volume
          readOnly: true
  # The secret data is exposed to Containers in the Pod through a Volume.
  volumes:
    - name: secret-volume
      secret:
        secretName: test-secret
```

1. Create the Pod:

```
kubectl apply -f https://k8s.io/examples/pods/inject/secret-pod.yaml
```

2. Verify that your Pod is running:

```
kubectl get pod secret-test-pod
```

Output:

| NAME | READY | STATUS | RESTARTS | AGE |
|-----------------|-------|---------|----------|-----|
| secret-test-pod | 1/1 | Running | 0 | 42m |

3. Get a shell into the Container that is running in your Pod:

```
kubectl exec -i -t secret-test-pod -- /bin/bash
```

4. The secret data is exposed to the Container through a Volume mounted under `/etc/secret-volume`.

In your shell, list the files in the `/etc/secret-volume` directory:

```
# Run this in the shell inside the container
ls /etc/secret-volume
```

The output shows two files, one for each piece of secret data:

```
password username
```

In your shell, display the contents of the `username` and `password` files:

5.

```
# Run this in the shell inside the container
echo "$( cat /etc/secret-volume/username )"
echo "$( cat /etc/secret-volume/password )"
```

The output is your username and password:

```
my-app
39528$vdg7Jb
```

Modify your image or command line so that the program looks for files in the `mountPath` directory. Each key in the Secret data map becomes a file name in this directory.

Project Secret keys to specific file paths

You can also control the paths within the volume where Secret keys are projected. Use the `.spec.volumes[].secret.items` field to change the target path of each key:

```
apiVersion: v1
kind: Pod
metadata:
  name: mypod
spec:
  containers:
  - name: mypod
    image: redis
    volumeMounts:
    - name: foo
      mountPath: "/etc/foo"
      readOnly: true
  volumes:
  - name: foo
    secret:
      secretName: mysecret
      items:
      - key: username
        path: my-group/my-username
```

When you deploy this Pod, the following happens:

- The `username` key from `mysecret` is available to the container at the path `/etc/foo/my-group/my-username` instead of at `/etc/foo/username`.
- The `password` key from that Secret object is not projected.

If you list keys explicitly using `.spec.volumes[].secret.items`, consider the following:

- Only keys specified in `items` are projected.
- To consume all keys from the Secret, all of them must be listed in the `items` field.
- All listed keys must exist in the corresponding Secret. Otherwise, the volume is not created.

Set POSIX permissions for Secret keys

You can set the POSIX file access permission bits for a single Secret key. If you don't specify any permissions, 0644 is used by default. You can also set a default POSIX file mode for the entire Secret volume, and you can override per key if needed.

For example, you can specify a default mode like this:

```
apiVersion: v1
kind: Pod
metadata:
  name: mypod
spec:
  containers:
  - name: mypod
    image: redis
    volumeMounts:
    - name: foo
      mountPath: "/etc/foo"
  volumes:
  - name: foo
    secret:
      secretName: mysecret
      defaultMode: 0400
```

The Secret is mounted on /etc/foo; all the files created by the secret volume mount have permission 0400.

Note:

If you're defining a Pod or a Pod template using JSON, beware that the JSON specification doesn't support octal literals for numbers because JSON considers 0400 to be the *decimal* value 400. In JSON, use decimal values for the defaultMode instead. If you're writing YAML, you can write the defaultMode in octal.

Define container environment variables using Secret data

You can consume the data in Secrets as environment variables in your containers.

If a container already consumes a Secret in an environment variable, a Secret update will not be seen by the container unless it is restarted. There are third party solutions for triggering restarts when secrets change.

Define a container environment variable with data from a single Secret

- Define an environment variable as a key-value pair in a Secret:

```
kubectl create secret generic backend-user --from-literal=backend-username='backend-admin'
```

- Assign the backend-username value defined in the Secret to the SECRET_USERNAME environment variable in the Pod specification.

[pods/inject/pod-single-secret-env-variable.yaml](https://k8s.io/examples/pods/inject/pod-single-secret-env-variable.yaml)

```
apiVersion: v1
kind: Pod
metadata:
  name: env-single-secret
spec:
  containers:
  - name: envvars-test-container
    image: nginx
    env:
    - name: SECRET_USERNAME
      valueFrom:
        secretKeyRef:
          name: backend-user
          key: backend-username
```

- Create the Pod:

```
kubectl create -f https://k8s.io/examples/pods/inject/pod-single-secret-env-variable.yaml
```

- In your shell, display the content of SECRET_USERNAME container environment variable.

```
kubectl exec -i -t env-single-secret -- /bin/sh -c 'echo $SECRET_USERNAME'
```

The output is similar to:

```
backend-admin
```

Define container environment variables with data from multiple Secrets

- As with the previous example, create the Secrets first.

```
kubectl create secret generic backend-user --from-literal=backend-username='backend-admin'
kubectl create secret generic db-user --from-literal=db-username='db-admin'
```

- Define the environment variables in the Pod specification.

[pods/inject/pod-multiple-secret-env-variable.yaml](https://k8s.io/examples/pods/inject/pod-multiple-secret-env-variable.yaml)

```
apiVersion: v1
kind: Pod
metadata:
  name: envvars-multiple-secrets
spec:
  containers:
  - name: envvars-test-container
    image: nginx
    env:
    - name: BACKEND_USERNAME
      valueFrom:
        secretKeyRef:
```

```
  name: backend-user
  key: backend-username
- name: DB_USERNAME
  valueFrom:
    secretKeyRef:
      name: db-user
      key: db-username
```

- Create the Pod:

```
kubectl create -f https://k8s.io/examples/pods/inject/pod-multiple-secret-env-variable.yaml
```

- In your shell, display the container environment variables.

```
kubectl exec -i -t envvars-multiple-secrets -- /bin/sh -c 'env | grep _USERNAME'
```

The output is similar to:

```
DB_USERNAME=db-admin
BACKEND_USERNAME=backend-admin
```

Configure all key-value pairs in a Secret as container environment variables

Note:

This functionality is available in Kubernetes v1.6 and later.

- Create a Secret containing multiple key-value pairs

```
kubectl create secret generic test-secret --from-literal=username='my-app' --from-literal=password='39528$vdg7Jb'
```

- Use envFrom to define all of the Secret's data as container environment variables. The key from the Secret becomes the environment variable name in the Pod.

[pods/inject/pod-secret-envFrom.yaml](https://k8s.io/examples/pods/inject/pod-secret-envFrom.yaml)

```
apiVersion: v1
kind: Pod
metadata:
  name: envfrom-secret
spec:
  containers:
  - name: envvars-test-container
    image: nginx
    envFrom:
    - secretRef:
        name: test-secret
```

- Create the Pod:

```
kubectl create -f https://k8s.io/examples/pods/inject/pod-secret-envFrom.yaml
```

- In your shell, display username and password container environment variables.

```
kubectl exec -i -t envfrom-secret -- /bin/sh -c 'echo "username: $username\npassword: $password\n"'
```

The output is similar to:

```
username: my-app
password: 39528$vdg7Jb
```

Example: Provide prod/test credentials to Pods using Secrets

This example illustrates a Pod which consumes a secret containing production credentials and another Pod which consumes a secret with test environment credentials.

1. Create a secret for prod environment credentials:

```
kubectl create secret generic prod-db-secret --from-literal=username=produser --from-literal=password=Y4nys7f11
```

The output is similar to:

```
secret "prod-db-secret" created
```

2. Create a secret for test environment credentials.

```
kubectl create secret generic test-db-secret --from-literal=username=testuser --from-literal=password=iluvtests
```

The output is similar to:

```
secret "test-db-secret" created
```

Note:

Special characters such as \$, \, *, =, and ! will be interpreted by your [shell](#) and require escaping.

In most shells, the easiest way to escape the password is to surround it with single quotes ('). For example, if your actual password is S!B*d\$zDsb=, you should execute the command as follows:

```
kubectl create secret generic dev-db-secret --from-literal=username=devuser --from-literal=password='S!B\*d$zDsb='
```

You do not need to escape special characters in passwords from files (--from-file).

3. Create the Pod manifests:

```

cat <<EOF > pod.yaml
apiVersion: v1
kind: List
items:
- kind: Pod
  apiVersion: v1
  metadata:
    name: prod-db-client-pod
    labels:
      name: prod-db-client
  spec:
    volumes:
    - name: secret-volume
      secret:
        secretName: prod-db-secret
    containers:
    - name: db-client-container
      image: myClientImage
      volumeMounts:
      - name: secret-volume
        readOnly: true
        mountPath: "/etc/secret-volume"
- kind: Pod
  apiVersion: v1
  metadata:
    name: test-db-client-pod
    labels:
      name: test-db-client
  spec:
    volumes:
    - name: secret-volume
      secret:
        secretName: test-db-secret
    containers:
    - name: db-client-container
      image: myClientImage
      volumeMounts:
      - name: secret-volume
        readOnly: true
        mountPath: "/etc/secret-volume"
EOF

```

Note:

How the specs for the two Pods differ only in one field; this facilitates creating Pods with different capabilities from a common Pod template.

4. Apply all those objects on the API server by running:

```
kubectl create -f pod.yaml
```

Both containers will have the following files present on their filesystems with the values for each container's environment:

```
/etc/secret-volume/username
/etc/secret-volume/password
```

You could further simplify the base Pod specification by using two service accounts:

1. `prod-user` with the `prod-db-secret`
2. `test-user` with the `test-db-secret`

The Pod specification is shortened to:

```
apiVersion: v1
kind: Pod
metadata:
  name: prod-db-client-pod
  labels:
    name: prod-db-client
spec:
  serviceAccount: prod-db-client
  containers:
  - name: db-client-container
    image: myClientImage
```

Run a Stateless Application Using a Deployment

This page shows how to run an application using a Kubernetes Deployment object.

Objectives

- Create an nginx deployment.
- Use kubectl to list information about the deployment.
- Update the deployment.

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version v1.9. To check the version, enter kubectl version.

Creating and exploring an nginx deployment

You can run an application by creating a Kubernetes Deployment object, and you can describe a Deployment in a YAML file. For example, this YAML file describes a Deployment that runs the nginx:1.14.2 Docker image:

[application/deployment.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
  name: nginx-deployment
spec:
  selector:
    matchLabels:
      app: nginx
  replicas: 2 # tells deployment to run 2 pods matching the template
  template:
    metadata:
```

```
labels:
  app: nginx
spec:
  containers:
  - name: nginx
    image: nginx:1.14.2
    ports:
    - containerPort: 80
```

1. Create a Deployment based on the YAML file:

```
kubectl apply -f https://k8s.io/examples/application/deployment.yaml
```

2. Display information about the Deployment:

```
kubectl describe deployment nginx-deployment
```

The output is similar to this:

```
Name:      nginx-deployment
Namespace: default
CreationTimestamp: Tue, 30 Aug 2016 18:11:37 -0700
Labels:    app=nginx
Annotations: deployment.kubernetes.io/revision=1
Selector:  app=nginx
Replicas:  2 desired | 2 updated | 2 total | 2 available | 0 unavailable
StrategyType: RollingUpdate
MinReadySeconds: 0
RollingUpdateStrategy: 1 max unavailable, 1 max surge
Pod Template:
  Labels:  app=nginx
  Containers:
    nginx:
      Image:      nginx:1.14.2
      Port:       80/TCP
      Environment: <none>
      Mounts:      <none>
      Volumes:     <none>
  Conditions:
    Type      Status Reason
    ----      -
    Available  True   MinimumReplicasAvailable
    Progressing True   NewReplicaSetAvailable
OldReplicaSets: <none>
NewReplicaSet:  nginx-deployment-1771418926 (2/2 replicas created)
No events.
```

3. List the Pods created by the deployment:

```
kubectl get pods -l app=nginx
```

The output is similar to this:

| NAME | READY | STATUS | RESTARTS | AGE |
|-----------------------------------|-------|---------|----------|-----|
| nginx-deployment-1771418926-7o5ns | 1/1 | Running | 0 | 16h |
| nginx-deployment-1771418926-r18az | 1/1 | Running | 0 | 16h |

4. Display information about a Pod:

```
kubectl describe pod <pod-name>
```

where <pod-name> is the name of one of your Pods.

Updating the deployment

You can update the deployment by applying a new YAML file. This YAML file specifies that the deployment should be updated to use nginx 1.16.1.

[application/deployment-update.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
  name: nginx-deployment
spec:
  selector:
    matchLabels:
      app: nginx
  replicas: 2
  template:
    metadata:
      labels:
        app: nginx
    spec:
      containers:
        - name: nginx
          image: nginx:1.16.1 # Update the version of nginx from 1.14.2 to 1.16.1
          ports:
            - containerPort: 80
```

1. Apply the new YAML file:

```
kubectl apply -f https://k8s.io/examples/application/deployment-update.yaml
```

2. Watch the deployment create pods with new names and delete the old pods:

```
kubectl get pods -l app=nginx
```

Scaling the application by increasing the replica count

You can increase the number of Pods in your Deployment by applying a new YAML file. This YAML file sets replicas to 4, which specifies that the Deployment should have four Pods:

[application/deployment-scale.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
  name: nginx-deployment
spec:
  selector:
    matchLabels:
      app: nginx
  replicas: 4 # Update the replicas from 2 to 4
  template:
    metadata:
      labels:
        app: nginx
    spec:
      containers:
      - name: nginx
        image: nginx:1.16.1
        ports:
        - containerPort: 80
```

1. Apply the new YAML file:

```
kubectl apply -f https://k8s.io/examples/application/deployment-scale.yaml
```

2. Verify that the Deployment has four Pods:

```
kubectl get pods -l app=nginx
```

The output is similar to this:

| NAME | READY | STATUS | RESTARTS | AGE |
|----------------------------------|-------|---------|----------|-----|
| nginx-deployment-148880595-4zdqq | 1/1 | Running | 0 | 25s |
| nginx-deployment-148880595-6zgi1 | 1/1 | Running | 0 | 25s |
| nginx-deployment-148880595-fxcez | 1/1 | Running | 0 | 2m |
| nginx-deployment-148880595-rwovn | 1/1 | Running | 0 | 2m |

Deleting a deployment

Delete the deployment by name:

```
kubectl delete deployment nginx-deployment
```

ReplicationControllers -- the Old Way

The preferred way to create a replicated application is to use a Deployment, which in turn uses a ReplicaSet. Before the Deployment and ReplicaSet were added to Kubernetes, replicated applications were configured using a [ReplicationController](#).

What's next

- Learn more about [Deployment objects](#).

Run a Single-Instance Stateful Application

This page shows you how to run a single-instance stateful application in Kubernetes using a PersistentVolume and a Deployment. The application is MySQL.

Objectives

- Create a PersistentVolume referencing a disk in your environment.
- Create a MySQL Deployment.
- Expose MySQL to other pods in the cluster at a known DNS name.

Before you begin

- You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter kubectl version.

- You need to either have a [dynamic PersistentVolume provisioner](#) with a default [StorageClass](#), or [statically provision PersistentVolumes](#) yourself to satisfy the [PersistentVolumeClaims](#) used here.

Deploy MySQL

You can run a stateful application by creating a Kubernetes Deployment and connecting it to an existing PersistentVolume using a PersistentVolumeClaim. For example, this YAML file describes a Deployment that runs MySQL and references the PersistentVolumeClaim. The file defines a volume mount for /var/lib/mysql, and then creates a PersistentVolumeClaim that looks for a 20G volume. This claim is satisfied by any existing volume that meets the requirements, or by a dynamic provisioner.

Note: The password is defined in the config yaml, and this is insecure. See [Kubernetes Secrets](#) for a secure solution.

[application/mysql/mysql-deployment.yaml](#)

```
apiVersion: v1
kind: Service
metadata:
  name: mysql
spec:
  ports:
    - port: 3306
  selector:
    app: mysql
```

```

clusterIP: None
---
apiVersion: apps/v1
kind: Deployment
metadata:
  name: mysql
spec:
  selector:
    matchLabels:
      app: mysql
  strategy:
    type: Recreate
  template:
    metadata:
      labels:
        app: mysql
    spec:
      containers:
        - image: mysql:5.6
          name: mysql
          env:
            # Use secret in real usage
            - name: MYSQL_ROOT_PASSWORD
              value: password
          ports:
            - containerPort: 3306
              name: mysql
          volumeMounts:
            - name: mysql-persistent-storage
              mountPath: /var/lib/mysql
          volumes:
            - name: mysql-persistent-storage
              persistentVolumeClaim:
                claimName: mysql-pv-claim

```

[application/mysql/mysql-pv.yaml](#)

```

apiVersion: v1
kind: PersistentVolume
metadata:
  name: mysql-pv-volume
  labels:
    type: local
spec:
  storageClassName: manual
  capacity:
    storage: 20Gi
  accessModes:
    - ReadWriteOnce
  hostPath:
    path: "/mnt/data"
---
apiVersion: v1

```

```

kind: PersistentVolumeClaim
metadata:
  name: mysql-pv-claim
spec:
  storageClassName: manual
  accessModes:
    - ReadWriteOnce
resources:
  requests:
    storage: 20Gi

```

1. Deploy the PV and PVC of the YAML file:

```
kubectl apply -f https://k8s.io/examples/application/mysql/mysql-pv.yaml
```

2. Deploy the contents of the YAML file:

```
kubectl apply -f https://k8s.io/examples/application/mysql/mysql-deployment.yaml
```

3. Display information about the Deployment:

```
kubectl describe deployment mysql
```

The output is similar to this:

```

Name:          mysql
Namespace:     default
CreationTimestamp:  Tue, 01 Nov 2016 11:18:45 -0700
Labels:        app=mysql

```

```

Progressing True ReplicaSetUpdated
OldReplicaSets: <none>
NewReplicaSet:  mysql-63082529 (1/1 replicas created)
Events:
  FirstSeen    LastSeen    Count   From              SubobjectPath  Type      Reason
  Message
  -----
  33s          33s         1       {deployment-controller }      Normal    ScalingReplicaSet
  Scaled up replica set mysql-63082529 to 1

```

4. List the pods created by the Deployment:

```
kubectl get pods -l app=mysql
```

The output is similar to this:

```

NAME                READY   STATUS    RESTARTS   AGE
mysql-63082529-2z3ki 1/1     Running   0          3m

```

5. Inspect the PersistentVolumeClaim:

```
kubectl describe pvc mysql-pv-claim
```

The output is similar to this:

```

Name:          mysql-pv-claim
Namespace:     default
StorageClass:
Status:        Bound
Volume:        mysql-pv-volume
Labels:        <none>
Annotations:   pv.kubernetes.io/bind-completed=yes
               pv.kubernetes.io/bound-by-controller=yes
Capacity:      20Gi
Access Modes:  RWO
Events:        <none>

```

Accessing the MySQL instance

The preceding YAML file creates a service that allows other Pods in the cluster to access the database. The Service option `clusterIP: None` lets the Service DNS name resolve directly to the Pod's IP address. This is optimal when you have only one Pod behind a Service and you don't intend to increase the number of Pods.

Run a MySQL client to connect to the server:

```
kubectl run -it --rm --image=mysql:5.6 --restart=Never mysql-client -- mysql -h mysql -ppassword
```

This command creates a new Pod in the cluster running a MySQL client and connects it to the server through the Service. If it connects, you know your stateful MySQL database is up and running.

Waiting for pod default/mysql-client-274442439-zyp6i to be running, status is Pending, pod ready: false
If you don't see a command prompt, try pressing enter.

```
mysql>
```

Updating

The image or any other part of the Deployment can be updated as usual with the `kubectl apply` command. Here are some precautions that are specific to stateful apps:

- Don't scale the app. This setup is for single-instance apps only. The underlying `PersistentVolume` can only be mounted to one Pod. For clustered stateful apps, see the [StatefulSet documentation](#).
- Use `strategy: type: Recreate` in the Deployment configuration YAML file. This instructs Kubernetes to *not* use rolling updates. Rolling updates will not work, as you cannot have more than one Pod running at a time. The Recreate strategy will stop the first pod before creating a new one with the updated configuration.

Deleting a deployment

Delete the deployed objects by name:

```
kubectl delete deployment,svc mysql
kubectl delete pvc mysql-pv-claim
kubectl delete pv mysql-pv-volume
```

If you manually provisioned a `PersistentVolume`, you also need to manually delete it, as well as release the underlying resource. If you used a dynamic provisioner, it automatically deletes the `PersistentVolume` when it sees that you deleted the `PersistentVolumeClaim`. Some dynamic provisioners (such as those for EBS and PD) also release the underlying resource upon deleting the `PersistentVolume`.

Run a Replicated Stateful Application

This page shows how to run a replicated stateful application using a [StatefulSet](#). This application is a replicated MySQL database. The example topology has a single primary server and multiple replicas, using asynchronous row-based replication.

Note:

This is not a production configuration. MySQL settings remain on insecure defaults to keep the focus on general patterns for running stateful applications in Kubernetes.

Before you begin

- You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:
 - [Killercodea](#)
 - [Play with Kubernetes](#)
- You need to either have a [dynamic PersistentVolume provisioner](#) with a default [StorageClass](#), or [statically provision PersistentVolumes](#) yourself to satisfy the [PersistentVolumeClaims](#) used here.
- This tutorial assumes you are familiar with [PersistentVolumes](#) and [StatefulSets](#), as well as other core concepts like [Pods](#), [Services](#), and [ConfigMaps](#).
- Some familiarity with MySQL helps, but this tutorial aims to present general patterns that should be useful for other systems.
- You are using the default namespace or another namespace that does not contain any conflicting objects.

Objectives

- Deploy a replicated MySQL topology with a StatefulSet.
- Send MySQL client traffic.
- Observe resistance to downtime.
- Scale the StatefulSet up and down.

Deploy MySQL

The example MySQL deployment consists of a ConfigMap, two Services, and a StatefulSet.

Create a ConfigMap

Create the ConfigMap from the following YAML configuration file:

[application/mysql/mysql-configmap.yaml](#)

```
apiVersion: v1
kind: ConfigMap
metadata:
  name: mysql
  labels:
    app: mysql
    app.kubernetes.io/name: mysql
```

```
data:
  primary.cnf: |
    # Apply this config only on the primary.
    [mysqld]
    log-bin
  replica.cnf: |
    # Apply this config only on replicas.
    [mysqld]
    super-read-only
```

```
kubectl apply -f https://k8s.io/examples/application/mysql/mysql-configmap.yaml
```

This ConfigMap provides my.cnf overrides that let you independently control configuration on the primary MySQL server and its replicas. In this case, you want the primary server to be able to serve replication logs to replicas and you want replicas to reject any writes that don't come via replication.

There's nothing special about the ConfigMap itself that causes different portions to apply to different Pods. Each Pod decides which portion to look at as it's initializing, based on information provided by the StatefulSet controller.

Create Services

Create the Services from the following YAML configuration file:

[application/mysql/mysql-services.yaml](https://k8s.io/examples/application/mysql/mysql-services.yaml)

```
# Headless service for stable DNS entries of StatefulSet members.
apiVersion: v1
kind: Service
metadata:
  name: mysql
  labels:
    app: mysql
    app.kubernetes.io/name: mysql
spec:
  ports:
  - name: mysql
    port: 3306
  clusterIP: None
  selector:
    app: mysql
---
# Client service for connecting to any MySQL instance for reads.
# For writes, you must instead connect to the primary: mysql-0.mysql.
apiVersion: v1
kind: Service
metadata:
  name: mysql-read
  labels:
    app: mysql
    app.kubernetes.io/name: mysql
```

```
  readonly: "true"
spec:
  ports:
  - name: mysql
    port: 3306
  selector:
    app: mysql
```

```
kubectl apply -f https://k8s.io/examples/application/mysql/mysql-services.yaml
```

The headless Service provides a home for the DNS entries that the StatefulSet [controllers](#) creates for each Pod that's part of the set. Because the headless Service is named mysql, the Pods are accessible by resolving <pod-name>.mysql from within any other Pod in the same Kubernetes cluster and namespace.

The client Service, called mysql-read, is a normal Service with its own cluster IP that distributes connections across all MySQL Pods that report being Ready. The set of potential endpoints includes the primary MySQL server and all replicas.

Note that only read queries can use the load-balanced client Service. Because there is only one primary MySQL server, clients should connect directly to the primary MySQL Pod (through its DNS entry within the headless Service) to execute writes.

Create the StatefulSet

Finally, create the StatefulSet from the following YAML configuration file:

[application/mysql/mysql-statefulset.yaml](#)

```
apiVersion: apps/v1
kind: StatefulSet
metadata:
  name: mysql
spec:
  selector:
    matchLabels:
      app: mysql
      app.kubernetes.io/name: mysql
  serviceName: mysql
  replicas: 3
  template:
    metadata:
      labels:
        app: mysql
        app.kubernetes.io/name: mysql
    spec:
      initContainers:
      - name: init-mysql
        image: mysql:5.7
        command:
        - bash
        - "-c"
        - |
```

```

set -ex
# Generate mysql server-id from pod ordinal index.
[[ $HOSTNAME =~ -([0-9]+)$ ]] || exit 1
ordinal=${BASH_REMATCH[1]}
echo [mysqld] > /mnt/conf.d/server-id.cnf
# Add an offset to avoid reserved server-id=0 value.
echo server-id=$((100 + $ordinal)) >> /mnt/conf.d/server-id.cnf
# Copy appropriate conf.d files from config-map to emptyDir.
if [[ $ordinal -eq 0 ]]; then
    cp /mnt/config-map/primary.cnf /mnt/conf.d/
else
    cp /mnt/config-map/replica.cnf /mnt/conf.d/
fi
volumeMounts:
- name: conf
  mountPath: /mnt/conf.d
- name: config-map
  mountPath: /mnt/config-map
- name: clone-mysql
  image: gcr.io/google-samples/xtrabackup:1.0
  command:
  - bash
  - "-c"
  - |
    set -ex
    # Skip the clone if data already exists.
    [[ -d /var/lib/mysql/mysql ]] && exit 0
    # Skip the clone on primary (ordinal index 0).
    [[ `hostname` =~ -([0-9]+)$ ]] || exit 1
    ordinal=${BASH_REMATCH[1]}
    [[ $ordinal -eq 0 ]] && exit 0
    # Clone data from previous peer.
    ncat --recv-only mysql-$$($ordinal-1).mysql 3307 | xbstream -x -C /var/lib/mysql
    # Prepare the backup.
    xtrabackup --prepare --target-dir=/var/lib/mysql
  volumeMounts:
  - name: data
    mountPath: /var/lib/mysql
    subPath: mysql
  - name: conf
    mountPath: /etc/mysql/conf.d
containers:

    - bash
    - "-c"
    - |
      set -ex
      cd /var/lib/mysql

      # Determine binlog position of cloned data, if any.
      if [[ -f xtrabackup_slave_info && "x$(<xtrabackup_slave_info)" != "x" ]]; then
        # XtraBackup already generated a partial "CHANGE MASTER TO" query
        # because we're cloning from an existing replica. (Need to remove the trailing semicolon!)
        cat xtrabackup_slave_info | sed -E 's/;$//g' > change_master_to.sql.in
        # Ignore xtrabackup_binlog_info in this case (it's useless).
        rm -f xtrabackup_slave_info xtrabackup_binlog_info
      elif [[ -f xtrabackup_binlog_info ]]; then
        # We're cloning directly from primary. Parse binlog position.
        [[ `cat xtrabackup_binlog_info` =~ ^(.?)[[:space:]]+(.?)$ ]] || exit 1
        rm -f xtrabackup_binlog_info xtrabackup_slave_info
        echo "CHANGE MASTER TO MASTER_LOG_FILE='${BASH_REMATCH[1]}',\
          MASTER_LOG_POS=${BASH_REMATCH[2]}" > change_master_to.sql.in
      fi

      # Check if we need to complete a clone by starting replication.
      if [[ -f change_master_to.sql.in ]]; then
        echo "Waiting for mysqld to be ready (accepting connections)"
        until mysql -h 127.0.0.1 -e "SELECT 1"; do sleep 1; done

        echo "Initializing replication from clone position"

```

```

mysql -h 127.0.0.1 \
-e "$(<change_master_to.sql.in), \
    MASTER_HOST='mysql-0.mysql', \
    MASTER_USER='root', \
    MASTER_PASSWORD='', \
    MASTER_CONNECT_RETRY=10; \
    START SLAVE;" || exit 1
# In case of container restart, attempt this at-most-once.
mv change_master_to.sql.in change_master_to.sql.orig
fi

# Start a server to send backups when requested by peers.
exec ncat --listen --keep-open --send-only --max-conns=1 3307 -c \
    "xtrabackup --backup --slave-info --stream=xbstream --host=127.0.0.1 --user=root"
volumeMounts:
- name: data
  mountPath: /var/lib/mysql
  subPath: mysql
- name: conf
  mountPath: /etc/mysql/conf.d
resources:
  requests:
    cpu: 100m
    memory: 100Mi
volumes:
- name: conf
  emptyDir: {}
- name: config-map
  configMap:
    name: mysql
volumeClaimTemplates:
- metadata:
    name: data
  spec:
    accessModes: ["ReadWriteOnce"]
    resources:
      requests:
        storage: 10Gi

```

```
kubectl apply -f https://k8s.io/examples/application/mysql/mysql-statefulset.yaml
```

You can watch the startup progress by running:

```
kubectl get pods -l app=mysql --watch
```

After a while, you should see all 3 Pods become Running:

| NAME | READY | STATUS | RESTARTS | AGE |
|---------|-------|---------|----------|-----|
| mysql-0 | 2/2 | Running | 0 | 2m |
| mysql-1 | 2/2 | Running | 0 | 1m |
| mysql-2 | 2/2 | Running | 0 | 1m |

Press **Ctrl+C** to cancel the watch.

Note:

If you don't see any progress, make sure you have a dynamic PersistentVolume provisioner enabled, as mentioned in the [prerequisites](#).

This manifest uses a variety of techniques for managing stateful Pods as part of a StatefulSet. The next section highlights some of these techniques to explain what happens as the StatefulSet creates Pods.

Understanding stateful Pod initialization

The StatefulSet controller starts Pods one at a time, in order by their ordinal index. It waits until each Pod reports being Ready before starting the next one.

In addition, the controller assigns each Pod a unique, stable name of the form `<statefulset-name>--<ordinal-index>`, which results in Pods named `mysql-0`, `mysql-1`, and `mysql-2`.

The Pod template in the above StatefulSet manifest takes advantage of these properties to perform orderly startup of MySQL replication.

Generating configuration

Before starting any of the containers in the Pod spec, the Pod first runs any [init containers](#) in the order defined.

The first init container, named `init-mysql`, generates special MySQL config files based on the ordinal index.

The script determines its own ordinal index by extracting it from the end of the Pod name, which is returned by the `hostname` command. Then it saves the ordinal (with a numeric offset to avoid reserved values) into a file called `server-id.cnf` in the MySQL `conf.d` directory. This translates the unique, stable identity provided by the StatefulSet into the domain of MySQL server IDs, which require the same properties.

The script in the `init-mysql` container also applies either `primary.cnf` or `replica.cnf` from the ConfigMap by copying the contents into `conf.d`. Because the example topology consists of a single primary MySQL server and any number of replicas, the script assigns ordinal 0 to be the primary server, and everyone else to be replicas. Combined with the StatefulSet controller's [deployment order guarantee](#), this ensures the primary MySQL server is Ready before creating replicas, so they can begin replicating.

Cloning existing data

In general, when a new Pod joins the set as a replica, it must assume the primary MySQL server might already have data on it. It also must assume that the replication logs might not go all the way back to the beginning of time. These conservative assumptions are the key to allow a running StatefulSet to scale up and down over time, rather than being fixed at its initial size.

The second init container, named `clone-mysql`, performs a clone operation on a replica Pod the first time it starts up on an empty PersistentVolume. That means it copies all existing data from another running Pod, so its local state is consistent enough to begin replicating from the primary server.

MySQL itself does not provide a mechanism to do this, so the example uses a popular open-source tool called Percona XtraBackup. During the clone, the source MySQL server might suffer reduced performance. To minimize impact on the primary MySQL server, the script instructs each Pod to clone from the Pod whose ordinal index is one lower. This works because the StatefulSet controller always ensures Pod N is Ready before starting Pod N+1.

Starting replication

After the init containers complete successfully, the regular containers run. The MySQL Pods consist of a mysql container that runs the actual mysqld server, and an xtrabackup container that acts as a [sidecar](#).

The xtrabackup sidecar looks at the cloned data files and determines if it's necessary to initialize MySQL replication on the replica. If so, it waits for mysqld to be ready and then executes the CHANGE MASTER TO and START SLAVE commands with replication parameters extracted from the XtraBackup clone files.

Once a replica begins replication, it remembers its primary MySQL server and reconnects automatically if the server restarts or the connection dies. Also, because replicas look for the primary server at its stable DNS name (mysql-0.mysql), they automatically find the primary server even if it gets a new Pod IP due to being rescheduled.

Lastly, after starting replication, the xtrabackup container listens for connections from other Pods requesting a data clone. This server remains up indefinitely in case the StatefulSet scales up, or in case the next Pod loses its PersistentVolumeClaim and needs to redo the clone.

Sending client traffic

You can send test queries to the primary MySQL server (hostname mysql-0.mysql) by running a temporary container with the mysql:5.7 image and running the mysql client binary.

```
kubectrl run mysql-client --image=mysql:5.7 -i --rm --restart=Never --\
mysql -h mysql-0.mysql <<EOF
CREATE DATABASE test;
CREATE TABLE test.messages (message VARCHAR(250));
INSERT INTO test.messages VALUES ('hello');
EOF
```

Use the hostname mysql-read to send test queries to any server that reports being Ready:

```
kubectrl run mysql-client --image=mysql:5.7 -i -t --rm --restart=Never --\
mysql -h mysql-read -e "SELECT * FROM test.messages"
```

You should get output like this:

```
Waiting for pod default/mysql-client to be running, status is Pending, pod ready: false
+-----+
| message |
+-----+
| hello   |
+-----+
pod "mysql-client" deleted
```

To demonstrate that the mysql-read Service distributes connections across servers, you can run `SELECT @@server_id` in a loop:

```
kubectrl run mysql-client-loop --image=mysql:5.7 -i -t --rm --restart=Never --\
  bash -ic "while sleep 1; do mysql -h mysql-read -e 'SELECT @@server_id,NOW()'; done"
```

You should see the reported `@@server_id` change randomly, because a different endpoint might be selected upon each connection attempt:

```
+-----+-----+
| @@server_id | NOW() |
+-----+-----+
|      100 | 2006-01-02 15:04:05 |
+-----+-----+
| @@server_id | NOW() |
+-----+-----+
|      102 | 2006-01-02 15:04:06 |
+-----+-----+
| @@server_id | NOW() |
+-----+-----+
|      101 | 2006-01-02 15:04:07 |
+-----+-----+
```

You can press **Ctrl+C** when you want to stop the loop, but it's useful to keep it running in another window so you can see the effects of the following steps.

Simulate Pod and Node failure

To demonstrate the increased availability of reading from the pool of replicas instead of a single server, keep the `SELECT @@server_id` loop from above running while you force a Pod out of the Ready state.

Break the Readiness probe

The [readiness probe](#) for the mysql container runs the command `mysql -h 127.0.0.1 -e 'SELECT 1'` to make sure the server is up and able to execute queries.

One way to force this readiness probe to fail is to break that command:

```
kubectrl exec mysql-2 -c mysql -- mv /usr/bin/mysql /usr/bin/mysql.off
```

This reaches into the actual container's filesystem for Pod `mysql-2` and renames the `mysql` command so the readiness probe can't find it. After a few seconds, the Pod should report one of its containers as not Ready, which you can check by running:

```
kubectrl get pod mysql-2
```

Look for 1/2 in the READY column:

| NAME | READY | STATUS | RESTARTS | AGE |
|---------|-------|---------|----------|-----|
| mysql-2 | 1/2 | Running | 0 | 3m |

At this point, you should see your `SELECT @@server_id` loop continue to run, although it never reports 102 anymore. Recall that the `init-mysql` script defined `server-id` as `100 + $ordinal`, so server ID 102 corresponds to Pod `mysql-2`.

Now repair the Pod and it should reappear in the loop output after a few seconds:

```
kubectl exec mysql-2 -c mysql -- mv /usr/bin/mysql.off /usr/bin/mysql
```

Delete Pods

The `StatefulSet` also recreates Pods if they're deleted, similar to what a `ReplicaSet` does for stateless Pods.

```
kubectl delete pod mysql-2
```

The `StatefulSet` controller notices that no `mysql-2` Pod exists anymore, and creates a new one with the same name and linked to the same `PersistentVolumeClaim`. You should see server ID 102 disappear from the loop output for a while and then return on its own.

Drain a Node

If your Kubernetes cluster has multiple Nodes, you can simulate Node downtime (such as when Nodes are upgraded) by issuing a [drain](#).

First determine which Node one of the MySQL Pods is on:

```
kubectl get pod mysql-2 -o wide
```

The Node name should show up in the last column:

| NAME | READY | STATUS | RESTARTS | AGE | IP | NODE |
|---------|-------|---------|----------|-----|-------------|----------------------|
| mysql-2 | 2/2 | Running | 0 | 15m | 10.244.5.27 | kubernetes-node-9l2t |

Then, drain the Node by running the following command, which cordons it so no new Pods may schedule there, and then evicts any existing Pods. Replace `<node-name>` with the name of the Node you found in the last step.

Caution:

Draining a Node can impact other workloads and applications running on the same node. Only perform the following step in a test cluster.

```
# See above advice about impact on other workloads
kubectl drain <node-name> --force --delete-emptydir-data --ignore-daemonsets
```

Now you can watch as the Pod reschedules on a different Node:

```
kubectl get pod mysql-2 -o wide --watch
```

It should look something like this:

| NAME | READY | STATUS | RESTARTS | AGE | IP | NODE |
|---------|-------|-------------|----------|-----|-------------|----------------------|
| mysql-2 | 2/2 | Terminating | 0 | 15m | 10.244.1.56 | kubernetes-node-9l2t |
| [...] | | | | | | |

| | | | | | | |
|---------|-----|-----------------|---|-----|-------------|----------------------|
| mysql-2 | 0/2 | Pending | 0 | 0s | <none> | kubernetes-node-fjlm |
| mysql-2 | 0/2 | Init:0/2 | 0 | 0s | <none> | kubernetes-node-fjlm |
| mysql-2 | 0/2 | Init:1/2 | 0 | 20s | 10.244.5.32 | kubernetes-node-fjlm |
| mysql-2 | 0/2 | PodInitializing | 0 | 21s | 10.244.5.32 | kubernetes-node-fjlm |
| mysql-2 | 1/2 | Running | 0 | 22s | 10.244.5.32 | kubernetes-node-fjlm |
| mysql-2 | 2/2 | Running | 0 | 30s | 10.244.5.32 | kubernetes-node-fjlm |

And again, you should see server ID 102 disappear from the SELECT @@server_id loop output for a while and then return.

Now uncordon the Node to return it to a normal state:

```
kubectl uncordon <node-name>
```

Scaling the number of replicas

When you use MySQL replication, you can scale your read query capacity by adding replicas. For a StatefulSet, you can achieve this with a single command:

```
kubectl scale statefulset mysql --replicas=5
```

Watch the new Pods come up by running:

```
kubectl get pods -l app=mysql --watch
```

Once they're up, you should see server IDs 103 and 104 start appearing in the SELECT @@server_id loop output.

You can also verify that these new servers have the data you added before they existed:

```
kubectl run mysql-client --image=mysql:5.7 -i -t --rm --restart=Never --\
mysql -h mysql-3.mysql -e "SELECT * FROM test.messages"
```

Waiting for pod default/mysql-client to be running, status is Pending, pod ready: false

```
+-----+
| message |
+-----+
| hello  |
+-----+
```

pod "mysql-client" deleted

Scaling back down is also seamless:

```
kubectl scale statefulset mysql --replicas=3
```

Note:

Although scaling up creates new PersistentVolumeClaims automatically, scaling down does not automatically delete these PVCs.

This gives you the choice to keep those initialized PVCs around to make scaling back up quicker, or to extract data before deleting them.

You can see this by running:

```
kubectrl get pvc -l app=mysql
```

Which shows that all 5 PVCs still exist, despite having scaled the StatefulSet down to 3:

| NAME | STATUS | VOLUME | CAPACITY | ACCESSMODES | AGE |
|--------------|--------|--|----------|-------------|-----|
| data-mysql-0 | Bound | pvc-8acbf5dc-b103-11e6-93fa-42010a800002 | 10Gi | RWO | 20m |
| data-mysql-1 | Bound | pvc-8ad39820-b103-11e6-93fa-42010a800002 | 10Gi | RWO | 20m |
| data-mysql-2 | Bound | pvc-8ad69a6d-b103-11e6-93fa-42010a800002 | 10Gi | RWO | 20m |
| data-mysql-3 | Bound | pvc-50043c45-b1c5-11e6-93fa-42010a800002 | 10Gi | RWO | 2m |
| data-mysql-4 | Bound | pvc-500a9957-b1c5-11e6-93fa-42010a800002 | 10Gi | RWO | 2m |

If you don't intend to reuse the extra PVCs, you can delete them:

```
kubectrl delete pvc data-mysql-3  
kubectrl delete pvc data-mysql-4
```

Cleaning up

1. Cancel the SELECT @@server_id loop by pressing **Ctrl+C** in its terminal, or running the following from another terminal:

```
kubectrl delete pod mysql-client-loop --now
```

2. Delete the StatefulSet. This also begins terminating the Pods.

```
kubectrl delete statefulset mysql
```

3. Verify that the Pods disappear. They might take some time to finish terminating.

```
kubectrl get pods -l app=mysql
```

You'll know the Pods have terminated when the above returns:

```
No resources found.
```

4. Delete the ConfigMap, Services, and PersistentVolumeClaims.

```
kubectrl delete configmap,service,pvc -l app=mysql
```

5. If you manually provisioned PersistentVolumes, you also need to manually delete them, as well as release the underlying resources. If you used a dynamic provisioner, it automatically deletes the PersistentVolumes when it sees that you deleted the PersistentVolumeClaims. Some dynamic provisioners (such as those for EBS and PD) also release the underlying resources upon deleting the PersistentVolumes.

What's next

- Learn more about [scaling a StatefulSet](#).

- Learn more about [deleting a StatefulSet](#).
- Learn more about [force deleting StatefulSet Pods](#).
- Look in the [Helm Charts repository](#) for other stateful application examples.

Scale a StatefulSet

This task shows how to scale a StatefulSet. Scaling a StatefulSet refers to increasing or decreasing the number of replicas.

Before you begin

- StatefulSets are only available in Kubernetes version 1.5 or later. To check your version of Kubernetes, run `kubectl version`.
- Not all stateful applications scale nicely. If you are unsure about whether to scale your StatefulSets, see [StatefulSet concepts](#) or [StatefulSet tutorial](#) for further information.
- You should perform scaling only when you are confident that your stateful application cluster is completely healthy.

Scaling StatefulSets

Use kubectl to scale StatefulSets

First, find the StatefulSet you want to scale.

```
kubectl get statefulsets <stateful-set-name>
```

Change the number of replicas of your StatefulSet:

```
kubectl scale statefulsets <stateful-set-name> --replicas=<new-replicas>
```

Make in-place updates on your StatefulSets

Alternatively, you can do [in-place updates](#) on your StatefulSets.

If your StatefulSet was initially created with `kubectl apply`, update `.spec.replicas` of the StatefulSet manifests, and then do a `kubectl apply`:

```
kubectl apply -f <stateful-set-file-updated>
```

Otherwise, edit that field with `kubectl edit`:

```
kubectl edit statefulsets <stateful-set-name>
```

Or use `kubectl patch`:

```
kubectl patch statefulsets <stateful-set-name> -p '{"spec":{"replicas":<new-replicas>}}'
```

Troubleshooting

Scaling down does not work right

You cannot scale down a StatefulSet when any of the stateful Pods it manages is unhealthy. Scaling down only takes place after those stateful Pods become running and ready.

If `spec.replicas > 1`, Kubernetes cannot determine the reason for an unhealthy Pod. It might be the result of a permanent fault or of a transient fault. A transient fault can be caused by a restart required by upgrading or maintenance.

If the Pod is unhealthy due to a permanent fault, scaling without correcting the fault may lead to a state where the StatefulSet membership drops below a certain minimum number of replicas that are needed to function correctly. This may cause your StatefulSet to become unavailable.

If the Pod is unhealthy due to a transient fault and the Pod might become available again, the transient error may interfere with your scale-up or scale-down operation. Some distributed databases have issues when nodes join and leave at the same time. It is better to reason about scaling operations at the application level in these cases, and perform scaling only when you are sure that your stateful application cluster is completely healthy.

What's next

- Learn more about [deleting a StatefulSet](#).

Delete a StatefulSet

This task shows you how to delete a [StatefulSet](#).

Before you begin

- This task assumes you have an application running on your cluster represented by a StatefulSet.

Deleting a StatefulSet

You can delete a StatefulSet in the same way you delete other resources in Kubernetes: use the `kubectl delete` command, and specify the StatefulSet either by file or by name.

```
kubectl delete -f <file.yaml>
```

```
kubectl delete statefulsets <statefulset-name>
```

You may need to delete the associated headless service separately after the StatefulSet itself is deleted.

```
kubectl delete service <service-name>
```

When deleting a StatefulSet through `kubectl`, the StatefulSet scales down to 0. All Pods that are part of this workload are also deleted. If you want to delete only the StatefulSet and not the Pods, use `--cascade=orphan`. For example:

```
kubectl delete -f <file.yaml> --cascade=orphan
```

By passing `--cascade=orphan` to `kubectl delete`, the Pods managed by the StatefulSet are left behind even after the StatefulSet object itself is deleted. If the pods have a label `app.kubernetes.io/name=MyApp`, you can then delete them as follows:

```
kubectl delete pods -l app.kubernetes.io/name=MyApp
```

Persistent Volumes

Deleting the Pods in a StatefulSet will not delete the associated volumes. This is to ensure that you have the chance to copy data off the volume before deleting it. Deleting the PVC after the pods have terminated might trigger deletion of the backing Persistent Volumes depending on the storage class and reclaim policy. You should never assume ability to access a volume after claim deletion.

Note:

Use caution when deleting a PVC, as it may lead to data loss.

Complete deletion of a StatefulSet

To delete everything in a StatefulSet, including the associated pods, you can run a series of commands similar to the following:

```
grace=$(kubectl get pods <stateful-set-pod> --template '{{.spec.terminationGracePeriodSeconds}}')
kubectl delete statefulset -l app.kubernetes.io/name=MyApp
sleep $grace
kubectl delete pvc -l app.kubernetes.io/name=MyApp
```

In the example above, the Pods have the label `app.kubernetes.io/name=MyApp`; substitute your own label as appropriate.

Force deletion of StatefulSet pods

If you find that some pods in your StatefulSet are stuck in the 'Terminating' or 'Unknown' states for an extended period of time, you may need to manually intervene to forcefully delete the pods from the apiserver. This is a potentially dangerous task. Refer to [Force Delete StatefulSet Pods](#) for details.

What's next

Learn more about [force deleting StatefulSet Pods](#).

Force Delete StatefulSet Pods

This page shows how to delete Pods which are part of a [stateful set](#), and explains the considerations to keep in mind when doing so.

Before you begin

- This is a fairly advanced task and has the potential to violate some of the properties inherent to StatefulSet.
- Before proceeding, make yourself familiar with the considerations enumerated below.

StatefulSet considerations

In normal operation of a StatefulSet, there is **never** a need to force delete a StatefulSet Pod. The [StatefulSet controller](#) is responsible for creating, scaling and deleting members of the StatefulSet. It tries to ensure that the specified number of Pods from ordinal 0 through N-1 are alive and ready. StatefulSet ensures that, at any time, there is at most one Pod with a given identity running in a cluster. This is referred to as *at most one* semantics provided by a StatefulSet.

Manual force deletion should be undertaken with caution, as it has the potential to violate the at most one semantics inherent to StatefulSet. StatefulSets may be used to run distributed and clustered applications which have a need for a stable network identity and stable storage. These applications often have configuration which relies on an ensemble of a fixed number of members with fixed identities. Having multiple members with the same identity can be disastrous and may lead to data loss (e.g. split brain scenario in quorum-based systems).

Delete Pods

You can perform a graceful pod deletion with the following command:

```
kubectl delete pods <pod>
```

For the above to lead to graceful termination, the Pod **must not** specify a `pod.Spec.TerminationGracePeriodSeconds` of 0. The practice of setting a `pod.Spec.TerminationGracePeriodSeconds` of 0 seconds is unsafe and strongly discouraged for StatefulSet Pods. Graceful deletion is safe and will ensure that the Pod [shuts down gracefully](#) before the kubelet deletes the name from the apiserver.

A Pod is not deleted automatically when a node is unreachable. The Pods running on an unreachable Node enter the 'Terminating' or 'Unknown' state after a [timeout](#). Pods may also enter these states when the user attempts graceful deletion of a Pod on an unreachable Node. The only ways in which a Pod in such a state can be removed from the apiserver are as follows:

- The Node object is deleted (either by you, or by the [Node Controller](#)).
- The kubelet on the unresponsive Node starts responding, kills the Pod and removes the entry from the apiserver.
- Force deletion of the Pod by the user.

The recommended best practice is to use the first or second approach. If a Node is confirmed to be dead (e.g. permanently disconnected from the network, powered down, etc), then delete the Node object. If the Node is suffering from a network partition, then try to resolve this or wait for it to resolve. When the partition heals, the kubelet will complete the deletion of the Pod and free up its name in the apiserver.

Normally, the system completes the deletion once the Pod is no longer running on a Node, or the Node is deleted by an administrator. You may override this by force deleting the Pod.

Force Deletion

Force deletions **do not** wait for confirmation from the kubelet that the Pod has been terminated. Irrespective of whether a force deletion is successful in killing a Pod, it will immediately free up the name from the apiserver. This would let the StatefulSet controller create a replacement Pod with that same identity; this can lead to the duplication of a still-running Pod, and if said Pod can still communicate with the other members of the StatefulSet, will violate the at most one semantics that StatefulSet is designed to guarantee.

When you force delete a StatefulSet pod, you are asserting that the Pod in question will never again make contact with other Pods in the StatefulSet and its name can be safely freed up for a replacement to be created.

If you want to delete a Pod forcibly using kubectl version ≥ 1.5 , do the following:

```
kubectl delete pods <pod> --grace-period=0 --force
```

If you're using any version of kubectl ≤ 1.4 , you should omit the `--force` option and use:

```
kubectl delete pods <pod> --grace-period=0
```

If even after these commands the pod is stuck on Unknown state, use the following command to remove the pod from the cluster:

```
kubectl patch pod <pod> -p '{"metadata":{"finalizers":null}}'
```

Always perform force deletion of StatefulSet Pods carefully and with complete knowledge of the risks involved.

What's next

Learn more about [debugging a StatefulSet](#).

Horizontal Pod Autoscaling

In Kubernetes, a *HorizontalPodAutoscaler* automatically updates a workload resource (such as a [Deployment](#) or [StatefulSet](#)), with the aim of automatically scaling the workload to match demand.

Horizontal scaling means that the response to increased load is to deploy more [Pods](#). This is different from *vertical* scaling, which for Kubernetes would mean assigning more resources (for example: memory or CPU) to the Pods that are already running for the workload.

If the load decreases, and the number of Pods is above the configured minimum, the HorizontalPodAutoscaler instructs the workload resource (the Deployment, StatefulSet, or other similar resource) to scale back down.

Horizontal pod autoscaling does not apply to objects that can't be scaled (for example: a [DaemonSet](#).)

The HorizontalPodAutoscaler is implemented as a Kubernetes API resource and a [controller](#). The resource determines the behavior of the controller. The horizontal pod autoscaling controller, running within the Kubernetes [control plane](#), periodically adjusts the desired scale of its target (for example, a Deployment) to match observed metrics such as average CPU utilization, average memory utilization, or any other custom metric you specify.

There is [walkthrough example](#) of using horizontal pod autoscaling.

How does a HorizontalPodAutoscaler work?

```
graph BT
    hpa[Horizontal Pod Autoscaler] --> scale[Scale]
    subgraph rc [RC / Deployment]
        scale --> pod1[Pod 1]

Figure 1. HorizontalPodAutoscaler controls the scale of a Deployment and its ReplicaSet

Kubernetes implements horizontal pod autoscaling as a control loop that runs intermittently (it is not a continuous process). The interval is set by the `--horizontal-pod-autoscaler-sync-period` parameter to the [kube-controller-manager](#) (and the default interval is 15 seconds).

Once during each period, the controller manager queries the resource utilization against the metrics specified in each HorizontalPodAutoscaler definition. The controller manager finds the target resource defined by the `scaleTargetRef`, then selects the pods based on the target resource's `.spec.selector` labels, and obtains the metrics from either the resource metrics API (for per-pod resource metrics), or the custom metrics API (for all other metrics).

- For per-pod resource metrics (like CPU), the controller fetches the metrics from the resource metrics API for each Pod targeted by the HorizontalPodAutoscaler. Then, if a target utilization value is set, the controller calculates the utilization value as a percentage of the equivalent [resource request](#) on the containers in each Pod. If a target raw value is set, the raw metric values are used directly. The controller then takes the mean of the utilization or the raw value (depending on the type of target specified) across all targeted Pods, and produces a ratio used to scale the number of desired replicas.

Please note that if some of the Pod's containers do not have the relevant resource request set, CPU utilization for the Pod will not be defined and the autoscaler will not take any action for that metric. See the [algorithm details](#) section below for more information about how the autoscaling algorithm works.

- For per-pod custom metrics, the controller functions similarly to per-pod resource metrics, except that it works with raw values, not utilization values.
- For object metrics and external metrics, a single metric is fetched, which describes the object in question. This metric is compared to the target value, to produce a ratio as above. In the autoscaling/v2 API version, this value can optionally be divided by the number of Pods before the comparison is made.

The common use for HorizontalPodAutoscaler is to configure it to fetch metrics from [aggregated APIs](#) (metrics.k8s.io, custom.metrics.k8s.io, or external.metrics.k8s.io). The metrics.k8s.io API is usually provided by an add-on named Metrics Server, which needs to be launched separately. For more information about resource metrics, see [Metrics Server](#).

[Support for metrics APIs](#) explains the stability guarantees and support status for these different APIs.

The HorizontalPodAutoscaler controller accesses corresponding workload resources that support scaling (such as Deployments and StatefulSet). These resources each have a subresource named scale, an interface that allows you to dynamically set the number of replicas and examine each of their current states. For general information about subresources in the Kubernetes API, see [Kubernetes API Concepts](#).

Algorithm details

From the most basic perspective, the HorizontalPodAutoscaler controller operates on the ratio between desired metric value and current metric value:

```
desiredReplicas = ceil[currentReplicas * ( currentMetricValue / desiredMetricValue )]
```

For example, if the current metric value is 200m, and the desired value is 100m, the number of replicas will be doubled, since $200.0 / 100.0 == 2.0$. If the current value is instead 50m, you'll halve the number of replicas, since $50.0 / 100.0 == 0.5$. The control plane skips any scaling action if the ratio is sufficiently close to 1.0 (within a globally-configurable tolerance, 0.1 by default).

When a targetAverageValue or targetAverageUtilization is specified, the currentMetricValue is computed by taking the average of the given metric across all Pods in the HorizontalPodAutoscaler's scale target.

Before checking the tolerance and deciding on the final values, the control plane also considers whether any metrics are missing, and how many Pods are [Ready](#). All Pods with a deletion timestamp set (objects with a deletion timestamp are in the process of being shut down / removed) are ignored, and all failed Pods are discarded.

If a particular Pod is missing metrics, it is set aside for later; Pods with missing metrics will be used to adjust the final scaling amount.

When scaling on CPU, if any pod has yet to become ready (it's still initializing, or possibly is unhealthy) or the most recent metric point for the pod was before it became ready, that pod is set aside as well.

Due to technical constraints, the HorizontalPodAutoscaler controller cannot exactly determine the first time a pod becomes ready when determining whether to set aside certain CPU metrics. Instead, it considers a Pod "not yet ready" if it's unready and transitioned to ready within a

short, configurable window of time since it started. This value is configured with the `--horizontal-pod-autoscaler-initial-readiness-delay` flag, and its default is 30 seconds. Once a pod has become ready, it considers any transition to ready to be the first if it occurred within a longer, configurable time since it started. This value is configured with the `--horizontal-pod-autoscaler-cpu-initialization-period` flag, and its default is 5 minutes.

The $\text{currentMetricValue} / \text{desiredMetricValue}$ base scale ratio is then calculated using the remaining pods not set aside or discarded from above.

If there were any missing metrics, the control plane recomputes the average more conservatively, assuming those pods were consuming 100% of the desired value in case of a scale down, and 0% in case of a scale up. This dampens the magnitude of any potential scale.

Furthermore, if any not-yet-ready pods were present, and the workload would have scaled up without factoring in missing metrics or not-yet-ready pods, the controller conservatively assumes that the not-yet-ready pods are consuming 0% of the desired metric, further dampening the magnitude of a scale up.

After factoring in the not-yet-ready pods and missing metrics, the controller recalculates the usage ratio. If the new ratio reverses the scale direction, or is within the tolerance, the controller doesn't take any scaling action. In other cases, the new ratio is used to decide any change to the number of Pods.

Note that the *original* value for the average utilization is reported back via the HorizontalPodAutoscaler status, without factoring in the not-yet-ready pods or missing metrics, even when the new usage ratio is used.

If multiple metrics are specified in a HorizontalPodAutoscaler, this calculation is done for each metric, and then the largest of the desired replica counts is chosen. If any of these metrics cannot be converted into a desired replica count (e.g. due to an error fetching the metrics from the metrics APIs) and a scale down is suggested by the metrics which can be fetched, scaling is skipped. This means that the HPA is still capable of scaling up if one or more metrics give a `desiredReplicas` greater than the current value.

Finally, right before HPA scales the target, the scale recommendation is recorded. The controller considers all recommendations within a configurable window choosing the highest recommendation from within that window. This value can be configured using the `--horizontal-pod-autoscaler-downscale-stabilization` flag, which defaults to 5 minutes. This means that scaledowns will occur gradually, smoothing out the impact of rapidly fluctuating metric values.

API Object

The Horizontal Pod Autoscaler is an API resource in the Kubernetes autoscaling API group. The current stable version can be found in the `autoscaling/v2` API version which includes support for scaling on memory and custom metrics. The new fields introduced in `autoscaling/v2` are preserved as annotations when working with `autoscaling/v1`.

When you create a HorizontalPodAutoscaler API object, make sure the name specified is a valid [DNS subdomain name](#). More details about the API object can be found at [HorizontalPodAutoscaler Object](#).

Stability of workload scale

When managing the scale of a group of replicas using the HorizontalPodAutoscaler, it is possible that the number of replicas keeps fluctuating frequently due to the dynamic nature of the metrics evaluated. This is sometimes referred to as *thrashing*, or *flapping*. It's similar to the concept of *hysteresis* in cybernetics.

Autoscaling during rolling update

Kubernetes lets you perform a rolling update on a Deployment. In that case, the Deployment manages the underlying ReplicaSets for you. When you configure autoscaling for a Deployment, you bind a HorizontalPodAutoscaler to a single Deployment. The HorizontalPodAutoscaler manages the replicas field of the Deployment. The deployment controller is responsible for setting the replicas of the underlying ReplicaSets so that they add up to a suitable number during the rollout and also afterwards.

If you perform a rolling update of a StatefulSet that has an autoscaled number of replicas, the StatefulSet directly manages its set of Pods (there is no intermediate resource similar to ReplicaSet).

Support for resource metrics

Any HPA target can be scaled based on the resource usage of the pods in the scaling target. When defining the pod specification the resource requests like cpu and memory should be specified. This is used to determine the resource utilization and used by the HPA controller to scale the target up or down. To use resource utilization based scaling specify a metric source like this:

```
type: Resource
resource:
  name: cpu
  target:
    type: Utilization
    averageUtilization: 60
```

With this metric the HPA controller will keep the average utilization of the pods in the scaling target at 60%. Utilization is the ratio between the current usage of resource to the requested resources of the pod. See [Algorithm](#) for more details about how the utilization is calculated and averaged.

Note:

Since the resource usages of all the containers are summed up the total pod utilization may not accurately represent the individual container resource usage. This could lead to situations where a single container might be running with high usage and the HPA will not scale out because the overall pod usage is still within acceptable limits.

Container resource metrics

FEATURE STATE: Kubernetes v1.30 [stable]

The HorizontalPodAutoscaler API also supports a container metric source where the HPA can track the resource usage of individual containers across a set of Pods, in order to scale the target resource. This lets you configure scaling thresholds for the containers that matter most in a particular Pod. For example, if you have a web application and a sidecar container that provides logging, you can scale based on the resource use of the web application, ignoring the sidecar container and its resource use.

If you revise the target resource to have a new Pod specification with a different set of containers, you should revise the HPA spec if that newly added container should also be used for scaling. If the specified container in the metric source is not present or only present in a subset of the pods then those pods are ignored and the recommendation is recalculated. See [Algorithm](#) for more details about the calculation. To use container resources for autoscaling define a metric source as follows:

```
type: ContainerResource
containerResource:
  name: cpu
  container: application
  target:
    type: Utilization
    averageUtilization: 60
```

In the above example the HPA controller scales the target such that the average utilization of the cpu in the application container of all the pods is 60%.

Note:

If you change the name of a container that a HorizontalPodAutoscaler is tracking, you can make that change in a specific order to ensure scaling remains available and effective whilst the change is being applied. Before you update the resource that defines the container (such as a Deployment), you should update the associated HPA to track both the new and old container names. This way, the HPA is able to calculate a scaling recommendation throughout the update process.

Once you have rolled out the container name change to the workload resource, tidy up by removing the old container name from the HPA specification.

Scaling on custom metrics

FEATURE STATE: Kubernetes v1.23 [stable]

(the autoscaling/v2beta2 API version previously provided this ability as a beta feature)

Provided that you use the autoscaling/v2 API version, you can configure a HorizontalPodAutoscaler to scale based on a custom metric (that is not built in to Kubernetes or any Kubernetes component). The HorizontalPodAutoscaler controller then queries for these custom metrics from the Kubernetes API.

See [Support for metrics APIs](#) for the requirements.

Scaling on multiple metrics

FEATURE STATE: Kubernetes v1.23 [stable]

(the autoscaling/v2beta2 API version previously provided this ability as a beta feature)

Provided that you use the autoscaling/v2 API version, you can specify multiple metrics for a HorizontalPodAutoscaler to scale on. Then, the HorizontalPodAutoscaler controller evaluates each metric, and proposes a new scale based on that metric. The HorizontalPodAutoscaler takes the maximum scale recommended for each metric and sets the workload to that size (provided that this isn't larger than the overall maximum that you configured).

Support for metrics APIs

By default, the HorizontalPodAutoscaler controller retrieves metrics from a series of APIs. In order for it to access these APIs, cluster administrators must ensure that:

- The [API aggregation layer](#) is enabled.
- The corresponding APIs are registered:
 - For resource metrics, this is the metrics.k8s.io [API](#), generally provided by [metrics-server](#). It can be launched as a cluster add-on.
 - For custom metrics, this is the custom.metrics.k8s.io [API](#). It's provided by "adapter" API servers provided by metrics solution vendors. Check with your metrics pipeline to see if there is a Kubernetes metrics adapter available.
 - For external metrics, this is the external.metrics.k8s.io [API](#). It may be provided by the custom metrics adapters provided above.

For more information on these different metrics paths and how they differ please see the relevant design proposals for [the HPA V2](#), [custom.metrics.k8s.io](#) and [external.metrics.k8s.io](#).

For examples of how to use them see [the walkthrough for using custom metrics](#) and [the walkthrough for using external metrics](#).

Configurable scaling behavior

FEATURE STATE: Kubernetes v1.23 [stable]

(the autoscaling/v2beta2 API version previously provided this ability as a beta feature)

If you use the v2 HorizontalPodAutoscaler API, you can use the behavior field (see the [API reference](#)) to configure separate scale-up and scale-down behaviors. You specify these behaviours by setting scaleUp and / or scaleDown under the behavior field.

You can specify a *stabilization window* that prevents [flapping](#) the replica count for a scaling target. Scaling policies also let you control the rate of change of replicas while scaling.

Scaling policies

One or more scaling policies can be specified in the `behavior` section of the spec. When multiple policies are specified the policy which allows the highest amount of change is the policy which is selected by default. The following example shows this behavior while scaling down:

```
behavior:
  scaleDown:
    policies:
      - type: Pods
        value: 4
        periodSeconds: 60
      - type: Percent
        value: 10
        periodSeconds: 60
```

`periodSeconds` indicates the length of time in the past for which the policy must hold true. The maximum value that you can set for `periodSeconds` is 1800 (half an hour). The first policy (*Pods*) allows at most 4 replicas to be scaled down in one minute. The second policy (*Percent*) allows at most 10% of the current replicas to be scaled down in one minute.

Since by default the policy which allows the highest amount of change is selected, the second policy will only be used when the number of pod replicas is more than 40. With 40 or less replicas, the first policy will be applied. For instance if there are 80 replicas and the target has to be scaled down to 10 replicas then during the first step 8 replicas will be reduced. In the next iteration when the number of replicas is 72, 10% of the pods is 7.2 but the number is rounded up to 8. On each loop of the autoscaler controller the number of pods to be change is re-calculated based on the number of current replicas. When the number of replicas falls below 40 the first policy (*Pods*) is applied and 4 replicas will be reduced at a time.

The policy selection can be changed by specifying the `selectPolicy` field for a scaling direction. By setting the value to `Min` which would select the policy which allows the smallest change in the replica count. Setting the value to `Disabled` completely disables scaling in that direction.

Stabilization window

The stabilization window is used to restrict the [flapping](#) of replica count when the metrics used for scaling keep fluctuating. The autoscaling algorithm uses this window to infer a previous desired state and avoid unwanted changes to workload scale.

For example, in the following example snippet, a stabilization window is specified for `scaleDown`.

```
behavior:
  scaleDown:
    stabilizationWindowSeconds: 300
```

When the metrics indicate that the target should be scaled down the algorithm looks into previously computed desired states, and uses the highest value from the specified interval. In the above example, all desired states from the past 5 minutes will be considered.

This approximates a rolling maximum, and avoids having the scaling algorithm frequently remove Pods only to trigger recreating an equivalent Pod just moments later.

Default Behavior

To use the custom scaling not all fields have to be specified. Only values which need to be customized can be specified. These custom values are merged with default values. The default values match the existing behavior in the HPA algorithm.

```
behavior:
  scaleDown:
    stabilizationWindowSeconds: 300
  policies:
    - type: Percent
      value: 100
      periodSeconds: 15
  scaleUp:
    stabilizationWindowSeconds: 0
  policies:
    - type: Percent
      value: 100
      periodSeconds: 15
    - type: Pods
      value: 4
      periodSeconds: 15
  selectPolicy: Max
```

For scaling down the stabilization window is 300 seconds (or the value of the `--horizontal-pod-autoscaler-downscale-stabilization` flag if provided). There is only a single policy for scaling down which allows a 100% of the currently running replicas to be removed which means the scaling target can be scaled down to the minimum allowed replicas. For scaling up there is no stabilization window. When the metrics indicate that the target should be scaled up the target is scaled up immediately. There are 2 policies where 4 pods or a 100% of the currently running replicas may at most be added every 15 seconds till the HPA reaches its steady state.

Example: change downscale stabilization window

To provide a custom downscale stabilization window of 1 minute, the following behavior would be added to the HPA:

```
behavior:
  scaleDown:
    stabilizationWindowSeconds: 60
```

Example: limit scale down rate

To limit the rate at which pods are removed by the HPA to 10% per minute, the following behavior would be added to the HPA:

```
behavior:
  scaleDown:
    policies:
      - type: Percent
        value: 10
        periodSeconds: 60
```

To ensure that no more than 5 Pods are removed per minute, you can add a second scale-down policy with a fixed size of 5, and set `selectPolicy` to `minimum`. Setting `selectPolicy` to `Min` means that the autoscaler chooses the policy that affects the smallest number of Pods:

```
behavior:
  scaleDown:
    policies:
      - type: Percent
        value: 10
        periodSeconds: 60
      - type: Pods
        value: 5
        periodSeconds: 60
    selectPolicy: Min
```

Example: disable scale down

The `selectPolicy` value of `Disabled` turns off scaling the given direction. So to prevent downscaling the following policy would be used:

```
behavior:
  scaleDown:
    selectPolicy: Disabled
```

Support for HorizontalPodAutoscaler in kubectl

`HorizontalPodAutoscaler`, like every API resource, is supported in a standard way by `kubectl`. You can create a new autoscaler using `kubectl create` command. You can list autoscalers by `kubectl get hpa` or get detailed description by `kubectl describe hpa`. Finally, you can delete an autoscaler using `kubectl delete hpa`.

In addition, there is a special `kubectl autoscale` command for creating a `HorizontalPodAutoscaler` object. For instance, executing `kubectl autoscale rs foo --min=2 --max=5 --cpu-percent=80` will create an autoscaler for `ReplicaSet foo`, with target CPU utilization set to 80% and the number of replicas between 2 and 5.

Implicit maintenance-mode deactivation

You can implicitly deactivate the HPA for a target without the need to change the HPA configuration itself. If the target's desired replica count is set to 0, and the HPA's minimum replica count is greater than 0, the HPA stops adjusting the target (and sets the `ScalingActiveCondition` on itself to `false`) until you reactivate it by manually adjusting the target's desired replica count or HPA's minimum replica count.

Migrating Deployments and StatefulSets to horizontal autoscaling

When an HPA is enabled, it is recommended that the value of `spec.replicas` of the `Deployment` and / or `StatefulSet` be removed from their [manifest\(s\)](#). If this isn't done, any time a change to that object is applied, for example via `kubectl apply -f deployment.yaml`, this will instruct Kubernetes to scale the current number of Pods to the value of the `spec.replicas` key. This may not be desired and could be troublesome when an HPA is active.

Keep in mind that the removal of `spec.replicas` may incur a one-time degradation of Pod counts as the default value of this key is 1 (reference [Deployment Replicas](#)). Upon the update, all Pods except 1 will begin their termination procedures. Any deployment application afterwards will behave as normal and respect a rolling update configuration as desired. You can avoid this degradation by choosing one of the following two methods based on how you are modifying your deployments:

- [Client Side Apply \(this is the default\)](#)
- [Server Side Apply](#)

1. `kubectl apply edit-last-applied deployment/<deployment_name>`
2. In the editor, remove `spec.replicas`. When you save and exit the editor, `kubectl` applies the update. No changes to Pod counts happen at this step.
3. You can now remove `spec.replicas` from the manifest. If you use source code management, also commit your changes or take whatever other steps for revising the source code are appropriate for how you track updates.
4. From here on out you can run `kubectl apply -f deployment.yaml`

When using the [Server-Side Apply](#) you can follow the [transferring ownership](#) guidelines, which cover this exact use case.

What's next

If you configure autoscaling in your cluster, you may also want to consider using [cluster autoscaling](#) to ensure you are running the right number of nodes.

For more information on HorizontalPodAutoscaler:

- Read a [walkthrough example](#) for horizontal pod autoscaling.
- Read documentation for [kubectl autoscale](#).
- If you would like to write your own custom metrics adapter, check out the [boilerplate](#) to get started.
- Read the [API reference](#) for HorizontalPodAutoscaler.

HorizontalPodAutoscaler Walkthrough

A [HorizontalPodAutoscaler](#) (HPA for short) automatically updates a workload resource (such as a [Deployment](#) or [StatefulSet](#)), with the aim of automatically scaling the workload to match demand.

Horizontal scaling means that the response to increased load is to deploy more [Pods](#). This is different from *vertical* scaling, which for Kubernetes would mean assigning more resources (for example: memory or CPU) to the Pods that are already running for the workload.

If the load decreases, and the number of Pods is above the configured minimum, the HorizontalPodAutoscaler instructs the workload resource (the Deployment, StatefulSet, or other similar resource) to scale back down.

This document walks you through an example of enabling HorizontalPodAutoscaler to automatically manage scale for an example web app. This example workload is Apache httpd running some PHP code.

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version 1.23. To check the version, enter kubectl version. If you're running an older release of Kubernetes, refer to the version of the documentation for that release (see [available documentation versions](#)).

To follow this walkthrough, you also need to use a cluster that has a [Metrics Server](#) deployed and configured. The Kubernetes Metrics Server collects resource metrics from the [kubelets](#) in your cluster, and exposes those metrics through the [Kubernetes API](#), using an [APIService](#) to add new kinds of resource that represent metric readings.

To learn how to deploy the Metrics Server, see the [metrics-server documentation](#).

If you are running [Minikube](#), run the following command to enable metrics-server:

```
minikube addons enable metrics-server
```

Run and expose php-apache server

To demonstrate a HorizontalPodAutoscaler, you will first start a Deployment that runs a container using the hpa-example image, and expose it as a [Service](#) using the following manifest:

[application/php-apache.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
  name: php-apache
spec:
  selector:
    matchLabels:
      run: php-apache
  template:
    metadata:
      labels:
        run: php-apache
    spec:
      containers:
        - name: php-apache
          image: registry.k8s.io/hpa-example
          ports:
            - containerPort: 80
          resources:
            limits:
              cpu: 500m
```

```
    requests:
      cpu: 200m
---
apiVersion: v1
kind: Service
metadata:
  name: php-apache
  labels:
    run: php-apache
spec:
  ports:
    - port: 80
  selector:
    run: php-apache
```

To do so, run the following command:

```
kubectl apply -f https://k8s.io/examples/application/php-apache.yaml
```

```
deployment.apps/php-apache created
service/php-apache created
```

Create the HorizontalPodAutoscaler

Now that the server is running, create the autoscaler using kubectl. There is [kubectl autoscale](#) subcommand, part of kubectl, that helps you do this.

You will shortly run a command that creates a HorizontalPodAutoscaler that maintains between 1 and 10 replicas of the Pods controlled by the php-apache Deployment that you created in the first step of these instructions.

Roughly speaking, the HPA [controller](#) will increase and decrease the number of replicas (by updating the Deployment) to maintain an average CPU utilization across all Pods of 50%. The Deployment then updates the ReplicaSet - this is part of how all Deployments work in Kubernetes - and then the ReplicaSet either adds or removes Pods based on the change to its .spec.

Since each pod requests 200 milli-cores by kubectl run, this means an average CPU usage of 100 milli-cores. See [Algorithm details](#) for more details on the algorithm.

Create the HorizontalPodAutoscaler:

```
kubectl autoscale deployment php-apache --cpu-percent=50 --min=1 --max=10
```

```
horizontalpodautoscaler.autoscaling/php-apache autoscaled
```

You can check the current status of the newly-made HorizontalPodAutoscaler, by running:

```
# You can use "hpa" or "horizontalpodautoscaler"; either name works OK.
kubectl get hpa
```

The output is similar to:

| NAME | REFERENCE | TARGET | MINPODS | MAXPODS | REPLICAS | AGE |
|------------|-----------------------------|----------|---------|---------|----------|-----|
| php-apache | Deployment/php-apache/scale | 0% / 50% | 1 | 10 | 1 | 18s |

(if you see other HorizontalPodAutoscalers with different names, that means they already existed, and isn't usually a problem).

Please note that the current CPU consumption is 0% as there are no clients sending requests to the server (the TARGET column shows the average across all the Pods controlled by the corresponding deployment).

Increase the load

Next, see how the autoscaler reacts to increased load. To do this, you'll start a different Pod to act as a client. The container within the client Pod runs in an infinite loop, sending queries to the php-apache service.

```
# Run this in a separate terminal
# so that the load generation continues and you can carry on with the rest of the steps
kubectl run -i --tty load-generator --rm --image=busybox:1.28 --restart=Never -- /bin/sh -c "while sleep 0.01; do wget -q -O- http://php-apache; done"
```

Now run:

```
# type Ctrl+C to end the watch when you're ready
kubectl get hpa php-apache --watch
```

Within a minute or so, you should see the higher CPU load; for example:

| NAME | REFERENCE | TARGET | MINPODS | MAXPODS | REPLICAS | AGE |
|------------|-----------------------------|------------|---------|---------|----------|-----|
| php-apache | Deployment/php-apache/scale | 305% / 50% | 1 | 10 | 1 | 3m |

and then, more replicas. For example:

| NAME | REFERENCE | TARGET | MINPODS | MAXPODS | REPLICAS | AGE |
|------------|-----------------------------|------------|---------|---------|----------|-----|
| php-apache | Deployment/php-apache/scale | 305% / 50% | 1 | 10 | 7 | 3m |

Here, CPU consumption has increased to 305% of the request. As a result, the Deployment was resized to 7 replicas:

```
kubectl get deployment php-apache
```

You should see the replica count matching the figure from the HorizontalPodAutoscaler

| NAME | READY | UP-TO-DATE | AVAILABLE | AGE |
|------------|-------|------------|-----------|-----|
| php-apache | 7/7 | 7 | 7 | 19m |

Note:

It may take a few minutes to stabilize the number of replicas. Since the amount of load is not controlled in any way it may happen that the final number of replicas will differ from this example.

Stop generating load

To finish the example, stop sending the load.

In the terminal where you created the Pod that runs a busybox image, terminate the load generation by typing `<Ctrl> + C`.

Then verify the result state (after a minute or so):

```
# type Ctrl+C to end the watch when you're ready
kubectl get hpa php-apache --watch
```

The output is similar to:

| NAME | REFERENCE | TARGET | MINPODS | MAXPODS | REPLICAS | AGE |
|------------|-----------------------------|----------|---------|---------|----------|-----|
| php-apache | Deployment/php-apache/scale | 0% / 50% | 1 | 10 | 1 | 11m |

and the Deployment also shows that it has scaled down:

```
kubectl get deployment php-apache
```

| NAME | READY | UP-TO-DATE | AVAILABLE | AGE |
|------------|-------|------------|-----------|-----|
| php-apache | 1/1 | 1 | 1 | 27m |

Once CPU utilization dropped to 0, the HPA automatically scaled the number of replicas back down to 1.

Autoscaling the replicas may take a few minutes.

Autoscaling on multiple metrics and custom metrics

You can introduce additional metrics to use when autoscaling the php-apache Deployment by making use of the autoscaling/v2 API version.

First, get the YAML of your HorizontalPodAutoscaler in the autoscaling/v2 form:

```
kubectl get hpa php-apache -o yaml > /tmp/hpa-v2.yaml
```

Open the `/tmp/hpa-v2.yaml` file in an editor, and you should see YAML which looks like this:

```
apiVersion: autoscaling/v2
kind: HorizontalPodAutoscaler
metadata:
  name: php-apache
spec:
  scaleTargetRef:
    apiVersion: apps/v1
    kind: Deployment
    name: php-apache
  minReplicas: 1
  maxReplicas: 10
  metrics:
  - type: Resource
```

```
resource:
  name: cpu
  target:
    type: Utilization
    averageUtilization: 50
status:
  observedGeneration: 1
  lastScaleTime: <some-time>
  currentReplicas: 1
  desiredReplicas: 1
  currentMetrics:
  - type: Resource
    resource:
      name: cpu
      current:
        averageUtilization: 0
        averageValue: 0
```

Notice that the `targetCPUUtilizationPercentage` field has been replaced with an array called `metrics`. The CPU utilization metric is a *resource metric*, since it is represented as a percentage of a resource specified on pod containers. Notice that you can specify other resource metrics besides CPU. By default, the only other supported resource metric is memory. These resources do not change names from cluster to cluster, and should always be available, as long as the `metrics.k8s.io` API is available.

You can also specify resource metrics in terms of direct values, instead of as percentages of the requested value, by using a `target.type` of `AverageValue` instead of `Utilization`, and setting the corresponding `target.averageValue` field instead of the `target.averageUtilization`.

There are two other types of metrics, both of which are considered *custom metrics*: pod metrics and object metrics. These metrics may have names which are cluster specific, and require a more advanced cluster monitoring setup.

The first of these alternative metric types is *pod metrics*. These metrics describe Pods, and are averaged together across Pods and compared with a target value to determine the replica count. They work much like resource metrics, except that they *only* support a target type of `AverageValue`.

Pod metrics are specified using a metric block like this:

```
type: Pods
pods:
  metric:
    name: packets-per-second
  target:
    type: AverageValue
    averageValue: 1k
```

The second alternative metric type is *object metrics*. These metrics describe a different object in the same namespace, instead of describing Pods. The metrics are not necessarily fetched from the object; they only describe it. Object metrics support target types of both `Value` and `AverageValue`. With `Value`, the target is compared directly to the returned metric from the API. With `AverageValue`, the value returned from the custom metrics API is divided by the number

of Pods before being compared to the target. The following example is the YAML representation of the requests-per-second metric.

```
type: Object
object:
  metric:
    name: requests-per-second
  describedObject:
    apiVersion: networking.k8s.io/v1
    kind: Ingress
    name: main-route
target:
  type: Value
  value: 2k
```

If you provide multiple such metric blocks, the HorizontalPodAutoscaler will consider each metric in turn. The HorizontalPodAutoscaler will calculate proposed replica counts for each metric, and then choose the one with the highest replica count.

For example, if you had your monitoring system collecting metrics about network traffic, you could update the definition above using `kubectl edit` to look like this:

```
apiVersion: autoscaling/v2
kind: HorizontalPodAutoscaler
metadata:
  name: php-apache
spec:
  scaleTargetRef:
    apiVersion: apps/v1
    kind: Deployment
    name: php-apache
  minReplicas: 1
  maxReplicas: 10
  metrics:
  - type: Resource
    resource:
      name: cpu
      target:
        type: Utilization
        averageUtilization: 50
  - type: Pods
    pods:
      metric:
        name: packets-per-second
      target:
        type: AverageValue
        averageValue: 1k
  - type: Object
    object:
      metric:
        name: requests-per-second
      describedObject:
        apiVersion: networking.k8s.io/v1
```

```

    kind: Ingress
    name: main-route
  target:
    type: Value
    value: 10k
status:
  observedGeneration: 1
  lastScaleTime: <some-time>
  currentReplicas: 1
  desiredReplicas: 1
  currentMetrics:
  - type: Resource
    resource:
      name: cpu
    current:
      averageUtilization: 0
      averageValue: 0
  - type: Object
    object:
      metric:
        name: requests-per-second
      describedObject:
        apiVersion: networking.k8s.io/v1
        kind: Ingress
        name: main-route
      current:
        value: 10k

```

Then, your HorizontalPodAutoscaler would attempt to ensure that each pod was consuming roughly 50% of its requested CPU, serving 1000 packets per second, and that all pods behind the main-route Ingress were serving a total of 10000 requests per second.

Autoscaling on more specific metrics

Many metrics pipelines allow you to describe metrics either by name or by a set of additional descriptors called *labels*. For all non-resource metric types (pod, object, and external, described below), you can specify an additional label selector which is passed to your metric pipeline. For instance, if you collect a metric `http_requests` with the verb label, you can specify the following metric block to scale only on GET requests:

```

type: Object
object:
  metric:
    name: http_requests
    selector: {matchLabels: {verb: GET}}

```

This selector uses the same syntax as the full Kubernetes label selectors. The monitoring pipeline determines how to collapse multiple series into a single value, if the name and selector match multiple series. The selector is additive, and cannot select metrics that describe objects that are **not** the target object (the target pods in the case of the Pods type, and the described object in the case of the Object type).

Autoscaling on metrics not related to Kubernetes objects

Applications running on Kubernetes may need to autoscale based on metrics that don't have an obvious relationship to any object in the Kubernetes cluster, such as metrics describing a hosted service with no direct correlation to Kubernetes namespaces. In Kubernetes 1.10 and later, you can address this use case with *external metrics*.

Using external metrics requires knowledge of your monitoring system; the setup is similar to that required when using custom metrics. External metrics allow you to autoscale your cluster based on any metric available in your monitoring system. Provide a metric block with a name and selector, as above, and use the External metric type instead of Object. If multiple time series are matched by the metricSelector, the sum of their values is used by the HorizontalPodAutoscaler. External metrics support both the Value and AverageValue target types, which function exactly the same as when you use the Object type.

For example if your application processes tasks from a hosted queue service, you could add the following section to your HorizontalPodAutoscaler manifest to specify that you need one worker per 30 outstanding tasks.

```
- type: External
  external:
    metric:
      name: queue_messages_ready
      selector:
        matchLabels:
          queue: "worker_tasks"
    target:
      type: AverageValue
      averageValue: 30
```

When possible, it's preferable to use the custom metric target types instead of external metrics, since it's easier for cluster administrators to secure the custom metrics API. The external metrics API potentially allows access to any metric, so cluster administrators should take care when exposing it.

Appendix: Horizontal Pod Autoscaler Status Conditions

When using the autoscaling/v2 form of the HorizontalPodAutoscaler, you will be able to see *status conditions* set by Kubernetes on the HorizontalPodAutoscaler. These status conditions indicate whether or not the HorizontalPodAutoscaler is able to scale, and whether or not it is currently restricted in any way.

The conditions appear in the status.conditions field. To see the conditions affecting a HorizontalPodAutoscaler, we can use `kubectl describe hpa`:

```
kubectl describe hpa cm-test
```

```
Name:          cm-test
Namespace:     prom
Labels:        <none>
Annotations:   <none>
CreationTimestamp:  Fri, 16 Jun 2017 18:09:22 +0000
Reference:     ReplicationController/cm-test
```

```

Metrics:                ( current / target )
"http_requests" on pods: 66m / 500m
Min replicas:           1
Max replicas:           4
ReplicationController pods: 1 current / 1 desired
Conditions:
  Type                Status Reason                Message
  ----                -
  AbleToScale         True   ReadyForNewScale    the last scale time was sufficiently old as to
warrant a new scale
  ScalingActive        True   ValidMetricFound    the HPA was able to successfully calculate a
replica count from pods metric http_requests
  ScalingLimited       False  DesiredWithinRange  the desired replica count is within the
acceptable range
Events:

```

For this HorizontalPodAutoscaler, you can see several conditions in a healthy state. The first, `AbleToScale`, indicates whether or not the HPA is able to fetch and update scales, as well as whether or not any backoff-related conditions would prevent scaling. The second, `ScalingActive`, indicates whether or not the HPA is enabled (i.e. the replica count of the target is not zero) and is able to calculate desired scales. When it is `False`, it generally indicates problems with fetching metrics. Finally, the last condition, `ScalingLimited`, indicates that the desired scale was capped by the maximum or minimum of the HorizontalPodAutoscaler. This is an indication that you may wish to raise or lower the minimum or maximum replica count constraints on your HorizontalPodAutoscaler.

Quantities

All metrics in the HorizontalPodAutoscaler and metrics APIs are specified using a special whole-number notation known in Kubernetes as a [quantity](#). For example, the quantity 10500m would be written as 10.5 in decimal notation. The metrics APIs will return whole numbers without a suffix when possible, and will generally return quantities in milli-units otherwise. This means you might see your metric value fluctuate between 1 and 1500m, or 1 and 1.5 when written in decimal notation.

Other possible scenarios

Creating the autoscaler declaratively

Instead of using `kubectl autoscale` command to create a HorizontalPodAutoscaler imperatively we can use the following manifest to create it declaratively:

[application/hpa/php-apache.yaml](#)

```

apiVersion: autoscaling/v2
kind: HorizontalPodAutoscaler
metadata:
  name: php-apache
spec:
  scaleTargetRef:
    apiVersion: apps/v1
    kind: Deployment

```

```
name: php-apache
minReplicas: 1
maxReplicas: 10
metrics:
- type: Resource
  resource:
    name: cpu
    target:
      type: Utilization
      averageUtilization: 50
```

Then, create the autoscaler by executing the following command:

```
kubectl create -f https://k8s.io/examples/application/hpa/php-apache.yaml
```

```
horizontalpodautoscaler.autoscaling/php-apache created
```

Specifying a Disruption Budget for your Application

FEATURE STATE: Kubernetes v1.21 [stable]

This page shows how to limit the number of concurrent disruptions that your application experiences, allowing for higher availability while permitting the cluster administrator to manage the clusters nodes.

Before you begin

Your Kubernetes server must be at or later than version v1.21. To check the version, enter `kubectl version`.

- You are the owner of an application running on a Kubernetes cluster that requires high availability.
- You should know how to deploy [Replicated Stateless Applications](#) and/or [Replicated Stateful Applications](#).
- You should have read about [Pod Disruptions](#).
- You should confirm with your cluster owner or service provider that they respect Pod Disruption Budgets.

Protecting an Application with a PodDisruptionBudget

1. Identify what application you want to protect with a PodDisruptionBudget (PDB).
2. Think about how your application reacts to disruptions.
3. Create a PDB definition as a YAML file.
4. Create the PDB object from the YAML file.

Identify an Application to Protect

The most common use case when you want to protect an application specified by one of the built-in Kubernetes controllers:

- Deployment
- ReplicationController
- ReplicaSet
- StatefulSet

In this case, make a note of the controller's `.spec.selector`; the same selector goes into the PDBs `.spec.selector`.

From version 1.15 PDBs support custom controllers where the [scale subresource](#) is enabled.

You can also use PDBs with pods which are not controlled by one of the above controllers, or arbitrary groups of pods, but there are some restrictions, described in [Arbitrary workloads and arbitrary selectors](#).

Think about how your application reacts to disruptions

Decide how many instances can be down at the same time for a short period due to a voluntary disruption.

- Stateless frontends:
 - Concern: don't reduce serving capacity by more than 10%.
 - Solution: use PDB with `minAvailable 90%` for example.
- Single-instance Stateful Application:
 - Concern: do not terminate this application without talking to me.
 - Possible Solution 1: Do not use a PDB and tolerate occasional downtime.
 - Possible Solution 2: Set PDB with `maxUnavailable=0`. Have an understanding (outside of Kubernetes) that the cluster operator needs to consult you before termination. When the cluster operator contacts you, prepare for downtime, and then delete the PDB to indicate readiness for disruption. Recreate afterwards.
- Multiple-instance Stateful application such as Consul, ZooKeeper, or etcd:
 - Concern: Do not reduce number of instances below quorum, otherwise writes fail.
 - Possible Solution 1: set `maxUnavailable` to 1 (works with varying scale of application).
 - Possible Solution 2: set `minAvailable` to quorum-size (e.g. 3 when scale is 5). (Allows more disruptions at once).
- Restartable Batch Job:
 - Concern: Job needs to complete in case of voluntary disruption.
 - Possible solution: Do not create a PDB. The Job controller will create a replacement pod.

Rounding logic when specifying percentages

Values for `minAvailable` or `maxUnavailable` can be expressed as integers or as a percentage.

- When you specify an integer, it represents a number of Pods. For instance, if you set `minAvailable` to 10, then 10 Pods must always be available, even during a disruption.

- When you specify a percentage by setting the value to a string representation of a percentage (eg. "50%"), it represents a percentage of total Pods. For instance, if you set `minAvailable` to "50%", then at least 50% of the Pods remain available during a disruption.

When you specify the value as a percentage, it may not map to an exact number of Pods. For example, if you have 7 Pods and you set `minAvailable` to "50%", it's not immediately obvious whether that means 3 Pods or 4 Pods must be available. Kubernetes rounds up to the nearest integer, so in this case, 4 Pods must be available. When you specify the value `maxUnavailable` as a percentage, Kubernetes rounds up the number of Pods that may be disrupted. Thereby a disruption can exceed your defined `maxUnavailable` percentage. You can examine the [code](#) that controls this behavior.

Specifying a PodDisruptionBudget

A `PodDisruptionBudget` has three fields:

- A label selector `.spec.selector` to specify the set of pods to which it applies. This field is required.
- `.spec.minAvailable` which is a description of the number of pods from that set that must still be available after the eviction, even in the absence of the evicted pod. `minAvailable` can be either an absolute number or a percentage.
- `.spec.maxUnavailable` (available in Kubernetes 1.7 and higher) which is a description of the number of pods from that set that can be unavailable after the eviction. It can be either an absolute number or a percentage.

Note:

The behavior for an empty selector differs between the `policy/v1beta1` and `policy/v1` APIs for `PodDisruptionBudgets`. For `policy/v1beta1` an empty selector matches zero pods, while for `policy/v1` an empty selector matches every pod in the namespace.

You can specify only one of `maxUnavailable` and `minAvailable` in a single `PodDisruptionBudget`. `maxUnavailable` can only be used to control the eviction of pods that have an associated controller managing them. In the examples below, "desired replicas" is the scale of the controller managing the pods being selected by the `PodDisruptionBudget`.

Example 1: With a `minAvailable` of 5, evictions are allowed as long as they leave behind 5 or more [healthy](#) pods among those selected by the `PodDisruptionBudget`'s selector.

Example 2: With a `minAvailable` of 30%, evictions are allowed as long as at least 30% of the number of desired replicas are healthy.

Example 3: With a `maxUnavailable` of 5, evictions are allowed as long as there are at most 5 unhealthy replicas among the total number of desired replicas.

Example 4: With a `maxUnavailable` of 30%, evictions are allowed as long as the number of unhealthy replicas does not exceed 30% of the total number of desired replica rounded up to the nearest integer. If the total number of desired replicas is just one, that single replica is still allowed for disruption, leading to an effective unavailability of 100%.

In typical usage, a single budget would be used for a collection of pods managed by a controller—for example, the pods in a single `ReplicaSet` or `StatefulSet`.

Note:

A disruption budget does not truly guarantee that the specified number/percentage of pods will always be up. For example, a node that hosts a pod from the collection may fail when the collection is at the minimum size specified in the budget, thus bringing the number of available pods from the collection below the specified size. The budget can only protect against voluntary evictions, not all causes of unavailability.

If you set `maxUnavailable` to 0% or 0, or you set `minAvailable` to 100% or the number of replicas, you are requiring zero voluntary evictions. When you set zero voluntary evictions for a workload object such as `ReplicaSet`, then you cannot successfully drain a Node running one of those Pods. If you try to drain a Node where an unevictable Pod is running, the drain never completes. This is permitted as per the semantics of `PodDisruptionBudget`.

You can find examples of pod disruption budgets defined below. They match pods with the label `app: zookeeper`.

Example PDB Using `minAvailable`:

[policy/zookeeper-pod-disruption-budget-minavailable.yaml](#)

```
apiVersion: policy/v1
kind: PodDisruptionBudget
metadata:
  name: zk-pdb
spec:
  minAvailable: 2
  selector:
    matchLabels:
      app: zookeeper
```

Example PDB Using `maxUnavailable`:

[policy/zookeeper-pod-disruption-budget-maxunavailable.yaml](#)

```
apiVersion: policy/v1
kind: PodDisruptionBudget
metadata:
  name: zk-pdb
spec:
  maxUnavailable: 1
  selector:
    matchLabels:
      app: zookeeper
```

For example, if the above `zk-pdb` object selects the pods of a `StatefulSet` of size 3, both specifications have the exact same meaning. The use of `maxUnavailable` is recommended as it automatically responds to changes in the number of replicas of the corresponding controller.

Create the PDB object

You can create or update the PDB object using `kubectl`.

```
kubectl apply -f mypdb.yaml
```

Check the status of the PDB

Use `kubectl` to check that your PDB is created.

Assuming you don't actually have pods matching `app: zookeeper` in your namespace, then you'll see something like this:

```
kubectl get poddisruptionbudgets
```

| NAME | MIN AVAILABLE | MAX UNAVAILABLE | ALLOWED DISRUPTIONS | AGE |
|--------|---------------|-----------------|---------------------|-----|
| zk-pdb | 2 | N/A | 0 | 7s |

If there are matching pods (say, 3), then you would see something like this:

```
kubectl get poddisruptionbudgets
```

| NAME | MIN AVAILABLE | MAX UNAVAILABLE | ALLOWED DISRUPTIONS | AGE |
|--------|---------------|-----------------|---------------------|-----|
| zk-pdb | 2 | N/A | 1 | 7s |

The non-zero value for `ALLOWED DISRUPTIONS` means that the disruption controller has seen the pods, counted the matching pods, and updated the status of the PDB.

You can get more information about the status of a PDB with this command:

```
kubectl get poddisruptionbudgets zk-pdb -o yaml
```

```
apiVersion: policy/v1
kind: PodDisruptionBudget
metadata:
  annotations:
  ...
  creationTimestamp: "2020-03-04T04:22:56Z"
  generation: 1
  name: zk-pdb
  ...
status:
  currentHealthy: 3
  desiredHealthy: 2
  disruptionsAllowed: 1
  expectedPods: 3
  observedGeneration: 1
```

Healthiness of a Pod

The current implementation considers healthy pods, as pods that have `.status.conditions` item with `type="Ready"` and `status="True"`. These pods are tracked via `.status.currentHealthy` field in the PDB status.

Unhealthy Pod Eviction Policy

FEATURE STATE: Kubernetes v1.27 [beta]

Note:

This feature is enabled by default. You can disable it by disabling the `PDBUnhealthyPodEvictionPolicy` [feature gate](#) on the [API server](#).

`PodDisruptionBudget` guarding an application ensures that `.status.currentHealthy` number of pods does not fall below the number specified in `.status.desiredHealthy` by disallowing eviction of healthy pods. By using `.spec.unhealthyPodEvictionPolicy`, you can also define the criteria when unhealthy pods should be considered for eviction. The default behavior when no policy is specified corresponds to the `IfHealthyBudget` policy.

Policies:

IfHealthyBudget

Running pods (`.status.phase="Running"`), but not yet healthy can be evicted only if the guarded application is not disrupted (`.status.currentHealthy` is at least equal to `.status.desiredHealthy`).

This policy ensures that running pods of an already disrupted application have the best chance to become healthy. This has negative implications for draining nodes, which can be blocked by misbehaving applications that are guarded by a PDB. More specifically applications with pods in `CrashLoopBackOff` state (due to a bug or misconfiguration), or pods that are just failing to report the Ready condition.

AlwaysAllow

Running pods (`.status.phase="Running"`), but not yet healthy are considered disrupted and can be evicted regardless of whether the criteria in a PDB is met.

This means prospective running pods of a disrupted application might not get a chance to become healthy. By using this policy, cluster managers can easily evict misbehaving applications that are guarded by a PDB. More specifically applications with pods in `CrashLoopBackOff` state (due to a bug or misconfiguration), or pods that are just failing to report the Ready condition.

Note:

Pods in `Pending`, `Succeeded` or `Failed` phase are always considered for eviction.

Arbitrary workloads and arbitrary selectors

You can skip this section if you only use PDBs with the built-in workload resources (`Deployment`, `ReplicaSet`, `StatefulSet` and `ReplicationController`) or with [custom resources](#) that implement a scale [subresource](#), and where the PDB selector exactly matches the selector of the Pod's owning resource.

You can use a PDB with pods controlled by another resource, by an "operator", or bare pods, but with these restrictions:

- only `.spec.minAvailable` can be used, not `.spec.maxUnavailable`.
- only an integer value can be used with `.spec.minAvailable`, not a percentage.

It is not possible to use other availability configurations, because Kubernetes cannot derive a total number of pods without a supported owning resource.

You can use a selector which selects a subset or superset of the pods belonging to a workload resource. The eviction API will disallow eviction of any pod covered by multiple PDBs, so most users will want to avoid overlapping selectors. One reasonable use of overlapping PDBs is when pods are being transitioned from one PDB to another.

Accessing the Kubernetes API from a Pod

This guide demonstrates how to access the Kubernetes API from within a pod.

Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

Accessing the API from within a Pod

When accessing the API from within a Pod, locating and authenticating to the API server are slightly different to the external client case.

The easiest way to use the Kubernetes API from a Pod is to use one of the official [client libraries](#). These libraries can automatically discover the API server and authenticate.

Using Official Client Libraries

From within a Pod, the recommended ways to connect to the Kubernetes API are:

- For a Go client, use the official [Go client library](#). The `rest.InClusterConfig()` function handles API host discovery and authentication automatically. See [an example here](#).
- For a Python client, use the official [Python client library](#). The `config.load_incluster_config()` function handles API host discovery and authentication automatically. See [an example here](#).
- There are a number of other libraries available, please refer to the [Client Libraries](#) page.

In each case, the service account credentials of the Pod are used to communicate securely with the API server.

Directly accessing the REST API

While running in a Pod, your container can create an HTTPS URL for the Kubernetes API server by fetching the `KUBERNETES_SERVICE_HOST` and `KUBERNETES_SERVICE_PORT_HTTPS` environment variables. The API server's in-cluster address is also published to a Service named `kubernetes` in the default namespace so that pods may reference `kubernetes.default.svc` as a DNS name for the local API server.

Note:

Kubernetes does not guarantee that the API server has a valid certificate for the hostname `kubernetes.default.svc`; however, the control plane **is** expected to present a valid certificate for the hostname or IP address that `$KUBERNETES_SERVICE_HOST` represents.

The recommended way to authenticate to the API server is with a [service account](#) credential. By default, a Pod is associated with a service account, and a credential (token) for that service account is placed into the filesystem tree of each container in that Pod, at `/var/run/secrets/kubernetes.io/serviceaccount/token`.

If available, a certificate bundle is placed into the filesystem tree of each container at `/var/run/secrets/kubernetes.io/serviceaccount/ca.crt`, and should be used to verify the serving certificate of the API server.

Finally, the default namespace to be used for namespaced API operations is placed in a file at `/var/run/secrets/kubernetes.io/serviceaccount/namespace` in each container.

Using kubectl proxy

If you would like to query the API without an official client library, you can run `kubectl proxy` as the [command](#) of a new sidecar container in the Pod. This way, `kubectl proxy` will authenticate to the API and expose it on the localhost interface of the Pod, so that other containers in the Pod can use it directly.

Without using a proxy

It is possible to avoid using the `kubectl proxy` by passing the authentication token directly to the API server. The internal certificate secures the connection.

```
# Point to the internal API server hostname
APISERVER=https://kubernetes.default.svc

# Path to ServiceAccount token
SERVICEACCOUNT=/var/run/secrets/kubernetes.io/serviceaccount

# Read this Pod's namespace
NAMESPACE=$(cat ${SERVICEACCOUNT}/namespace)

# Read the ServiceAccount bearer token
TOKEN=$(cat ${SERVICEACCOUNT}/token)

# Reference the internal certificate authority (CA)
CACERT=${SERVICEACCOUNT}/ca.crt
```

```
# Explore the API with TOKEN
```

```
curl --cacert ${CACERT} --header "Authorization: Bearer ${TOKEN}" -X GET ${APISERVER}/api
```

The output will be similar to this:

```
{
  "kind": "APIVersions",
  "versions": ["v1"],
  "serverAddressByClientCIDRs": [
    {
      "clientCIDR": "0.0.0.0/0",
      "serverAddress": "10.0.1.149:443"
    }
  ]
}
```

Run Jobs

Run Jobs using parallel processing.

[Running Automated Tasks with a CronJob](#)

[Coarse Parallel Processing Using a Work Queue](#)

[Fine Parallel Processing Using a Work Queue](#)

[Indexed Job for Parallel Processing with Static Work Assignment](#)

[Job with Pod-to-Pod Communication](#)

[Parallel Processing using Expansions](#)

[Handling retrieable and non-retrieable pod failures with Pod failure policy](#)

Running Automated Tasks with a CronJob

This page shows how to run automated tasks using Kubernetes [CronJob](#) object.

Before you begin

- You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:
 - [Killercodea](#)
 - [Play with Kubernetes](#)

Creating a CronJob

Cron jobs require a config file. Here is a manifest for a CronJob that runs a simple demonstration task every minute:

[application/job/cronjob.yaml](https://k8s.io/examples/application/job/cronjob.yaml)

```
apiVersion: batch/v1
kind: CronJob
metadata:
  name: hello
spec:
  schedule: "* * * * *"
  jobTemplate:
    spec:
      template:
        spec:
          containers:
            - name: hello
              image: busybox:1.28
              imagePullPolicy: IfNotPresent
              command:
                - /bin/sh
                - -c
                - date; echo Hello from the Kubernetes cluster
          restartPolicy: OnFailure
```

Run the example CronJob by using this command:

```
kubectl create -f https://k8s.io/examples/application/job/cronjob.yaml
```

The output is similar to this:

```
cronjob.batch/hello created
```

After creating the cron job, get its status using this command:

```
kubectl get cronjob hello
```

The output is similar to this:

| NAME | SCHEDULE | SUSPEND | ACTIVE | LAST SCHEDULE | AGE |
|-------|-------------|---------|--------|---------------|-----|
| hello | */* * * * * | False | 0 | <none> | 10s |

As you can see from the results of the command, the cron job has not scheduled or run any jobs yet. Watch for the job to be created in around one minute:

```
kubectl get jobs --watch
```

The output is similar to this:

| NAME | COMPLETIONS | DURATION | AGE |
|------------------|-------------|----------|-----|
| hello-4111706356 | 0/1 | 0s | |

```
hello-4111706356 0/1      0s      0s
hello-4111706356 1/1      5s      5s
```

Now you've seen one running job scheduled by the "hello" cron job. You can stop watching the job and view the cron job again to see that it scheduled the job:

```
kubectrl get cronjob hello
```

The output is similar to this:

| NAME | SCHEDULE | SUSPEND | ACTIVE | LAST SCHEDULE | AGE |
|-------|--------------|---------|--------|---------------|-----|
| hello | * /1 * * * * | False | 0 | 50s | 75s |

You should see that the cron job hello successfully scheduled a job at the time specified in LAST SCHEDULE. There are currently 0 active jobs, meaning that the job has completed or failed.

Now, find the pods that the last scheduled job created and view the standard output of one of the pods.

Note:

The job name is different from the pod name.

```
# Replace "hello-4111706356" with the job name in your system
pods=$(kubectrl get pods --selector=job-name=hello-4111706356 --output=jsonpath={.items[*].metadata.name})
```

Show the pod log:

```
kubectrl logs $pods
```

The output is similar to this:

```
Fri Feb 22 11:02:09 UTC 2019
Hello from the Kubernetes cluster
```

Deleting a CronJob

When you don't need a cron job any more, delete it with `kubectrl delete cronjob <cronjob name>`:

```
kubectrl delete cronjob hello
```

Deleting the cron job removes all the jobs and pods it created and stops it from creating additional jobs. You can read more about removing jobs in [garbage collection](#).

Coarse Parallel Processing Using a Work Queue

In this example, you will run a Kubernetes Job with multiple parallel worker processes.

In this example, as each pod is created, it picks up one unit of work from a task queue, completes it, deletes it from the queue, and exits.

Here is an overview of the steps in this example:

1. **Start a message queue service.** In this example, you use RabbitMQ, but you could use another one. In practice you would set up a message queue service once and reuse it for many jobs.
2. **Create a queue, and fill it with messages.** Each message represents one task to be done. In this example, a message is an integer that we will do a lengthy computation on.
3. **Start a Job that works on tasks from the queue.** The Job starts several pods. Each pod takes one task from the message queue, processes it, and exits.

Before you begin

You should already be familiar with the basic, non-parallel, use of [Job](#).

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

You will need a container image registry where you can upload images to run in your cluster.

This task example also assumes that you have Docker installed locally.

Starting a message queue service

This example uses RabbitMQ, however, you can adapt the example to use another AMQP-type message service.

In practice you could set up a message queue service once in a cluster and reuse it for many jobs, as well as for long-running services.

Start RabbitMQ as follows:

```
# make a Service for the StatefulSet to use
kubectl create -f https://kubernetes.io/examples/application/job/rabbitmq/rabbitmq-
service.yaml
```

```
service "rabbitmq-service" created
```

```
kubectl create -f https://kubernetes.io/examples/application/job/rabbitmq/rabbitmq-
statefulset.yaml
```

```
statefulset "rabbitmq" created
```

Testing the message queue service

Now, we can experiment with accessing the message queue. We will create a temporary interactive pod, install some tools on it, and experiment with queues.

First create a temporary interactive Pod.

```
# Create a temporary interactive container
kubectl run -i --tty temp --image ubuntu:22.04
```

```
Waiting for pod default/temp-loe07 to be running, status is Pending, pod ready: false
... [ previous line repeats several times .. hit return when it stops ] ...
```

Note that your pod name and command prompt will be different.

Next install the `amqp-tools` so you can work with message queues. The next commands show what you need to run inside the interactive shell in that Pod:

```
apt-get update && apt-get install -y curl ca-certificates amqp-tools python3 dnsutils
```

Later, you will make a container image that includes these packages.

Next, you will check that you can discover the Service for RabbitMQ:

```
# Run these commands inside the Pod
# Note the rabbitmq-service has a DNS name, provided by Kubernetes:
nslookup rabbitmq-service
```

```
Server:      10.0.0.10
Address:     10.0.0.10#53
```

```
Name:  rabbitmq-service.default.svc.cluster.local
Address: 10.0.147.152
```

(the IP addresses will vary)

If the kube-dns addon is not set up correctly, the previous step may not work for you. You can also find the IP address for that Service in an environment variable:

```
# run this check inside the Pod
env | grep RABBITMQ_SERVICE | grep HOST
```

```
RABBITMQ_SERVICE_SERVICE_HOST=10.0.147.152
```

(the IP address will vary)

Next you will verify that you can create a queue, and publish and consume messages.

```
# Run these commands inside the Pod
# In the next line, rabbitmq-service is the hostname where the rabbitmq-service
# can be reached. 5672 is the standard port for rabbitmq.
export BROKER_URL=amqp://guest:guest@rabbitmq-service:5672
# If you could not resolve "rabbitmq-service" in the previous step,
# then use this command instead:
```

```
BROKER_URL=amqp://guest:guest@$RABBITMQ_SERVICE_SERVICE_HOST:5672
```

Now create a queue:

```
/usr/bin/amqp-declare-queue --url=$BROKER_URL -q foo -d
```

```
foo
```

Publish one message to the queue:

```
/usr/bin/amqp-publish --url=$BROKER_URL -r foo -p -b Hello
```

And get it back.

```
/usr/bin/amqp-consume --url=$BROKER_URL -q foo -c 1 cat && echo 1>&2
```

```
Hello
```

In the last command, the `amqp-consume` tool took one message (`-c 1`) from the queue, and passes that message to the standard input of an arbitrary command. In this case, the program `cat` prints out the characters read from standard input, and the `echo` adds a carriage return so the example is readable.

Fill the queue with tasks

Now, fill the queue with some simulated tasks. In this example, the tasks are strings to be printed.

In a practice, the content of the messages might be:

- names of files to that need to be processed
- extra flags to the program
- ranges of keys in a database table
- configuration parameters to a simulation
- frame numbers of a scene to be rendered

If there is large data that is needed in a read-only mode by all pods of the Job, you typically put that in a shared file system like NFS and mount that readonly on all the pods, or write the program in the pod so that it can natively read data from a cluster file system (for example: HDFS).

For this example, you will create the queue and fill it using the AMQP command line tools. In practice, you might write a program to fill the queue using an AMQP client library.

Run this on your computer, not in the Pod

```
/usr/bin/amqp-declare-queue --url=$BROKER_URL -q job1 -d
```

```
job1
```

Add items to the queue:

```
for f in apple banana cherry date fig grape lemon melon  
do
```

```
/usr/bin/amqp-publish --url=$BROKER_URL -r job1 -p -b $f
done
```

You added 8 messages to the queue.

Create a container image

Now you are ready to create an image that you will run as a Job.

The job will use the `amqp-consume` utility to read the message from the queue and run the actual work. Here is a very simple example program:

[application/job/rabbitmq/worker.py](#)

```
#!/usr/bin/env python

# Just prints standard out and sleeps for 10 seconds.
import sys
import time
print("Processing " + sys.stdin.readlines()[0])
time.sleep(10)
```

Give the script execution permission:

```
chmod +x worker.py
```

Now, build an image. Make a temporary directory, change to it, download the [Dockerfile](#), and [worker.py](#). In either case, build the image with this command:

```
docker build -t job-wq-1 .
```

For the [Docker Hub](#), tag your app image with your username and push to the Hub with the below commands. Replace `<username>` with your Hub username.

```
docker tag job-wq-1 <username>/job-wq-1
docker push <username>/job-wq-1
```

If you are using an alternative container image registry, tag the image and push it there instead.

Defining a Job

Here is a manifest for a Job. You'll need to make a copy of the Job manifest (call it `./job.yaml`), and edit the name of the container image to match the name you used.

[application/job/rabbitmq/job.yaml](#)

```
apiVersion: batch/v1
kind: Job
metadata:
  name: job-wq-1
spec:
  completions: 8
  parallelism: 2
```

```

template:
  metadata:
    name: job-wq-1
  spec:
    containers:
      - name: c
        image: gcr.io/<project>/job-wq-1
        env:
          - name: BROKER_URL
            value: amqp://guest:guest@rabbitmq-service:5672
          - name: QUEUE
            value: job1
        restartPolicy: OnFailure

```

In this example, each pod works on one item from the queue and then exits. So, the completion count of the Job corresponds to the number of work items done. That is why the example manifest has `.spec.completions` set to 8.

Running the Job

Now, run the Job:

```
# this assumes you downloaded and then edited the manifest already
kubectl apply -f ./job.yaml
```

You can wait for the Job to succeed, with a timeout:

```
# The check for condition name is case insensitive
kubectl wait --for=condition=complete --timeout=300s job/job-wq-1
```

Next, check on the Job:

```
kubectl describe jobs/job-wq-1
```

```

Name:          job-wq-1
Namespace:     default
Selector:      controller-uid=41d75705-92df-11e7-b85e-fa163ee3c11f
Labels:        controller-uid=41d75705-92df-11e7-b85e-fa163ee3c11f
                job-name=job-wq-1
Annotations:   <none>
Parallelism:   2
Completions:   8
Start Time:    Wed, 06 Sep 2022 16:42:02 +0000
Pods Statuses: 0 Running / 8 Succeeded / 0 Failed
Pod Template:
  Labels:  controller-uid=41d75705-92df-11e7-b85e-fa163ee3c11f

```

| | | | | | | | | |
|-----------|----------|-------|--------|---------------|------------------|------------------------|---------|--|
| QUEUE: | job1 | | | | | | | |
| Mounts: | <none> | | | | | | | |
| Volumes: | <none> | | | | | | | |
| Events: | | | | | | | | |
| FirstSeen | LastSeen | Count | From | SubobjectPath | Type | Reason | Message | |
| | | | | | | | | |
| 27s | 27s | 1 | {job } | Normal | SuccessfulCreate | Created pod: job-wq-1- | | |
| hcobb | 27s | 1 | {job } | Normal | SuccessfulCreate | Created pod: job-wq-1- | | |
| weytj | 27s | 1 | {job } | Normal | SuccessfulCreate | Created pod: job-wq-1- | | |
| qaam5 | 27s | 1 | {job } | Normal | SuccessfulCreate | Created pod: job-wq-1- | | |
| b67sr | 27s | 1 | {job } | Normal | SuccessfulCreate | Created pod: job-wq-1- | | |
| xe5hj | 26s | 1 | {job } | Normal | SuccessfulCreate | Created pod: job-wq-1- | | |
| w2zqe | 15s | 1 | {job } | Normal | SuccessfulCreate | Created pod: job-wq-1- | | |
| d6ppa | 14s | 1 | {job } | Normal | SuccessfulCreate | Created pod: job-wq-1- | | |
| p17e0 | 14s | 1 | {job } | Normal | SuccessfulCreate | Created pod: job-wq-1- | | |

All the pods for that Job succeeded! You're done.

Alternatives

This approach has the advantage that you do not need to modify your "worker" program to be aware that there is a work queue. You can include the worker program unmodified in your container image.

Using this approach does require that you run a message queue service. If running a queue service is inconvenient, you may want to consider one of the other [job patterns](#).

This approach creates a pod for every work item. If your work items only take a few seconds, though, creating a Pod for every work item may add a lot of overhead. Consider another design, such as in the [fine parallel work queue example](#), that executes multiple work items per Pod.

In this example, you used the `amqp-consume` utility to read the message from the queue and run the actual program. This has the advantage that you do not need to modify your program to be aware of the queue. The [fine parallel work queue example](#) shows how to communicate with the work queue using a client library.

Caveats

If the number of completions is set to less than the number of items in the queue, then not all items will be processed.

If the number of completions is set to more than the number of items in the queue, then the Job will not appear to be completed, even though all items in the queue have been processed. It will start additional pods which will block waiting for a message. You would need to make your

own mechanism to spot when there is work to do and measure the size of the queue, setting the number of completions to match.

There is an unlikely race with this pattern. If the container is killed in between the time that the message is acknowledged by the `amqp-consume` command and the time that the container exits with success, or if the node crashes before the kubelet is able to post the success of the pod back to the API server, then the Job will not appear to be complete, even though all items in the queue have been processed.

Fine Parallel Processing Using a Work Queue

In this example, you will run a Kubernetes Job that runs multiple parallel tasks as worker processes, each running as a separate Pod.

In this example, as each pod is created, it picks up one unit of work from a task queue, processes it, and repeats until the end of the queue is reached.

Here is an overview of the steps in this example:

1. **Start a storage service to hold the work queue.** In this example, you will use Redis to store work items. In the [previous example](#), you used RabbitMQ. In this example, you will use Redis and a custom work-queue client library; this is because AMQP does not provide a good way for clients to detect when a finite-length work queue is empty. In practice you would set up a store such as Redis once and reuse it for the work queues of many jobs, and other things.
2. **Create a queue, and fill it with messages.** Each message represents one task to be done. In this example, a message is an integer that we will do a lengthy computation on.
3. **Start a Job that works on tasks from the queue.** The Job starts several pods. Each pod takes one task from the message queue, processes it, and repeats until the end of the queue is reached.

Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

You will need a container image registry where you can upload images to run in your cluster. The example uses [Docker Hub](#), but you could adapt it to a different container image registry.

This task example also assumes that you have Docker installed locally. You use Docker to build container images.

Be familiar with the basic, non-parallel, use of [Job](#).

Starting Redis

For this example, for simplicity, you will start a single instance of Redis. See the [Redis Example](#) for an example of deploying Redis scalably and redundantly.

You could also download the following files directly:

- [redis-pod.yaml](#)
- [redis-service.yaml](#)
- [Dockerfile](#)
- [job.yaml](#)
- [rediswq.py](#)
- [worker.py](#)

To start a single instance of Redis, you need to create the redis pod and redis service:

```
kubectl apply -f https://k8s.io/examples/application/job/redis/redis-pod.yaml
kubectl apply -f https://k8s.io/examples/application/job/redis/redis-service.yaml
```

Filling the queue with tasks

Now let's fill the queue with some "tasks". In this example, the tasks are strings to be printed.

Start a temporary interactive pod for running the Redis CLI.

```
kubectl run -i --tty temp --image redis --command "/bin/sh"
```

```
Waiting for pod default/redis2-c7h78 to be running, status is Pending, pod ready: false
Hit enter for command prompt
```

Now hit enter, start the Redis CLI, and create a list with some work items in it.

```
redis-cli -h redis
```

```
redis:6379> rpush job2 "apple"
(integer) 1
redis:6379> rpush job2 "banana"
(integer) 2
redis:6379> rpush job2 "cherry"
(integer) 3
redis:6379> rpush job2 "date"
(integer) 4
redis:6379> rpush job2 "fig"
(integer) 5
redis:6379> rpush job2 "grape"
(integer) 6
redis:6379> rpush job2 "lemon"
(integer) 7
redis:6379> rpush job2 "melon"
(integer) 8
redis:6379> rpush job2 "orange"
(integer) 9
redis:6379> lrange job2 0 -1
```

- 1) "apple"
- 2) "banana"
- 3) "cherry"
- 4) "date"
- 5) "fig"
- 6) "grape"
- 7) "lemon"
- 8) "melon"
- 9) "orange"

So, the list with key job2 will be the work queue.

Note: if you do not have Kube DNS setup correctly, you may need to change the first step of the above block to `redis-cli -h $REDIS_SERVICE_HOST`.

Create a container image

Now you are ready to create an image that will process the work in that queue.

You're going to use a Python worker program with a Redis client to read the messages from the message queue.

A simple Redis work queue client library is provided, called `rediswq.py` ([Download](#)).

The "worker" program in each Pod of the Job uses the work queue client library to get work. Here it is:

[application/job/redis/worker.py](#)

```
#!/usr/bin/env python

import time
import rediswq

host="redis"
# Uncomment next two lines if you do not have Kube-DNS working.
# import os
# host = os.getenv("REDIS_SERVICE_HOST")

q = rediswq.RedisWQ(name="job2", host=host)
print("Worker with sessionID: " + q.sessionID())
print("Initial queue state: empty=" + str(q.empty()))
while not q.empty():
    item = q.lease(lease_secs=10, block=True, timeout=2)
    if item is not None:
        itemstr = item.decode("utf-8")
        print("Working on " + itemstr)
        time.sleep(10) # Put your actual work here instead of sleep.
        q.complete(item)
    else:
        print("Waiting for work")
print("Queue empty, exiting")
```

You could also download [worker.py](#), [rediswq.py](#), and [Dockerfile](#) files, then build the container image. Here's an example using Docker to do the image build:

```
docker build -t job-wq-2 .
```

Push the image

For the [Docker Hub](#), tag your app image with your username and push to the Hub with the below commands. Replace <username> with your Hub username.

```
docker tag job-wq-2 <username>/job-wq-2
docker push <username>/job-wq-2
```

You need to push to a public repository or [configure your cluster to be able to access your private repository](#).

Defining a Job

Here is a manifest for the Job you will create:

[application/job/redis/job.yaml](#)

```
apiVersion: batch/v1
kind: Job
metadata:
  name: job-wq-2
spec:
  parallelism: 2
  template:
    metadata:
      name: job-wq-2
    spec:
      containers:
        - name: c
          image: gcr.io/myproject/job-wq-2
      restartPolicy: OnFailure
```

Note:

Be sure to edit the manifest to change gcr.io/myproject to your own path.

In this example, each pod works on several items from the queue and then exits when there are no more items. Since the workers themselves detect when the workqueue is empty, and the Job controller does not know about the workqueue, it relies on the workers to signal when they are done working. The workers signal that the queue is empty by exiting with success. So, as soon as **any** worker exits with success, the controller knows the work is done, and that the Pods will exit soon. So, you need to leave the completion count of the Job unset. The job controller will wait for the other pods to complete too.

Running the Job

So, now run the Job:

```
# this assumes you downloaded and then edited the manifest already
kubectl apply -f ./job.yaml
```

Now wait a bit, then check on the Job:

```
kubectl describe jobs/job-wq-2
```

```
Name:          job-wq-2
Namespace:     default
Selector:      controller-uid=b1c7e4e3-92e1-11e7-b85e-fa163ee3c11f
Labels:        controller-uid=b1c7e4e3-92e1-11e7-b85e-fa163ee3c11f
                job-name=job-wq-2
Annotations:   <none>
Parallelism:   2
Completions:   <unset>
Start Time:    Mon, 11 Jan 2022 17:07:59 +0000
Pods Statuses: 1 Running / 0 Succeeded / 0 Failed
Pod Template:
  Labels:  controller-uid=b1c7e4e3-92e1-11e7-b85e-fa163ee3c11f
           job-name=job-wq-2
  Containers:
  c:
    Image:          container-registry.example/exampleproject/job-wq-2
    Port:
    Environment:    <none>
    Mounts:          <none>
    Volumes:         <none>
Events:
  FirstSeen    LastSeen    Count   From          SubobjectPath  Type      Reason          Message
  -----
  33s          33s         1       {job-controller }      Normal        SuccessfulCreate Created pod:
job-wq-2-lglf8
```

You can wait for the Job to succeed, with a timeout:

```
# The check for condition name is case insensitive
kubectl wait --for=condition=complete --timeout=300s job/job-wq-2
```

```
kubectl logs pods/job-wq-2-7r7b2
```

```
Worker with sessionID: bbd72d0a-9e5c-4dd6-abf6-416cc267991f
Initial queue state: empty=False
Working on banana
Working on date
Working on lemon
```

As you can see, one of the pods for this Job worked on several work units.

Alternatives

If running a queue service or modifying your containers to use a work queue is inconvenient, you may want to consider one of the other [job patterns](#).

If you have a continuous stream of background processing work to run, then consider running your background workers with a ReplicaSet instead, and consider running a background processing library such as <https://github.com/resque/resque>.

Indexed Job for Parallel Processing with Static Work Assignment

FEATURE STATE: Kubernetes v1.24 [stable]

In this example, you will run a Kubernetes Job that uses multiple parallel worker processes. Each worker is a different container running in its own Pod. The Pods have an *index number* that the control plane sets automatically, which allows each Pod to identify which part of the overall task to work on.

The pod index is available in the [annotation](#) `batch.kubernetes.io/job-completion-index` as a string representing its decimal value. In order for the containerized task process to obtain this index, you can publish the value of the annotation using the [downward API](#) mechanism. For convenience, the control plane automatically sets the downward API to expose the index in the `JOB_COMPLETION_INDEX` environment variable.

Here is an overview of the steps in this example:

1. **Define a Job manifest using indexed completion.** The downward API allows you to pass the pod index annotation as an environment variable or file to the container.
2. **Start an Indexed Job based on that manifest.**

Before you begin

You should already be familiar with the basic, non-parallel, use of [Job](#).

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version v1.21. To check the version, enter `kubectl version`.

Choose an approach

To access the work item from the worker program, you have a few options:

1. Read the `JOB_COMPLETION_INDEX` environment variable. The Job [controller](#) automatically links this variable to the annotation containing the completion index.
2. Read a file that contains the completion index.

3. Assuming that you can't modify the program, you can wrap it with a script that reads the index using any of the methods above and converts it into something that the program can use as input.

For this example, imagine that you chose option 3 and you want to run the [rev](#) utility. This program accepts a file as an argument and prints its content reversed.

```
rev data.txt
```

You'll use the rev tool from the [busybox](#) container image.

As this is only an example, each Pod only does a tiny piece of work (reversing a short string). In a real workload you might, for example, create a Job that represents the task of producing 60 seconds of video based on scene data. Each work item in the video rendering Job would be to render a particular frame of that video clip. Indexed completion would mean that each Pod in the Job knows which frame to render and publish, by counting frames from the start of the clip.

Define an Indexed Job

Here is a sample Job manifest that uses Indexed completion mode:

[application/job/indexed-job.yaml](#)

```
apiVersion: batch/v1
kind: Job
metadata:
  name: 'indexed-job'
spec:
  completions: 5
  parallelism: 3
  completionMode: Indexed
  template:
    spec:
      restartPolicy: Never
      initContainers:
        - name: 'input'
          image: 'docker.io/library/bash'
          command:
            - "bash"
            - "-c"
            - |
              items=(foo bar baz qux xyz)
              echo ${items[$JOB_COMPLETION_INDEX]} > /input/data.txt
      volumeMounts:
        - mountPath: /input
          name: input
      containers:
        - name: 'worker'
          image: 'docker.io/library/busybox'
          command:
            - "rev"
            - "/input/data.txt"
          volumeMounts:
```

```
- mountPath: /input
  name: input
volumes:
- name: input
  emptyDir: {}
```

In the example above, you use the builtin `JOB_COMPLETION_INDEX` environment variable set by the Job controller for all containers. An [init container](#) maps the index to a static value and writes it to a file that is shared with the container running the worker through an [emptyDir volume](#). Optionally, you can [define your own environment variable through the downward API](#) to publish the index to containers. You can also choose to load a list of values from a [ConfigMap as an environment variable or file](#).

Alternatively, you can directly [use the downward API to pass the annotation value as a volume file](#), like shown in the following example:

[application/job/indexed-job-vol.yaml](#)

```
apiVersion: batch/v1
kind: Job
metadata:
  name: 'indexed-job'
spec:
  completions: 5
  parallelism: 3
  completionMode: Indexed
  template:
    spec:
      restartPolicy: Never
      containers:
      - name: 'worker'
        image: 'docker.io/library/busybox'
        command:
        - "rev"
        - "/input/data.txt"
        volumeMounts:
        - mountPath: /input
          name: input
      volumes:
      - name: input
        downwardAPI:
          items:
          - path: "data.txt"
            fieldRef:
              fieldPath: metadata.annotations['batch.kubernetes.io/job-completion-index']
```

Running the Job

Now run the Job:

```
# This uses the first approach (relying on $JOB_COMPLETION_INDEX)
kubectl apply -f https://kubernetes.io/examples/application/job/indexed-job.yaml
```

When you create this Job, the control plane creates a series of Pods, one for each index you specified. The value of `.spec.parallelism` determines how many can run at once whereas `.spec.completions` determines how many Pods the Job creates in total.

Because `.spec.parallelism` is less than `.spec.completions`, the control plane waits for some of the first Pods to complete before starting more of them.

You can wait for the Job to succeed, with a timeout:

```
# The check for condition name is case insensitive
kubectl wait --for=condition=complete --timeout=300s job/indexed-job
```

Now, describe the Job and check that it was successful.

```
kubectl describe jobs/indexed-job
```

The output is similar to:

```
Name:          indexed-job
Namespace:     default
Selector:      controller-uid=bf865e04-0b67-483b-9a90-74cfc4c3e756
Labels:        controller-uid=bf865e04-0b67-483b-9a90-74cfc4c3e756
                job-name=indexed-job
Annotations:    <none>
Parallelism:    3
Completions:    5
Start Time:     Thu, 11 Mar 2021 15:47:34 +0000
Pods Statuses:  2 Running / 3 Succeeded / 0 Failed
Completed Indexes: 0-2
Pod Template:
  Labels:  controller-uid=bf865e04-0b67-483b-9a90-74cfc4c3e756
          job-name=indexed-job
  Init Containers:
  input:
    Image:   docker.io/library/bash
    Port:    <none>
    Host Port: <none>
    Command:
    bash
    -c
    items=(foo bar baz qux xyz)
    echo ${items[$JOB_COMPLETION_INDEX]} > /input/data.txt

  Environment: <none>
  Mounts:
    /input from input (rw)
  Containers:
  worker:
    Image:   docker.io/library/busybox
    Port:    <none>
    Host Port: <none>
    Command:
    rev
    /input/data.txt
```

```

Environment: <none>
Mounts:
  /input from input (rw)
Volumes:
input:
  Type:      EmptyDir (a temporary directory that shares a pod's lifetime)
  Medium:
  SizeLimit: <unset>
Events:
Type      Reason      Age   From          Message
----      -
Normal    SuccessfulCreate 4s    job-controller Created pod: indexed-job-njkjj
Normal    SuccessfulCreate 4s    job-controller Created pod: indexed-job-9kd4h
Normal    SuccessfulCreate 4s    job-controller Created pod: indexed-job-qjwsz
Normal    SuccessfulCreate 1s    job-controller Created pod: indexed-job-fdhq5
Normal    SuccessfulCreate 1s    job-controller Created pod: indexed-job-ncslj

```

In this example, you run the Job with custom values for each index. You can inspect the output of one of the pods:

```
kubectl logs indexed-job-fdhq5 # Change this to match the name of a Pod from that Job
```

The output is similar to:

```
xuq
```

Job with Pod-to-Pod Communication

In this example, you will run a Job in [Indexed completion mode](#) configured such that the pods created by the Job can communicate with each other using pod hostnames rather than pod IP addresses.

Pods within a Job might need to communicate among themselves. The user workload running in each pod could query the Kubernetes API server to learn the IPs of the other Pods, but it's much simpler to rely on Kubernetes' built-in DNS resolution.

Jobs in Indexed completion mode automatically set the pods' hostname to be in the format of `{jobName}-{completionIndex}`. You can use this format to deterministically build pod hostnames and enable pod communication *without* needing to create a client connection to the Kubernetes control plane to obtain pod hostnames/IPs via API requests.

This configuration is useful for use cases where pod networking is required but you don't want to depend on a network connection with the Kubernetes API server.

Before you begin

You should already be familiar with the basic use of [Job](#).

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at

least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version v1.21. To check the version, enter `kubectl version`.

Note:

If you are using MiniKube or a similar tool, you may need to take [extra steps](#) to ensure you have DNS.

Starting a Job with Pod-to-Pod Communication

To enable pod-to-pod communication using pod hostnames in a Job, you must do the following:

1. Set up a [headless Service](#) with a valid label selector for the pods created by your Job. The headless service must be in the same namespace as the Job. One easy way to do this is to use the job-name: `<your-job-name>` selector, since the job-name label will be automatically added by Kubernetes. This configuration will trigger the DNS system to create records of the hostnames of the pods running your Job.
2. Configure the headless service as subdomain service for the Job pods by including the following value in your Job template spec:

```
subdomain: <headless-svc-name>
```

Example

Below is a working example of a Job with pod-to-pod communication via pod hostnames enabled. The Job is completed only after all pods successfully ping each other using hostnames.

Note:

In the Bash script executed on each pod in the example below, the pod hostnames can be prefixed by the namespace as well if the pod needs to be reached from outside the namespace.

```
apiVersion: v1
kind: Service
metadata:
  name: headless-svc
spec:
  clusterIP: None # clusterIP must be None to create a headless service
  selector:
    job-name: example-job # must match Job name
---
apiVersion: batch/v1
kind: Job
metadata:
```

```

name: example-job
spec:
  completions: 3
  parallelism: 3
  completionMode: Indexed
  template:
    spec:
      subdomain: headless-svc # has to match Service name
      restartPolicy: Never
      containers:
      - name: example-workload
        image: bash:latest
        command:
        - bash
        - -c
        - |
          for i in 0 1 2
          do
            gotStatus="-1"
            wantStatus="0"
            while [ $gotStatus -ne $wantStatus ]
            do
              ping -c 1 example-job-{i}.headless-svc > /dev/null 2>&1
              gotStatus=$?
              if [ $gotStatus -ne $wantStatus ]; then
                echo "Failed to ping pod example-job-{i}.headless-svc, retrying in 1 second..."
                sleep 1
              fi
            done
            echo "Successfully pinged pod: example-job-{i}.headless-svc"
          done

```

After applying the example above, reach each other over the network using: `<pod-hostname>.<headless-service-name>`. You should see output similar to the following:

```
kubectl logs example-job-0-qws42
```

```

Failed to ping pod example-job-0.headless-svc, retrying in 1 second...
Successfully pinged pod: example-job-0.headless-svc
Successfully pinged pod: example-job-1.headless-svc
Successfully pinged pod: example-job-2.headless-svc

```

Note:

Keep in mind that the `<pod-hostname>.<headless-service-name>` name format used in this example would not work with DNS policy set to None or Default. You can learn more about pod DNS policies [here](#).

Parallel Processing using Expansions

This task demonstrates running multiple [Jobs](#) based on a common template. You can use this approach to process batches of work in parallel.

For this example there are only three items: *apple*, *banana*, and *cherry*. The sample Jobs process each item by printing a string then pausing.

See [using Jobs in real workloads](#) to learn about how this pattern fits more realistic use cases.

Before you begin

You should be familiar with the basic, non-parallel, use of [Job](#).

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercoda](#)
- [Play with Kubernetes](#)

For basic templating you need the command-line utility sed.

To follow the advanced templating example, you need a working installation of [Python](#), and the Jinja2 template library for Python.

Once you have Python set up, you can install Jinja2 by running:

```
pip install --user jinja2
```

Create Jobs based on a template

First, download the following template of a Job to a file called job-tmpl.yaml. Here's what you'll download:

[application/job/job-tmpl.yaml](#)

```
apiVersion: batch/v1
kind: Job
metadata:
  name: process-item-$ITEM
  labels:
    jobgroup: jobexample
spec:
  template:
    metadata:
      name: jobexample
      labels:
        jobgroup: jobexample
    spec:
```

```
containers:
- name: c
  image: busybox:1.28
  command: ["sh", "-c", "echo Processing item $ITEM && sleep 5"]
restartPolicy: Never
```

```
# Use curl to download job-tmpl.yaml
curl -L -s -O https://k8s.io/examples/application/job/job-tmpl.yaml
```

The file you downloaded is not yet a valid Kubernetes [manifest](#). Instead that template is a YAML representation of a Job object with some placeholders that need to be filled in before it can be used. The \$ITEM syntax is not meaningful to Kubernetes.

Create manifests from the template

The following shell snippet uses sed to replace the string \$ITEM with the loop variable, writing into a temporary directory named jobs. Run this now:

```
# Expand the template into multiple files, one for each item to be processed.
mkdir ./jobs
for i in apple banana cherry
do
  cat job-tmpl.yaml | sed "s/\$ITEM/\$i/" > ./jobs/job-$.yaml
done
```

Check if it worked:

```
ls jobs/
```

The output is similar to this:

```
job-apple.yaml
job-banana.yaml
job-cherry.yaml
```

You could use any type of template language (for example: Jinja2; ERB), or write a program to generate the Job manifests.

Create Jobs from the manifests

Next, create all the Jobs with one kubectl command:

```
kubectl create -f ./jobs
```

The output is similar to this:

```
job.batch/process-item-apple created
job.batch/process-item-banana created
job.batch/process-item-cherry created
```

Now, check on the jobs:

```
kubectl get jobs -l jobgroup=jobexample
```

The output is similar to this:

| NAME | COMPLETIONS | DURATION | AGE |
|---------------------|-------------|----------|-----|
| process-item-apple | 1/1 | 14s | 22s |
| process-item-banana | 1/1 | 12s | 21s |
| process-item-cherry | 1/1 | 12s | 20s |

Using the `-l` option to `kubectl` selects only the Jobs that are part of this group of jobs (there might be other unrelated jobs in the system).

You can check on the Pods as well using the same [label selector](#):

```
kubectl get pods -l jobgroup=jobexample
```

The output is similar to:

| NAME | READY | STATUS | RESTARTS | AGE |
|---------------------------|-------|-----------|----------|-----|
| process-item-apple-kixwv | 0/1 | Completed | 0 | 4m |
| process-item-banana-wrsf7 | 0/1 | Completed | 0 | 4m |
| process-item-cherry-dnfu9 | 0/1 | Completed | 0 | 4m |

We can use this single command to check on the output of all jobs at once:

```
kubectl logs -f -l jobgroup=jobexample
```

The output should be:

```
Processing item apple
Processing item banana
Processing item cherry
```

Clean up

```
# Remove the Jobs you created
# Your cluster automatically cleans up their Pods
kubectl delete job -l jobgroup=jobexample
```

Use advanced template parameters

In the [first example](#), each instance of the template had one parameter, and that parameter was also used in the Job's name. However, [names](#) are restricted to contain only certain characters.

This slightly more complex example uses the [Jinja template language](#) to generate manifests and then objects from those manifests, with a multiple parameters for each Job.

For this part of the task, you are going to use a one-line Python script to convert the template to a set of manifests.

First, copy and paste the following template of a Job object, into a file called `job.yaml.jinja2`:

```
{% set params = [{ "name": "apple", "url": "http://dbpedia.org/resource/Apple", },
                  { "name": "banana", "url": "http://dbpedia.org/resource/Banana", },
                  { "name": "cherry", "url": "http://dbpedia.org/resource/Cherry" }]
%}
```

```
{% for p in params %}
{% set name = p["name"] %}
{% set url = p["url"] %}
---
apiVersion: batch/v1
kind: Job
metadata:
  name: jobexample-{{ name }}
  labels:
    jobgroup: jobexample
spec:
  template:
    metadata:
      name: jobexample
      labels:
        jobgroup: jobexample
    spec:
      containers:
      - name: c
        image: busybox:1.28
        command: ["sh", "-c", "echo Processing URL {{ url }} && sleep 5"]
        restartPolicy: Never
{% endfor %}
```

The above template defines two parameters for each Job object using a list of python dicts (lines 1-4). A for loop emits one Job manifest for each set of parameters (remaining lines).

This example relies on a feature of YAML. One YAML file can contain multiple documents (Kubernetes manifests, in this case), separated by `---` on a line by itself. You can pipe the output directly to `kubectl` to create the Jobs.

Next, use this one-line Python program to expand the template:

```
alias render_template='python -c "from jinja2 import Template; import sys;
print(Template(sys.stdin.read()).render());"'
```

Use `render_template` to convert the parameters and template into a single YAML file containing Kubernetes manifests:

```
# This requires the alias you defined earlier
cat job.yaml.jinja2 | render_template > jobs.yaml
```

You can view `jobs.yaml` to verify that the `render_template` script worked correctly.

Once you are happy that `render_template` is working how you intend, you can pipe its output into `kubectl`:

```
cat job.yaml.jinja2 | render_template | kubectl apply -f -
```

Kubernetes accepts and runs the Jobs you created.

Clean up

```
# Remove the Jobs you created
# Your cluster automatically cleans up their Pods
kubectl delete job -l jobgroup=jobexample
```

Using Jobs in real workloads

In a real use case, each Job performs some substantial computation, such as rendering a frame of a movie, or processing a range of rows in a database. If you were rendering a movie you would set \$ITEM to the frame number. If you were processing rows from a database table, you would set \$ITEM to represent the range of database rows to process.

In the task, you ran a command to collect the output from Pods by fetching their logs. In a real use case, each Pod for a Job writes its output to durable storage before completing. You can use a PersistentVolume for each Job, or an external storage service. For example, if you are rendering frames for a movie, use HTTP to PUT the rendered frame data to a URL, using a different URL for each frame.

Labels on Jobs and Pods

After you create a Job, Kubernetes automatically adds additional [labels](#) that distinguish one Job's pods from another Job's pods.

In this example, each Job and its Pod template have a label: jobgroup=jobexample.

Kubernetes itself pays no attention to labels named jobgroup. Setting a label for all the Jobs you create from a template makes it convenient to operate on all those Jobs at once. In the [first example](#) you used a template to create several Jobs. The template ensures that each Pod also gets the same label, so you can check on all Pods for these templated Jobs with a single command.

Note:

The label key jobgroup is not special or reserved. You can pick your own labelling scheme. There are [recommended labels](#) that you can use if you wish.

Alternatives

If you plan to create a large number of Job objects, you may find that:

- Even using labels, managing so many Jobs is cumbersome.
- If you create many Jobs in a batch, you might place high load on the Kubernetes control plane. Alternatively, the Kubernetes API server could rate limit you, temporarily rejecting your requests with a 429 status.
- You are limited by a [resource quota](#) on Jobs: the API server permanently rejects some of your requests when you create a great deal of work in one batch.

There are other [job patterns](#) that you can use to process large amounts of work without creating very many Job objects.

You could also consider writing your own [controller](#) to manage Job objects automatically.

Handling retrieable and non-retrieable pod failures with Pod failure policy

FEATURE STATE: Kubernetes v1.26 [beta]

This document shows you how to use the [Pod failure policy](#), in combination with the default [Pod backoff failure policy](#), to improve the control over the handling of container- or Pod-level failure within a [Job](#).

The definition of Pod failure policy may help you to:

- better utilize the computational resources by avoiding unnecessary Pod retries.
- avoid Job failures due to Pod disruptions (such [preemption](#), [API-initiated eviction](#) or [taint](#)-based eviction).

Before you begin

You should already be familiar with the basic use of [Job](#).

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version v1.25. To check the version, enter kubectl version.

Ensure that the [feature gates](#) PodDisruptionConditions and JobPodFailurePolicy are both enabled in your cluster.

Using Pod failure policy to avoid unnecessary Pod retries

With the following example, you can learn how to use Pod failure policy to avoid unnecessary Pod restarts when a Pod failure indicates a non-retrieable software bug.

First, create a Job based on the config:

[/controllers/job-pod-failure-policy-failjob.yaml](#)

```
apiVersion: batch/v1
kind: Job
metadata:
  name: job-pod-failure-policy-failjob
spec:
  completions: 8
```

```
parallelism: 2
template:
  spec:
    restartPolicy: Never
    containers:
      - name: main
        image: docker.io/library/bash:5
        command: ["bash"]
        args:
          - -c
          - echo "Hello world! I'm going to exit with 42 to simulate a software bug." && sleep 30 &&
            exit 42
    backoffLimit: 6
    podFailurePolicy:
      rules:
        - action: FailJob
      onExitCodes:
        containerName: main
        operator: In
        values: [42]
```

by running:

```
kubectl create -f job-pod-failure-policy-failjob.yaml
```

After around 30s the entire Job should be terminated. Inspect the status of the Job by running:

```
kubectl get jobs -l job-name=job-pod-failure-policy-failjob -o yaml
```

In the Job status, see a job Failed condition with the field reason equal PodFailurePolicy. Additionally, the message field contains a more detailed information about the Job termination, such as: Container main for pod default/job-pod-failure-policy-failjob-8ckj8 failed with exit code 42 matching FailJob rule at index 0.

For comparison, if the Pod failure policy was disabled it would take 6 retries of the Pod, taking at least 2 minutes.

Clean up

Delete the Job you created:

```
kubectl delete jobs/job-pod-failure-policy-failjob
```

The cluster automatically cleans up the Pods.

Using Pod failure policy to ignore Pod disruptions

With the following example, you can learn how to use Pod failure policy to ignore Pod disruptions from incrementing the Pod retry counter towards the `.spec.backoffLimit` limit.

Caution:

Timing is important for this example, so you may want to read the steps before execution. In order to trigger a Pod disruption it is important to drain the node while the Pod is running on it (within 90s since the Pod is scheduled).

1. Create a Job based on the config:

[/controllers/job-pod-failure-policy-ignore.yaml](#)

```
apiVersion: batch/v1
kind: Job
metadata:
  name: job-pod-failure-policy-ignore
spec:
  completions: 4
  parallelism: 2
  template:
    spec:
      restartPolicy: Never
      containers:
      - name: main
        image: docker.io/library/bash:5
        command: ["bash"]
        args:
        - -c
        - echo "Hello world! I'm going to exit with 0 (success)." && sleep 90 && exit 0
      backoffLimit: 0
      podFailurePolicy:
        rules:
        - action: Ignore
          onPodConditions:
          - type: DisruptionTarget
```

by running:

```
kubectl create -f job-pod-failure-policy-ignore.yaml
```

2. Run this command to check the nodeName the Pod is scheduled to:

```
nodeName=$(kubectl get pods -l job-name=job-pod-failure-policy-ignore -o jsonpath='{.items[0].spec.nodeName}')
```

3. Drain the node to evict the Pod before it completes (within 90s):

```
kubectl drain nodes/$nodeName --ignore-daemonsets --grace-period=0
```

4. Inspect the .status.failed to check the counter for the Job is not incremented:

```
kubectl get jobs -l job-name=job-pod-failure-policy-ignore -o yaml
```

5. Uncordon the node:

```
kubectl uncordon nodes/$nodeName
```

The Job resumes and succeeds.

For comparison, if the Pod failure policy was disabled the Pod disruption would result in terminating the entire Job (as the `.spec.backoffLimit` is set to 0).

Cleaning up

Delete the Job you created:

```
kubectl delete jobs/job-pod-failure-policy-ignore
```

The cluster automatically cleans up the Pods.

Using Pod failure policy to avoid unnecessary Pod retries based on custom Pod Conditions

With the following example, you can learn how to use Pod failure policy to avoid unnecessary Pod restarts based on custom Pod Conditions.

Note:

The example below works since version 1.27 as it relies on transitioning of deleted pods, in the Pending phase, to a terminal phase (see: [Pod Phase](#)).

1. First, create a Job based on the config:

</controllers/job-pod-failure-policy-config-issue.yaml>

```
apiVersion: batch/v1
kind: Job
metadata:
  name: job-pod-failure-policy-config-issue
spec:
  completions: 8
  parallelism: 2
  template:
    spec:
      restartPolicy: Never
      containers:
        - name: main
          image: "non-existing-repo/non-existing-image:example"
      backoffLimit: 6
      podFailurePolicy:
        rules:
          - action: FailJob
            onPodConditions:
              - type: ConfigIssue
```

by running:

```
kubectl create -f job-pod-failure-policy-config-issue.yaml
```

Note that, the image is misconfigured, as it does not exist.

2. Inspect the status of the job's Pods by running:

```
kubectl get pods -l job-name=job-pod-failure-policy-config-issue -o yaml
```

You will see output similar to this:

```
containerStatuses:
- image: non-existing-repo/non-existing-image:example
  ...
  state:
    waiting:
      message: Back-off pulling image "non-existing-repo/non-existing-image:example"
      reason: ImagePullBackOff
    ...
phase: Pending
```

Note that the pod remains in the Pending phase as it fails to pull the misconfigured image. This, in principle, could be a transient issue and the image could get pulled. However, in this case, the image does not exist so we indicate this fact by a custom condition.

3. Add the custom condition. First prepare the patch by running:

```
cat <<EOF > patch.yaml
status:
  conditions:
  - type: ConfigIssue
    status: "True"
    reason: "NonExistingImage"
    lastTransitionTime: "$(date -u +"%Y-%m-%dT%H:%M:%SZ")"
EOF
```

Second, select one of the pods created by the job by running:

```
podName=$(kubectl get pods -l job-name=job-pod-failure-policy-config-issue -o
jsonpath='{.items[0].metadata.name}')
```

Then, apply the patch on one of the pods by running the following command:

```
kubectl patch pod $podName --subresource=status --patch-file=patch.yaml
```

If applied successfully, you will get a notification like this:

```
pod/job-pod-failure-policy-config-issue-k6pvp patched
```

4. Delete the pod to transition it to Failed phase, by running the command:

```
kubectl delete pods/$podName
```

5. Inspect the status of the Job by running:

```
kubectl get jobs -l job-name=job-pod-failure-policy-config-issue -o yaml
```

In the Job status, see a job Failed condition with the field reason equal PodFailurePolicy. Additionally, the message field contains a more detailed information about the Job termination, such as:
Pod default/job-pod-failure-policy-config-issue-k6pvp has condition ConfigIssue matching FailJob rule at index 0.

Note:

In a production environment, the steps 3 and 4 should be automated by a user-provided controller.

Cleaning up

Delete the Job you created:

```
kubectrl delete jobs/job-pod-failure-policy-config-issue
```

The cluster automatically cleans up the Pods.

Alternatives

You could rely solely on the [Pod backoff failure policy](#), by specifying the Job's .spec.backoffLimit field. However, in many situations it is problematic to find a balance between setting a low value for .spec.backoffLimit to avoid unnecessary Pod retries, yet high enough to make sure the Job would not be terminated by Pod disruptions.

Access Applications in a Cluster

Configure load balancing, port forwarding, or setup firewall or DNS configurations to access applications in a cluster.

[Deploy and Access the Kubernetes Dashboard](#)

Deploy the web UI (Kubernetes Dashboard) and access it.

[Accessing Clusters](#)

[Configure Access to Multiple Clusters](#)

[Use Port Forwarding to Access Applications in a Cluster](#)

[Use a Service to Access an Application in a Cluster](#)

[Connect a Frontend to a Backend Using Services](#)

[Create an External Load Balancer](#)

[List All Container Images Running in a Cluster](#)

[Set up Ingress on Minikube with the NGINX Ingress Controller](#)

[Communicate Between Containers in the Same Pod Using a Shared Volume](#)

[Configure DNS for a Cluster](#)

[Access Services Running on Clusters](#)

Deploy and Access the Kubernetes Dashboard

Deploy the web UI (Kubernetes Dashboard) and access it.

Dashboard is a web-based Kubernetes user interface. You can use Dashboard to deploy containerized applications to a Kubernetes cluster, troubleshoot your containerized application, and manage the cluster resources. You can use Dashboard to get an overview of applications running on your cluster, as well as for creating or modifying individual Kubernetes resources (such as Deployments, Jobs, DaemonSets, etc). For example, you can scale a Deployment, initiate a rolling update, restart a pod or deploy new applications using a deploy wizard.

Dashboard also provides information on the state of Kubernetes resources in your cluster and on any errors that may have occurred.

Kubernetes Dashboard UI

Deploying the Dashboard UI

Note:

Kubernetes Dashboard supports only Helm-based installation currently as it is faster and gives us better control over all dependencies required by Dashboard to run.

The Dashboard UI is not deployed by default. To deploy it, run the following command:

```
# Add kubernetes-dashboard repository
helm repo add kubernetes-dashboard https://kubernetes.github.io/dashboard/
# Deploy a Helm Release named "kubernetes-dashboard" using the kubernetes-dashboard chart
helm upgrade --install kubernetes-dashboard kubernetes-dashboard/kubernetes-dashboard --
create-namespace --namespace kubernetes-dashboard
```

Accessing the Dashboard UI

To protect your cluster data, Dashboard deploys with a minimal RBAC configuration by default. Currently, Dashboard only supports logging in with a Bearer Token. To create a token for this demo, you can follow our guide on [creating a sample user](#).

Warning:

The sample user created in the tutorial will have administrative privileges and is for educational purposes only.

Command line proxy

You can enable access to the Dashboard using the `kubectl` command-line tool, by running the following command:

```
kubectl proxy
```

Kubectl will make Dashboard available at <http://localhost:8001/api/v1/namespaces/kubernetes-dashboard/services/https:kubernetes-dashboard:/proxy/>.

The UI can *only* be accessed from the machine where the command is executed. See `kubectl proxy --help` for more options.

Note:

The kubeconfig authentication method does **not** support external identity providers or X.509 certificate-based authentication.

Welcome view

When you access Dashboard on an empty cluster, you'll see the welcome page. This page contains a link to this document as well as a button to deploy your first application. In addition, you can view which system applications are running by default in the kube-system [namespace](#) of your cluster, for example the Dashboard itself.

Kubernetes Dashboard welcome page

Deploying containerized applications

Dashboard lets you create and deploy a containerized application as a Deployment and optional Service with a simple wizard. You can either manually specify application details, or upload a YAML or JSON *manifest* file containing application configuration.

Click the **CREATE** button in the upper right corner of any page to begin.

Specifying application details

The deploy wizard expects that you provide the following information:

- **App name** (mandatory): Name for your application. A [label](#) with the name will be added to the Deployment and Service, if any, that will be deployed.

The application name must be unique within the selected Kubernetes [namespace](#). It must start with a lowercase character, and end with a lowercase character or a number, and contain only lowercase letters, numbers and dashes (-). It is limited to 24 characters. Leading and trailing spaces are ignored.

- **Container image** (mandatory): The URL of a public Docker [container image](#) on any registry, or a private image (commonly hosted on the Google Container Registry or Docker Hub). The container image specification must end with a colon.
- **Number of pods** (mandatory): The target number of Pods you want your application to be deployed in. The value must be a positive integer.

A [Deployment](#) will be created to maintain the desired number of Pods across your cluster.

- **Service** (optional): For some parts of your application (e.g. frontends) you may want to expose a [Service](#) onto an external, maybe public IP address outside of your cluster (external Service).

Note:

For external Services, you may need to open up one or more ports to do so.

Other Services that are only visible from inside the cluster are called internal Services.

Irrespective of the Service type, if you choose to create a Service and your container listens on a port (incoming), you need to specify two ports. The Service will be created mapping the port (incoming) to the target port seen by the container. This Service will route to your deployed Pods. Supported protocols are TCP and UDP. The internal DNS name for this Service will be the value you specified as application name above.

If needed, you can expand the **Advanced options** section where you can specify more settings:

- **Description:** The text you enter here will be added as an [annotation](#) to the Deployment and displayed in the application's details.
- **Labels:** Default [labels](#) to be used for your application are application name and version. You can specify additional labels to be applied to the Deployment, Service (if any), and Pods, such as release, environment, tier, partition, and release track.

Example:

```
release=1.0
tier=frontend
environment=pod
track=stable
```

- **Namespace:** Kubernetes supports multiple virtual clusters backed by the same physical cluster. These virtual clusters are called [namespaces](#). They let you partition resources into logically named groups.

Dashboard offers all available namespaces in a dropdown list, and allows you to create a new namespace. The namespace name may contain a maximum of 63 alphanumeric characters and dashes (-) but can not contain capital letters. Namespace names should not consist of only numbers. If the name is set as a number, such as 10, the pod will be put in the default namespace.

In case the creation of the namespace is successful, it is selected by default. If the creation fails, the first namespace is selected.

- **Image Pull Secret:** In case the specified Docker container image is private, it may require [pull secret](#) credentials.

Dashboard offers all available secrets in a dropdown list, and allows you to create a new secret. The secret name must follow the DNS domain name syntax, for example `new.image-pull.secret`. The content of a secret must be base64-encoded and specified in a [.dockercfg](#) file. The secret name may consist of a maximum of 253 characters.

In case the creation of the image pull secret is successful, it is selected by default. If the creation fails, no secret is applied.

- **CPU requirement (cores) and Memory requirement (MiB):** You can specify the minimum [resource limits](#) for the container. By default, Pods run with unbounded CPU and memory limits.
- **Run command and Run command arguments:** By default, your containers run the specified Docker image's default [entrypoint command](#). You can use the command options and arguments to override the default.
- **Run as privileged:** This setting determines whether processes in [privileged containers](#) are equivalent to processes running as root on the host. Privileged containers can make use of capabilities like manipulating the network stack and accessing devices.
- **Environment variables:** Kubernetes exposes Services through [environment variables](#). You can compose environment variable or pass arguments to your commands using the values of environment variables. They can be used in applications to find a Service. Values can reference other variables using the `$(VAR_NAME)` syntax.

Uploading a YAML or JSON file

Kubernetes supports declarative configuration. In this style, all configuration is stored in manifests (YAML or JSON configuration files). The manifests use Kubernetes [API](#) resource schemas.

As an alternative to specifying application details in the deploy wizard, you can define your application in one or more manifests, and upload the files using Dashboard.

Using Dashboard

Following sections describe views of the Kubernetes Dashboard UI; what they provide and how can they be used.

Navigation

When there are Kubernetes objects defined in the cluster, Dashboard shows them in the initial view. By default only objects from the *default* namespace are shown and this can be changed using the namespace selector located in the navigation menu.

Dashboard shows most Kubernetes object kinds and groups them in a few menu categories.

Admin overview

For cluster and namespace administrators, Dashboard lists Nodes, Namespaces and PersistentVolumes and has detail views for them. Node list view contains CPU and memory usage metrics aggregated across all Nodes. The details view shows the metrics for a Node, its specification, status, allocated resources, events and pods running on the node.

Workloads

Shows all applications running in the selected namespace. The view lists applications by workload kind (for example: Deployments, ReplicaSets, StatefulSets). Each workload kind can be viewed separately. The lists summarize actionable information about the workloads, such as the number of ready pods for a ReplicaSet or current memory usage for a Pod.

Detail views for workloads show status and specification information and surface relationships between objects. For example, Pods that ReplicaSet is controlling or new ReplicaSets and HorizontalPodAutoscalers for Deployments.

Services

Shows Kubernetes resources that allow for exposing services to external world and discovering them within a cluster. For that reason, Service and Ingress views show Pods targeted by them, internal endpoints for cluster connections and external endpoints for external users.

Storage

Storage view shows PersistentVolumeClaim resources which are used by applications for storing data.

ConfigMaps and Secrets

Shows all Kubernetes resources that are used for live configuration of applications running in clusters. The view allows for editing and managing config objects and displays secrets hidden by default.

Logs viewer

Pod lists and detail pages link to a logs viewer that is built into Dashboard. The viewer allows for drilling down logs from containers belonging to a single Pod.

Logs viewer

What's next

For more information, see the [Kubernetes Dashboard project page](#).

Accessing Clusters

This topic discusses multiple ways to interact with clusters.

Accessing for the first time with kubectl

When accessing the Kubernetes API for the first time, we suggest using the Kubernetes CLI, kubectl.

To access a cluster, you need to know the location of the cluster and have credentials to access it. Typically, this is automatically set-up when you work through a [Getting started guide](#), or someone else set up the cluster and provided you with credentials and a location.

Check the location and credentials that kubectl knows about with this command:

```
kubectl config view
```

Many of the [examples](#) provide an introduction to using kubectl, and complete documentation is found in the [kubectl reference](#).

Directly accessing the REST API

Kubectl handles locating and authenticating to the apiserver. If you want to directly access the REST API with an http client like curl or wget, or a browser, there are several ways to locate and authenticate:

- Run kubectl in proxy mode.
 - Recommended approach.
 - Uses stored apiserver location.
 - Verifies identity of apiserver using self-signed cert. No MITM possible.
 - Authenticates to apiserver.
 - In future, may do intelligent client-side load-balancing and failover.
- Provide the location and credentials directly to the http client.
 - Alternate approach.
 - Works with some types of client code that are confused by using a proxy.
 - Need to import a root cert into your browser to protect against MITM.

Using kubectl proxy

The following command runs kubectl in a mode where it acts as a reverse proxy. It handles locating the apiserver and authenticating. Run it like this:

```
kubectl proxy --port=8080
```

See [kubectl proxy](#) for more details.

Then you can explore the API with curl, wget, or a browser, replacing localhost with [::1] for IPv6, like so:

```
curl http://localhost:8080/api/
```

The output is similar to this:

```
{
  "kind": "APIVersions",
  "versions": [
    "v1"
```

```

],
"serverAddressByClientCIDRs": [
  {
    "clientCIDR": "0.0.0.0/0",
    "serverAddress": "10.0.1.149:443"
  }
]
}

```

Without kubectl proxy

Use `kubectl apply` and `kubectl describe secret...` to create a token for the default service account with `grep/cut`:

First, create the Secret, requesting a token for the default ServiceAccount:

```

kubectl apply -f - <<EOF
apiVersion: v1
kind: Secret
metadata:
  name: default-token
  annotations:
    kubernetes.io/service-account.name: default
type: kubernetes.io/service-account-token
EOF

```

Next, wait for the token controller to populate the Secret with a token:

```

while ! kubectl describe secret default-token | grep -E '^token' >/dev/null; do
  echo "waiting for token..." >&2
  sleep 1
done

```

Capture and use the generated token:

```

APISERVER=$(kubectl config view --minify | grep server | cut -f 2- -d ":" | tr -d " ")
TOKEN=$(kubectl describe secret default-token | grep -E '^token' | cut -f2 -d ':' | tr -d " ")

curl $APISERVER/api --header "Authorization: Bearer $TOKEN" --insecure

```

The output is similar to this:

```

{
  "kind": "APIVersions",
  "versions": [
    "v1"
  ],
  "serverAddressByClientCIDRs": [
    {
      "clientCIDR": "0.0.0.0/0",
      "serverAddress": "10.0.1.149:443"
    }
  ]
}

```

Using jsonpath:

```
APISERVER=$(kubectl config view --minify -o jsonpath='{.clusters[0].cluster.server}')
TOKEN=$(kubectl get secret default-token -o jsonpath='{.data.token}' | base64 --decode)

curl $APISERVER/api --header "Authorization: Bearer $TOKEN" --insecure
```

The output is similar to this:

```
{
  "kind": "APIVersions",
  "versions": [
    "v1"
  ],
  "serverAddressByClientCIDRs": [
    {
      "clientCIDR": "0.0.0.0/0",
      "serverAddress": "10.0.1.149:443"
    }
  ]
}
```

The above examples use the `--insecure` flag. This leaves it subject to MITM attacks. When `kubectl` accesses the cluster it uses a stored root certificate and client certificates to access the server. (These are installed in the `~/.kube` directory). Since cluster certificates are typically self-signed, it may take special configuration to get your http client to use root certificate.

On some clusters, the apiserver does not require authentication; it may serve on localhost, or be protected by a firewall. There is not a standard for this. [Controlling Access to the API](#) describes how a cluster admin can configure this.

Programmatic access to the API

Kubernetes officially supports [Go](#) and [Python](#) client libraries.

Go client

- To get the library, run the following command: `go get k8s.io/client-go@kubernetes-<kubernetes-version-number>`, see [INSTALL.md](#) for detailed installation instructions. See <https://github.com/kubernetes/client-go> to see which versions are supported.
- Write an application atop of the client-go clients. Note that client-go defines its own API objects, so if needed, please import API definitions from client-go rather than from the main repository, e.g., `import "k8s.io/client-go/kubernetes"` is correct.

The Go client can use the same [kubeconfig file](#) as the `kubectl` CLI does to locate and authenticate to the apiserver. See this [example](#).

If the application is deployed as a Pod in the cluster, please refer to the [next section](#).

Python client

To use [Python client](#), run the following command: `pip install kubernetes`. See [Python Client Library page](#) for more installation options.

The Python client can use the same [kubeconfig file](#) as the kubectl CLI does to locate and authenticate to the apiserver. See this [example](#).

Other languages

There are [client libraries](#) for accessing the API from other languages. See documentation for other libraries for how they authenticate.

Accessing the API from a Pod

When accessing the API from a pod, locating and authenticating to the API server are somewhat different.

Please check [Accessing the API from within a Pod](#) for more details.

Accessing services running on the cluster

The previous section describes how to connect to the Kubernetes API server. For information about connecting to other services running on a Kubernetes cluster, see [Access Cluster Services](#).

Requesting redirects

The redirect capabilities have been deprecated and removed. Please use a proxy (see below) instead.

So many proxies

There are several different proxies you may encounter when using Kubernetes:

1. The [kubectl proxy](#):

- runs on a user's desktop or in a pod
- proxies from a localhost address to the Kubernetes apiserver
- client to proxy uses HTTP
- proxy to apiserver uses HTTPS
- locates apiserver
- adds authentication headers

2. The [apiserver proxy](#):

- is a bastion built into the apiserver
- connects a user outside of the cluster to cluster IPs which otherwise might not be reachable
- runs in the apiserver processes
- client to proxy uses HTTPS (or http if apiserver so configured)
- proxy to target may use HTTP or HTTPS as chosen by proxy using available information
- can be used to reach a Node, Pod, or Service
- does load balancing when used to reach a Service

The [kube proxy](#):

3.

- runs on each node
- proxies UDP and TCP
- does not understand HTTP
- provides load balancing
- is only used to reach services

4. A Proxy/Load-balancer in front of apiserver(s):

- existence and implementation varies from cluster to cluster (e.g. nginx)
- sits between all clients and one or more apiservers
- acts as load balancer if there are several apiservers.

5. Cloud Load Balancers on external services:

- are provided by some cloud providers (e.g. AWS ELB, Google Cloud Load Balancer)
- are created automatically when the Kubernetes service has type LoadBalancer
- use UDP/TCP only
- implementation varies by cloud provider.

Kubernetes users will typically not need to worry about anything other than the first two types. The cluster admin will typically ensure that the latter types are set up correctly.

Configure Access to Multiple Clusters

This page shows how to configure access to multiple clusters by using configuration files. After your clusters, users, and contexts are defined in one or more configuration files, you can quickly switch between clusters by using the `kubectl config use-context` command.

Note:

A file that is used to configure access to a cluster is sometimes called a *kubeconfig file*. This is a generic way of referring to configuration files. It does not mean that there is a file named `kubeconfig`.

Warning:

Only use kubeconfig files from trusted sources. Using a specially-crafted kubeconfig file could result in malicious code execution or file exposure. If you must use an untrusted kubeconfig file, inspect it carefully first, much as you would a shell script.

Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercoda](#)
- [Play with Kubernetes](#)

To check that [kubect](#)l is installed, run `kubect`l version --client. The kubectl version should be [within one minor version](#) of your cluster's API server.

Define clusters, users, and contexts

Suppose you have two clusters, one for development work and one for test work. In the development cluster, your frontend developers work in a namespace called frontend, and your storage developers work in a namespace called storage. In your test cluster, developers work in the default namespace, or they create auxiliary namespaces as they see fit. Access to the development cluster requires authentication by certificate. Access to the test cluster requires authentication by username and password.

Create a directory named config-exercise. In your config-exercise directory, create a file named config-demo with this content:

```
apiVersion: v1
kind: Config
preferences: {}

clusters:
- cluster:
  name: development
- cluster:
  name: test

users:
- name: developer
- name: experimenter

contexts:
- context:
  name: dev-frontend
- context:
  name: dev-storage
- context:
  name: exp-test
```

A configuration file describes clusters, users, and contexts. Your config-demo file has the framework to describe two clusters, two users, and three contexts.

Go to your config-exercise directory. Enter these commands to add cluster details to your configuration file:

```
kubectl config --kubeconfig=config-demo set-cluster development --server=https://1.2.3.4 --
certificate-authority=fake-ca-file
kubectl config --kubeconfig=config-demo set-cluster test --server=https://5.6.7.8 --insecure-
skip-tls-verify
```

Add user details to your configuration file:

Caution:

Storing passwords in Kubernetes client config is risky. A better alternative would be to use a credential plugin and store them separately. See: [client-go credential plugins](#)

```
kubectcl config --kubeconfig=config-demo set-credentials developer --client-certificate=fake-  
cert-file --client-key=fake-key-seefile  
kubectcl config --kubeconfig=config-demo set-credentials experimenter --username=exp --  
password=some-password
```

Note:

- To delete a user you can run `kubectcl --kubeconfig=config-demo config unset users.<name>`
- To remove a cluster, you can run `kubectcl --kubeconfig=config-demo config unset clusters.<name>`
- To remove a context, you can run `kubectcl --kubeconfig=config-demo config unset contexts.<name>`

Add context details to your configuration file:

```
kubectcl config --kubeconfig=config-demo set-context dev-frontend --cluster=development --  
namespace=frontend --user=developer  
kubectcl config --kubeconfig=config-demo set-context dev-storage --cluster=development --  
namespace=storage --user=developer  
kubectcl config --kubeconfig=config-demo set-context exp-test --cluster=test --namespace=defau  
lt --user=experimenter
```

Open your config-demo file to see the added details. As an alternative to opening the config-demo file, you can use the config view command.

```
kubectcl config --kubeconfig=config-demo view
```

The output shows the two clusters, two users, and three contexts:

```
apiVersion: v1  
clusters:  
- cluster:  
  certificate-authority: fake-ca-file  
  server: https://1.2.3.4  
  name: development  
- cluster:  
  insecure-skip-tls-verify: true  
  server: https://5.6.7.8  
  name: test  
contexts:  
- context:  
  cluster: development  
  namespace: frontend  
  user: developer  
  name: dev-frontend  
- context:  
  cluster: development
```

```

  namespace: storage
  user: developer
name: dev-storage
- context:
  cluster: test
  namespace: default
  user: experimenter
  name: exp-test
current-context: ""
kind: Config
preferences: {}
users:
- name: developer
  user:
    client-certificate: fake-cert-file
    client-key: fake-key-file
- name: experimenter
  user:
    # Documentation note (this comment is NOT part of the command output).
    # Storing passwords in Kubernetes client config is risky.
    # A better alternative would be to use a credential plugin
    # and store the credentials separately.
    # See https://kubernetes.io/docs/reference/access-authn-authz/authentication/#client-go-credential-plugins
    password: some-password
    username: exp

```

The fake-ca-file, fake-cert-file and fake-key-file above are the placeholders for the pathnames of the certificate files. You need to change these to the actual pathnames of certificate files in your environment.

Sometimes you may want to use Base64-encoded data embedded here instead of separate certificate files; in that case you need to add the suffix -data to the keys, for example, certificate-authority-data, client-certificate-data, client-key-data.

Each context is a triple (cluster, user, namespace). For example, the dev-frontend context says, "Use the credentials of the developer user to access the frontend namespace of the development cluster".

Set the current context:

```
kubectrl config --kubeconfig=config-demo use-context dev-frontend
```

Now whenever you enter a kubectrl command, the action will apply to the cluster, and namespace listed in the dev-frontend context. And the command will use the credentials of the user listed in the dev-frontend context.

To see only the configuration information associated with the current context, use the --minify flag.

```
kubectrl config --kubeconfig=config-demo view --minify
```

The output shows configuration information associated with the dev-frontend context:

```
apiVersion: v1
clusters:
- cluster:
  certificate-authority: fake-ca-file
  server: https://1.2.3.4
  name: development
contexts:
- context:
  cluster: development
  namespace: frontend
  user: developer
  name: dev-frontend
current-context: dev-frontend
kind: Config
preferences: {}
users:
- name: developer
  user:
    client-certificate: fake-cert-file
    client-key: fake-key-file
```

Now suppose you want to work for a while in the test cluster.

Change the current context to exp-test:

```
kubectl config --kubeconfig=config-demo use-context exp-test
```

Now any kubectl command you give will apply to the default namespace of the test cluster. And the command will use the credentials of the user listed in the exp-test context.

View configuration associated with the new current context, exp-test.

```
kubectl config --kubeconfig=config-demo view --minify
```

Finally, suppose you want to work for a while in the storage namespace of the development cluster.

Change the current context to dev-storage:

```
kubectl config --kubeconfig=config-demo use-context dev-storage
```

View configuration associated with the new current context, dev-storage.

```
kubectl config --kubeconfig=config-demo view --minify
```

Create a second configuration file

In your config-exercise directory, create a file named config-demo-2 with this content:

```
apiVersion: v1
kind: Config
preferences: {}

contexts:
```

```
- context:
  cluster: development
  namespace: ramp
  user: developer
  name: dev-ramp-up
```

The preceding configuration file defines a new context named `dev-ramp-up`.

Set the KUBECONFIG environment variable

See whether you have an environment variable named `KUBECONFIG`. If so, save the current value of your `KUBECONFIG` environment variable, so you can restore it later. For example:

Linux

```
export KUBECONFIG_SAVED="$KUBECONFIG"
```

Windows PowerShell

```
$Env:KUBECONFIG_SAVED=$ENV:KUBECONFIG
```

The `KUBECONFIG` environment variable is a list of paths to configuration files. The list is colon-delimited for Linux and Mac, and semicolon-delimited for Windows. If you have a `KUBECONFIG` environment variable, familiarize yourself with the configuration files in the list.

Temporarily append two paths to your `KUBECONFIG` environment variable. For example:

Linux

```
export KUBECONFIG="${KUBECONFIG}:config-demo:config-demo-2"
```

Windows PowerShell

```
$Env:KUBECONFIG=("config-demo;config-demo-2")
```

In your `config-exercise` directory, enter this command:

```
kubectl config view
```

The output shows merged information from all the files listed in your `KUBECONFIG` environment variable. In particular, notice that the merged information has the `dev-ramp-up` context from the `config-demo-2` file and the three contexts from the `config-demo` file:

```
contexts:
- context:
  cluster: development
  namespace: frontend
  user: developer
  name: dev-frontend
- context:
  cluster: development
  namespace: ramp
```

```
  user: developer
  name: dev-ramp-up
- context:
  cluster: development
  namespace: storage
  user: developer
  name: dev-storage
- context:
  cluster: test
  namespace: default
  user: experimenter
  name: exp-test
```

For more information about how kubeconfig files are merged, see [Organizing Cluster Access Using kubeconfig Files](#)

Explore the \$HOME/.kube directory

If you already have a cluster, and you can use `kubectl` to interact with the cluster, then you probably have a file named `config` in the `$HOME/.kube` directory.

Go to `$HOME/.kube`, and see what files are there. Typically, there is a file named `config`. There might also be other configuration files in this directory. Briefly familiarize yourself with the contents of these files.

Append \$HOME/.kube/config to your KUBECONFIG environment variable

If you have a `$HOME/.kube/config` file, and it's not already listed in your `KUBECONFIG` environment variable, append it to your `KUBECONFIG` environment variable now. For example:

Linux

```
export KUBECONFIG="${KUBECONFIG};${HOME}/.kube/config"
```

Windows Powershell

```
$Env:KUBECONFIG="$Env:KUBECONFIG;$HOME\.kube\config"
```

View configuration information merged from all the files that are now listed in your `KUBECONFIG` environment variable. In your `config-exercise` directory, enter:

```
kubectl config view
```

Clean up

Return your `KUBECONFIG` environment variable to its original value. For example:

Linux

```
export KUBECONFIG="$KUBECONFIG_SAVED"
```

Windows PowerShell

```
$Env:KUBECONFIG=$ENV:KUBECONFIG_SAVED
```

Check the subject represented by the kubeconfig

It is not always obvious what attributes (username, groups) you will get after authenticating to the cluster. It can be even more challenging if you are managing more than one cluster at the same time.

There is a `kubectl` subcommand to check subject attributes, such as username, for your selected Kubernetes client context: `kubectl auth whoami`.

Read [API access to authentication information for a client](#) to learn about this in more detail.

- [kubectl config](#)

Use Port Forwarding to Access Applications in a Cluster

This page shows how to use `kubectl port-forward` to connect to a MongoDB server running in a Kubernetes cluster. This type of connection can be useful for database debugging.

Before you begin

- You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version v1.10. To check the version, enter `kubectl version`.

- Install [MongoDB Shell](#).

Creating MongoDB deployment and service

1. Create a Deployment that runs MongoDB:

```
kubectl apply -f https://k8s.io/examples/application/mongodb/mongo-deployment.yaml
```

The output of a successful command verifies that the deployment was created:

```
deployment.apps/mongo created
```

View the pod status to check that it is ready:

```
kubectl get pods
```

The output displays the pod created:

| NAME | READY | STATUS | RESTARTS | AGE |
|------------------------|-------|---------|----------|------|
| mongo-75f59d57f4-4nd6q | 1/1 | Running | 0 | 2m4s |

View the Deployment's status:

```
kubectl get deployment
```

The output displays that the Deployment was created:

| NAME | READY | UP-TO-DATE | AVAILABLE | AGE |
|-------|-------|------------|-----------|-------|
| mongo | 1/1 | 1 | 1 | 2m21s |

The Deployment automatically manages a ReplicaSet. View the ReplicaSet status using:

```
kubectl get replicaset
```

The output displays that the ReplicaSet was created:

| NAME | DESIRED | CURRENT | READY | AGE |
|------------------|---------|---------|-------|-------|
| mongo-75f59d57f4 | 1 | 1 | 1 | 3m12s |

2. Create a Service to expose MongoDB on the network:

```
kubectl apply -f https://k8s.io/examples/application/mongodb/mongo-service.yaml
```

The output of a successful command verifies that the Service was created:

```
service/mongo created
```

Check the Service created:

```
kubectl get service mongo
```

The output displays the service created:

| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE |
|-------|-----------|--------------|-------------|-----------|-----|
| mongo | ClusterIP | 10.96.41.183 | <none> | 27017/TCP | 11s |

3. Verify that the MongoDB server is running in the Pod, and listening on port 27017:

```
# Change mongo-75f59d57f4-4nd6q to the name of the Pod
kubectl get pod mongo-75f59d57f4-4nd6q --template='{{(index (index .spec.containers 0).ports 0).containerPort}}{{"\n"}}'
```

The output displays the port for MongoDB in that Pod:

```
27017
```

27017 is the official TCP port for MongoDB.

Forward a local port to a port on the Pod

1. `kubectl port-forward` allows using resource name, such as a pod name, to select a matching pod to port forward to.

```
# Change mongo-75f59d57f4-4nd6q to the name of the Pod
kubectl port-forward mongo-75f59d57f4-4nd6q 28015:27017
```

which is the same as

```
kubectl port-forward pods/mongo-75f59d57f4-4nd6q 28015:27017
```

or

```
kubectl port-forward deployment/mongo 28015:27017
```

or

```
kubectl port-forward replicaset/mongo-75f59d57f4 28015:27017
```

or

```
kubectl port-forward service/mongo 28015:27017
```

Any of the above commands works. The output is similar to this:

```
Forwarding from 127.0.0.1:28015 -> 27017
Forwarding from [::1]:28015 -> 27017
```

Note:

`kubectl port-forward` does not return. To continue with the exercises, you will need to open another terminal.

2. Start the MongoDB command line interface:

```
mongosh --port 28015
```

3. At the MongoDB command line prompt, enter the `ping` command:

```
db.runCommand( { ping: 1 } )
```

A successful ping request returns:

```
{ ok: 1 }
```

Optionally let *kubect* choose the local port

If you don't need a specific local port, you can let *kubect* choose and allocate the local port and thus relieve you from having to manage local port conflicts, with the slightly simpler syntax:

```
kubect port-forward deployment/mongo :27017
```

The *kubect* tool finds a local port number that is not in use (avoiding low ports numbers, because these might be used by other applications). The output is similar to:

```
Forwarding from 127.0.0.1:63753 -> 27017  
Forwarding from [::1]:63753 -> 27017
```

Discussion

Connections made to local port 28015 are forwarded to port 27017 of the Pod that is running the MongoDB server. With this connection in place, you can use your local workstation to debug the database that is running in the Pod.

Note:

kubect port-forward is implemented for TCP ports only. The support for UDP protocol is tracked in [issue 47862](#).

What's next

Learn more about [kubect port-forward](#).

Use a Service to Access an Application in a Cluster

This page shows how to create a Kubernetes Service object that external clients can use to access an application running in a cluster. The Service provides load balancing for an application that has two running instances.

Before you begin

You need to have a Kubernetes cluster, and the *kubect* command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

Objectives

- Run two instances of a Hello World application.

- Create a Service object that exposes a node port.
- Use the Service object to access the running application.

Creating a service for an application running in two pods

Here is the configuration file for the application Deployment:

[service/access/hello-application.yaml](https://k8s.io/examples/service/access/hello-application.yaml)

```
apiVersion: apps/v1
kind: Deployment
metadata:
  name: hello-world
spec:
  selector:
    matchLabels:
      run: load-balancer-example
  replicas: 2
  template:
    metadata:
      labels:
        run: load-balancer-example
    spec:
      containers:
        - name: hello-world
          image: gcr.io/google-samples/node-hello:1.0
          ports:
            - containerPort: 8080
              protocol: TCP
```

1. Run a Hello World application in your cluster: Create the application Deployment using the file above:

```
kubectl apply -f https://k8s.io/examples/service/access/hello-application.yaml
```

The preceding command creates a [Deployment](#) and an associated [ReplicaSet](#). The ReplicaSet has two [Pods](#) each of which runs the Hello World application.

2. Display information about the Deployment:

```
kubectl get deployments hello-world
kubectl describe deployments hello-world
```

3. Display information about your ReplicaSet objects:

```
kubectl get replicaset
kubectl describe replicaset
```

4. Create a Service object that exposes the deployment:

```
kubectl expose deployment hello-world --type=NodePort --name=example-service
```

5. Display information about the Service:

```
kubectl describe services example-service
```

The output is similar to this:

```
Name:          example-service
Namespace:     default
Labels:        run=load-balancer-example
Annotations:   <none>
Selector:      run=load-balancer-example
Type:          NodePort
IP:            10.32.0.16
Port:          <unset> 8080/TCP
TargetPort:    8080/TCP
NodePort:      <unset> 31496/TCP
Endpoints:     10.200.1.4:8080,10.200.2.5:8080
Session Affinity: None
Events:        <none>
```

Make a note of the NodePort value for the Service. For example, in the preceding output, the NodePort value is 31496.

6. List the pods that are running the Hello World application:

```
kubectl get pods --selector="run=load-balancer-example" --output=wide
```

The output is similar to this:

| NAME | READY | STATUS | ... | IP | NODE |
|------------------------------|-------|---------|-----|------------|---------|
| hello-world-2895499144-bsbk5 | 1/1 | Running | ... | 10.200.1.4 | worker1 |
| hello-world-2895499144-m1pwt | 1/1 | Running | ... | 10.200.2.5 | worker2 |

7. Get the public IP address of one of your nodes that is running a Hello World pod. How you get this address depends on how you set up your cluster. For example, if you are using Minikube, you can see the node address by running `kubectl cluster-info`. If you are using Google Compute Engine instances, you can use the `gcloud compute instances list` command to see the public addresses of your nodes.
8. On your chosen node, create a firewall rule that allows TCP traffic on your node port. For example, if your Service has a NodePort value of 31568, create a firewall rule that allows TCP traffic on port 31568. Different cloud providers offer different ways of configuring firewall rules.
9. Use the node address and node port to access the Hello World application:

```
curl http://<public-node-ip>:<node-port>
```

where `<public-node-ip>` is the public IP address of your node, and `<node-port>` is the NodePort value for your service. The response to a successful request is a hello message:

```
Hello Kubernetes!
```

Using a service configuration file

As an alternative to using `kubectl expose`, you can use a [service configuration file](#) to create a Service.

Cleaning up

To delete the Service, enter this command:

```
kubectl delete services example-service
```

To delete the Deployment, the ReplicaSet, and the Pods that are running the Hello World application, enter this command:

```
kubectl delete deployment hello-world
```

What's next

Follow the [Connecting Applications with Services](#) tutorial.

Connect a Frontend to a Backend Using Services

This task shows how to create a *frontend* and a *backend* microservice. The backend microservice is a hello greeter. The frontend exposes the backend using nginx and a Kubernetes [Service](#) object.

Objectives

- Create and run a sample hello backend microservice using a [Deployment](#) object.
- Use a Service object to send traffic to the backend microservice's multiple replicas.
- Create and run a nginx frontend microservice, also using a Deployment object.
- Configure the frontend microservice to send traffic to the backend microservice.
- Use a Service object of type=LoadBalancer to expose the frontend microservice outside the cluster.

Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

This task uses [Services with external load balancers](#), which require a supported environment. If your environment does not support this, you can use a Service of type [NodePort](#) instead.

Creating the backend using a Deployment

The backend is a simple hello greeter microservice. Here is the configuration file for the backend Deployment:

[service/access/backend-deployment.yaml](#)

```
---
apiVersion: apps/v1
kind: Deployment
metadata:
  name: backend
spec:
  selector:
    matchLabels:
      app: hello
      tier: backend
      track: stable
  replicas: 3
  template:
    metadata:
      labels:
        app: hello
        tier: backend
        track: stable
    spec:
      containers:
        - name: hello
          image: "gcr.io/google-samples/hello-go-gke:1.0"
          ports:
            - name: http
              containerPort: 80
...

```

Create the backend Deployment:

```
kubectl apply -f https://k8s.io/examples/service/access/backend-deployment.yaml
```

View information about the backend Deployment:

```
kubectl describe deployment backend
```

The output is similar to this:

```
Name:                backend
Namespace:           default
CreationTimestamp:    Mon, 24 Oct 2016 14:21:02 -0700
Labels:               app=hello
                     tier=backend
                     track=stable

```

```

Annotations:      deployment.kubernetes.io/revision=1

```

Creating the hello Service object

The key to sending requests from a frontend to a backend is the backend Service. A Service creates a persistent IP address and DNS name entry so that the backend microservice can always be reached. A Service uses [selectors](#) to find the Pods that it routes traffic to.

First, explore the Service configuration file:

[service/access/backend-service.yaml](#)

```

---
apiVersion: v1
kind: Service
metadata:
  name: hello
spec:
  selector:
    app: hello
    tier: backend
  ports:
  - protocol: TCP
    port: 80
    targetPort: http
...

```

In the configuration file, you can see that the Service, named `hello` routes traffic to Pods that have the labels `app: hello` and `tier: backend`.

Create the backend Service:

```
kubectl apply -f https://k8s.io/examples/service/access/backend-service.yaml
```

At this point, you have a backend Deployment running three replicas of your `hello` application, and you have a Service that can route traffic to them. However, this service is neither available nor resolvable outside the cluster.

Creating the frontend

Now that you have your backend running, you can create a frontend that is accessible outside the cluster, and connects to the backend by proxying requests to it.

The frontend sends requests to the backend worker Pods by using the DNS name given to the backend Service. The DNS name is `hello`, which is the value of the `name` field in the `examples/service/access/backend-service.yaml` configuration file.

The Pods in the frontend Deployment run a `nginx` image that is configured to proxy requests to the `hello` backend Service. Here is the `nginx` configuration file:

[service/access/frontend-nginx.conf](https://k8s.io/examples/service/access/frontend-nginx.conf)

```
# The identifier Backend is internal to nginx, and used to name this specific upstream
upstream Backend {
    # hello is the internal DNS name used by the backend Service inside Kubernetes
    server hello;
}

server {
    listen 80;

    location / {
        # The following statement will proxy traffic to the upstream named Backend
        proxy_pass http://Backend;
    }
}
```

Similar to the backend, the frontend has a Deployment and a Service. An important difference to notice between the backend and frontend services, is that the configuration for the frontend Service has `type: LoadBalancer`, which means that the Service uses a load balancer provisioned by your cloud provider and will be accessible from outside the cluster.

[service/access/frontend-service.yaml](https://k8s.io/examples/service/access/frontend-service.yaml)

```
---
apiVersion: v1
```

```
kind: Service
metadata:
  name: frontend
spec:
  selector:
    app: hello
    tier: frontend
  ports:
  - protocol: "TCP"
    port: 80
    targetPort: 80
  type: LoadBalancer
...
```

[service/access/frontend-deployment.yaml](https://k8s.io/examples/service/access/frontend-deployment.yaml)

```
---
apiVersion: apps/v1
kind: Deployment
metadata:
  name: frontend
spec:
  selector:
    matchLabels:
      app: hello
      tier: frontend
      track: stable
  replicas: 1
  template:
    metadata:
      labels:
        app: hello
        tier: frontend
        track: stable
    spec:
      containers:
      - name: nginx
        image: "gcr.io/google-samples/hello-frontend:1.0"
        lifecycle:
          preStop:
            exec:
              command: ["/usr/sbin/nginx","-s","quit"]
...
```

Create the frontend Deployment and Service:

```
kubectl apply -f https://k8s.io/examples/service/access/frontend-deployment.yaml
kubectl apply -f https://k8s.io/examples/service/access/frontend-service.yaml
```

The output verifies that both resources were created:

```
deployment.apps/frontend created
service/frontend created
```

Note:

The nginx configuration is baked into the [container image](#). A better way to do this would be to use a [ConfigMap](#), so that you can change the configuration more easily.

Interact with the frontend Service

Once you've created a Service of type LoadBalancer, you can use this command to find the external IP:

```
kubectl get service frontend --watch
```

This displays the configuration for the frontend Service and watches for changes. Initially, the external IP is listed as <pending>:

| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE |
|----------|--------------|---------------|-------------|---------|-----|
| frontend | LoadBalancer | 10.51.252.116 | <pending> | 80/TCP | 10s |

As soon as an external IP is provisioned, however, the configuration updates to include the new IP under the EXTERNAL-IP heading:

| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE |
|----------|--------------|---------------|-----------------|---------|-----|
| frontend | LoadBalancer | 10.51.252.116 | XXX.XXX.XXX.XXX | 80/TCP | 1m |

That IP can now be used to interact with the frontend service from outside the cluster.

Send traffic through the frontend

The frontend and backend are now connected. You can hit the endpoint by using the curl command on the external IP of your frontend Service.

```
curl http://${EXTERNAL_IP} # replace this with the EXTERNAL-IP you saw earlier
```

The output shows the message generated by the backend:

```
{"message":"Hello"}
```

Cleaning up

To delete the Services, enter this command:

```
kubectl delete services frontend backend
```

To delete the Deployments, the ReplicaSets and the Pods that are running the backend and frontend applications, enter this command:

```
kubectl delete deployment frontend backend
```

- Learn more about [ConfigMaps](#)
- Learn more about [DNS for Service and Pods](#)

Create an External Load Balancer

This page shows how to create an external load balancer.

When creating a [Service](#), you have the option of automatically creating a cloud load balancer. This provides an externally-accessible IP address that sends traffic to the correct port on your cluster nodes, *provided your cluster runs in a supported environment and is configured with the correct cloud load balancer provider package.*

You can also use an [Ingress](#) in place of Service. For more information, check the [Ingress](#) documentation.

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Your cluster must be running in a cloud or other environment that already has support for configuring external load balancers.

Create a Service

Create a Service from a manifest

To create an external load balancer, add the following line to your Service manifest:

```
type: LoadBalancer
```

Your manifest might then look like:

```
apiVersion: v1
kind: Service
metadata:
  name: example-service
spec:
  selector:
    app: example
  ports:
    - port: 8765
      targetPort: 9376
  type: LoadBalancer
```

Create a Service using kubectl

You can alternatively create the service with the `kubectl expose` command and its `--type=LoadBalancer` flag:

```
kubectl expose deployment example --port=8765 --target-port=9376 \
  --name=example-service --type=LoadBalancer
```

This command creates a new Service using the same selectors as the referenced resource (in the case of the example above, a [Deployment](#) named example).

For more information, including optional flags, refer to the [kubectl expose reference](#).

Finding your IP address

You can find the IP address created for your service by getting the service information through `kubectl`:

```
kubectl describe services example-service
```

which should produce output similar to:

```
Name:          example-service
Namespace:     default
Labels:        app=example
Annotations:   <none>
Selector:      app=example
Type:          LoadBalancer
IP Families:   <none>
IP:            10.3.22.96
IPs:           10.3.22.96
LoadBalancer Ingress: 192.0.2.89
Port:          <unset> 8765/TCP
TargetPort:    9376/TCP
NodePort:      <unset> 30593/TCP
Endpoints:     172.17.0.3:9376
Session Affinity: None
External Traffic Policy: Cluster
Events:        <none>
```

The load balancer's IP address is listed next to `LoadBalancer Ingress`.

Note:

If you are running your service on Minikube, you can find the assigned IP address and port with:

```
minikube service example-service --url
```

Preserving the client source IP

By default, the source IP seen in the target container is *not the original source IP* of the client. To enable preservation of the client IP, the following fields can be configured in the `.spec` of the Service:

- `.spec.externalTrafficPolicy` - denotes if this Service desires to route external traffic to node-local or cluster-wide endpoints. There are two available options: Cluster (default) and Local. Cluster obscures the client source IP and may cause a second hop to another node, but should have good overall load-spreading. Local preserves the client source IP and avoids a second hop for LoadBalancer and NodePort type Services, but risks potentially imbalanced traffic spreading.
- `.spec.healthCheckNodePort` - specifies the health check node port (numeric port number) for the service. If you don't specify `healthCheckNodePort`, the service controller allocates a port from your cluster's NodePort range.
You can configure that range by setting an API server command line option, `--service-node-port-range`. The Service will use the user-specified `healthCheckNodePort` value if you specify it, provided that the Service type is set to LoadBalancer and `externalTrafficPolicy` is set to Local.

Setting `externalTrafficPolicy` to Local in the Service manifest activates this feature. For example:

```
apiVersion: v1
kind: Service
metadata:
  name: example-service
spec:
  selector:
    app: example
  ports:
    - port: 8765
      targetPort: 9376
  externalTrafficPolicy: Local
  type: LoadBalancer
```

Caveats and limitations when preserving source IPs

Load balancing services from some cloud providers do not let you configure different weights for each target.

With each target weighted equally in terms of sending traffic to Nodes, external traffic is not equally load balanced across different Pods. The external load balancer is unaware of the number of Pods on each node that are used as a target.

Where $\text{NumServicePods} \ll \text{NumNodes}$ or $\text{NumServicePods} \gg \text{NumNodes}$, a fairly close-to-equal distribution will be seen, even without weights.

Internal pod to pod traffic should behave similar to ClusterIP services, with equal probability across all pods.

Garbage collecting load balancers

FEATURE STATE: Kubernetes v1.17 [stable]

In usual case, the correlating load balancer resources in cloud provider should be cleaned up soon after a LoadBalancer type Service is deleted. But it is known that there are various corner cases where cloud resources are orphaned after the associated Service is deleted. Finalizer Protection for Service LoadBalancers was introduced to prevent this from happening. By using finalizers, a Service resource will never be deleted until the correlating load balancer resources are also deleted.

Specifically, if a Service has type LoadBalancer, the service controller will attach a finalizer named `service.kubernetes.io/load-balancer-cleanup`. The finalizer will only be removed after the load balancer resource is cleaned up. This prevents dangling load balancer resources even in corner cases such as the service controller crashing.

External load balancer providers

It is important to note that the datapath for this functionality is provided by a load balancer external to the Kubernetes cluster.

When the Service type is set to LoadBalancer, Kubernetes provides functionality equivalent to type equals ClusterIP to pods within the cluster and extends it by programming the (external to Kubernetes) load balancer with entries for the nodes hosting the relevant Kubernetes pods. The Kubernetes control plane automates the creation of the external load balancer, health checks (if needed), and packet filtering rules (if needed). Once the cloud provider allocates an IP address for the load balancer, the control plane looks up that external IP address and populates it into the Service object.

- Read about [Ingress](#)

List All Container Images Running in a Cluster

This page shows how to use `kubectl` to list all of the Container images for Pods running in a cluster.

Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at

least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

In this exercise you will use `kubectl` to fetch all of the Pods running in a cluster, and format the output to pull out the list of Containers for each.

List all Container images in all namespaces

- Fetch all Pods in all namespaces using `kubectl get pods --all-namespaces`
- Format the output to include only the list of Container image names using `-o jsonpath={.items[*].spec['initContainers', 'containers'][*].image}`. This will recursively parse out the image field from the returned json.
 - See the [jsonpath reference](#) for further information on how to use jsonpath.
- Format the output using standard tools: `tr`, `sort`, `uniq`
 - Use `tr` to replace spaces with newlines
 - Use `sort` to sort the results
 - Use `uniq` to aggregate image counts

```
kubectl get pods --all-namespaces -o jsonpath="{.items[*].spec['initContainers', 'containers']
[*].image}" | \
tr -s '[:space:]' '\n' | \
sort | \
uniq -c
```

The jsonpath is interpreted as follows:

- `.items[*]`: for each returned value
- `.spec`: get the spec
- `['initContainers', 'containers'][*]`: for each container
- `.image`: get the image

Note:

When fetching a single Pod by name, for example `kubectl get pod nginx`, the `.items[*]` portion of the path should be omitted because a single Pod is returned instead of a list of items.

List Container images by Pod

The formatting can be controlled further by using the `range` operation to iterate over elements individually.

```
kubectl get pods --all-namespaces -o jsonpath='{range .items[*]}{"\n"}{{.metadata.name}}{":\t"}
{range .spec.containers[*]}{.image}}{"", ""}{end}{end}' | \
sort
```

List Container images filtering by Pod label

To target only Pods matching a specific label, use the `-l` flag. The following matches only Pods with labels matching `app=nginx`.

```
kubectl get pods --all-namespaces -o jsonpath="{.items[*].spec.containers[*].image}" -l app=nginx
```

List Container images filtering by Pod namespace

To target only pods in a specific namespace, use the `namespace` flag. The following matches only Pods in the `kube-system` namespace.

```
kubectl get pods --namespace kube-system -o jsonpath="{.items[*].spec.containers[*].image}"
```

List Container images using a go-template instead of jsonpath

As an alternative to `jsonpath`, Kubectl supports using [go-templates](#) for formatting the output:

```
kubectl get pods --all-namespaces -o go-template --template="{{range .items}}\n{{range .spec.containers}}{{.image}} {{end}}{{end}}\n"
```

Set up Ingress on Minikube with the NGINX Ingress Controller

An [Ingress](#) is an API object that defines rules which allow external access to services in a cluster. An [Ingress controller](#) fulfills the rules set in the Ingress.

This page shows you how to set up a simple Ingress which routes requests to Service 'web' or 'web2' depending on the HTTP URI.

Before you begin

This tutorial assumes that you are using `minikube` to run a local Kubernetes cluster. Visit [Install tools](#) to learn how to install `minikube`.

Note:

This tutorial uses a container that requires the AMD64 architecture. If you are using minikube on a computer with a different CPU architecture, you could try using minikube with a driver that can emulate AMD64. For example, the Docker Desktop driver can do this.

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version 1.19. To check the version, enter kubectl version. If you are using an older Kubernetes version, switch to the documentation for that version.

Create a minikube cluster

If you haven't already set up a cluster locally, run minikube start to create a cluster.

Enable the Ingress controller

1. To enable the NGINX Ingress controller, run the following command:

```
minikube addons enable ingress
```

2. Verify that the NGINX Ingress controller is running

```
kubectl get pods -n ingress-nginx
```

Note:

It can take up to a minute before you see these pods running OK.

The output is similar to:

| NAME | READY | STATUS | RESTARTS | AGE |
|---|-------|-----------|----------|-----|
| ingress-nginx-admission-create-g9g49 | 0/1 | Completed | 0 | 11m |
| ingress-nginx-admission-patch-rqp78 | 0/1 | Completed | 1 | 11m |
| ingress-nginx-controller-59b45fb494-26npt | 1/1 | Running | 0 | 11m |

Deploy a hello, world app

1. Create a Deployment using the following command:

```
kubectl create deployment web --image=gcr.io/google-samples/hello-app:1.0
```

The output should be:

```
deployment.apps/web created
```

Verify that the Deployment is in a Ready state:

```
kubectl get deployment web
```

The output should be similar to:

| NAME | READY | UP-TO-DATE | AVAILABLE | AGE |
|------|-------|------------|-----------|-----|
| web | 1/1 | 1 | 1 | 53s |

2. Expose the Deployment:

```
kubectl expose deployment web --type=NodePort --port=8080
```

The output should be:

```
service/web exposed
```

3. Verify the Service is created and is available on a node port:

```
kubectl get service web
```

The output is similar to:

| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE |
|------|----------|----------------|-------------|----------------|-----|
| web | NodePort | 10.104.133.249 | <none> | 8080:31637/TCP | 12m |

4. Visit the Service via NodePort, using the [minikube service](#) command. Follow the instructions for your platform:

- [Linux](#)
- [MacOS](#)

```
minikube service web --url
```

The output is similar to:

```
http://172.17.0.15:31637
```

Invoke the URL obtained in the output of the previous step:

```
curl http://172.17.0.15:31637
```

```
# The command must be run in a separate terminal.  
minikube service web --url
```

The output is similar to:

```
http://127.0.0.1:62445
```

! Because you are using a Docker driver on darwin, the terminal needs to be open to run it.

From a different terminal, invoke the URL obtained in the output of the previous step:

```
curl http://127.0.0.1:62445
```

The output is similar to:

```
Hello, world!  
Version: 1.0.0  
Hostname: web-55b8c6998d-8k564
```

You can now access the sample application via the Minikube IP address and NodePort. The next step lets you access the application using the Ingress resource.

Create an Ingress

The following manifest defines an Ingress that sends traffic to your Service via `hello-world.example`.

1. Create `example-ingress.yaml` from the following file:

[service/networking/example-ingress.yaml](https://k8s.io/examples/service/networking/example-ingress.yaml)

```
apiVersion: networking.k8s.io/v1  
kind: Ingress  
metadata:  
  name: example-ingress  
  annotations:  
    nginx.ingress.kubernetes.io/rewrite-target: /$1  
spec:  
  rules:  
    - host: hello-world.example  
      http:  
        paths:  
          - path: /  
            pathType: Prefix  
            backend:  
              service:  
                name: web  
                port:  
                  number: 8080
```

2. Create the Ingress object by running the following command:

```
kubectl apply -f https://k8s.io/examples/service/networking/example-ingress.yaml
```

The output should be:

```
ingress.networking.k8s.io/example-ingress created
```

3. Verify the IP address is set:

```
kubectl get ingress
```

Note:

This can take a couple of minutes.

You should see an IPv4 address in the ADDRESS column; for example:

| NAME | CLASS | HOSTS | ADDRESS | PORTS | AGE |
|-----------------|-------|---------------------|-------------|-------|-----|
| example-ingress | nginx | hello-world.example | 172.17.0.15 | 80 | 38s |

4. Verify that the Ingress controller is directing traffic, by following the instructions for your platform:

Note:

The network is limited if using the Docker driver on MacOS (Darwin) and the Node IP is not reachable directly. To get ingress to work you'll need to open a new terminal and run minikube tunnel.

sudo permission is required for it, so provide the password when prompted.

- [Linux](#)
- [MacOS](#)

```
curl --resolve "hello-world.example:80:$( minikube ip )" -i http://hello-world.example
```

```
minikube tunnel
```

The output is similar to:

```
Tunnel successfully started
```

```
NOTE: Please do not close this terminal as this process must stay alive for the tunnel to be accessible ...
```

```
The service/ingress example-ingress requires privileged ports to be exposed: [80 443]
sudo permission will be asked for it.
Starting tunnel for service example-ingress.
```

From within a new terminal, invoke the following command:

```
curl --resolve "hello-world.example:80:127.0.0.1" -i http://hello-world.example
```

You should see:

```
Hello, world!
Version: 1.0.0
Hostname: web-55b8c6998d-8k564
```

5. Optionally, you can also visit hello-world.example from your browser.

Add a line to the bottom of the /etc/hosts file on your computer (you will need administrator access):

- [Linux](#)
- [MacOS](#)

Look up the external IP address as reported by minikube

```
minikube ip
```

```
172.17.0.15 hello-world.example
```

Note:

Change the IP address to match the output from minikube ip.

```
127.0.0.1 hello-world.example
```

After you make this change, your web browser sends requests for hello-world.example URLs to Minikube.

Create a second Deployment

1. Create another Deployment using the following command:

```
kubectl create deployment web2 --image=gcr.io/google-samples/hello-app:2.0
```

The output should be:

```
deployment.apps/web2 created
```

Verify that the Deployment is in a Ready state:

```
kubectl get deployment web2
```

The output should be similar to:

| NAME | READY | UP-TO-DATE | AVAILABLE | AGE |
|------|-------|------------|-----------|-----|
| web2 | 1/1 | 1 | 1 | 16s |

2. Expose the second Deployment:

```
kubectl expose deployment web2 --port=8080 --type=NodePort
```

The output should be:

```
service/web2 exposed
```

Edit the existing Ingress

1. Edit the existing example-ingress.yaml manifest, and add the following lines at the end:

```
- path: /v2
  pathType: Prefix
  backend:
    service:
      name: web2
```

```
port:
  number: 8080
```

2. Apply the changes:

```
kubectl apply -f example-ingress.yaml
```

You should see:

```
ingress.networking/example-ingress configured
```

Test your Ingress

1. Access the 1st version of the Hello World app.

- [Linux](#)
- [MacOS](#)

```
curl --resolve "hello-world.example:80:$( minikube ip )" -i http://hello-world.example
```

```
minikube tunnel
```

The output is similar to:

```
Tunnel successfully started
```

```
NOTE: Please do not close this terminal as this process must stay alive for the tunnel to be accessible ...
```

```
The service/ingress example-ingress requires privileged ports to be exposed: [80 443]
sudo permission will be asked for it.
Starting tunnel for service example-ingress.
```

From within a new terminal, invoke the following command:

```
curl --resolve "hello-world.example:80:127.0.0.1" -i http://hello-world.example
```

The output is similar to:

```
Hello, world!
Version: 1.0.0
Hostname: web-55b8c6998d-8k564
```

2. Access the 2nd version of the Hello World app.

- [Linux](#)
- [MacOS](#)

```
curl --resolve "hello-world.example:80:$( minikube ip )" -i http://hello-world.example/v2
```

```
minikube tunnel
```

The output is similar to:

```
Tunnel successfully started
```

NOTE: Please do not close this terminal as this process must stay alive for the tunnel to be accessible ...

The service/ingress example-ingress requires privileged ports to be exposed: [80 443] sudo permission will be asked for it.
Starting tunnel for service example-ingress.

From within a new terminal, invoke the following command:

```
curl --resolve "hello-world.example:80:127.0.0.1" -i http://hello-world.example/v2
```

The output is similar to:

```
Hello, world!  
Version: 2.0.0  
Hostname: web2-75cd47646f-t8cjk
```

Note:

If you did the optional step to update `/etc/hosts`, you can also visit `hello-world.example` and `hello-world.example/v2` from your browser.

Communicate Between Containers in the Same Pod Using a Shared Volume

This page shows how to use a Volume to communicate between two Containers running in the same Pod. See also how to allow processes to communicate by [sharing process namespace](#) between containers.

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter kubectl version.

Creating a Pod that runs two Containers

In this exercise, you create a Pod that runs two Containers. The two containers share a Volume that they can use to communicate. Here is the configuration file for the Pod:

[pods/two-container-pod.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
  name: two-containers
spec:

  restartPolicy: Never

  volumes:
  - name: shared-data
    emptyDir: {}

  containers:

  - name: nginx-container
    image: nginx
    volumeMounts:
    - name: shared-data
      mountPath: /usr/share/nginx/html

  - name: debian-container
    image: debian
    volumeMounts:
    - name: shared-data
      mountPath: /pod-data
    command: ["/bin/sh"]
    args: ["-c", "echo Hello from the debian container > /pod-data/index.html"]
```

In the configuration file, you can see that the Pod has a Volume named shared-data.

The first container listed in the configuration file runs an nginx server. The mount path for the shared Volume is /usr/share/nginx/html. The second container is based on the debian image, and has a mount path of /pod-data. The second container runs the following command and then terminates.

```
echo Hello from the debian container > /pod-data/index.html
```

Notice that the second container writes the index.html file in the root directory of the nginx server.

Create the Pod and the two Containers:

```
kubectl apply -f https://k8s.io/examples/pods/two-container-pod.yaml
```

View information about the Pod and the Containers:

```
kubectl get pod two-containers --output=yaml
```

Here is a portion of the output:

```
apiVersion: v1
kind: Pod
metadata:
  ...
  name: two-containers
  namespace: default
  ...
spec:
  ...
  containerStatuses:

  - containerID: docker://c1d8abd1 ...
    image: debian
    ...
    lastState:
      terminated:
        ...
    name: debian-container
    ...

  - containerID: docker://96c1ff2c5bb ...
    image: nginx
    ...
    name: nginx-container
    ...
    state:
      running:
        ...
```

You can see that the debian Container has terminated, and the nginx Container is still running.

Get a shell to nginx Container:

```
kubectl exec -it two-containers -c nginx-container -- /bin/bash
```

In your shell, verify that nginx is running:

```
root@two-containers:/# apt-get update
root@two-containers:/# apt-get install curl procps
root@two-containers:/# ps aux
```

The output is similar to this:

| USER | PID | ... | STAT | START | TIME | COMMAND |
|------|-----|-----|------|-------|------|--|
| root | 1 | ... | Ss | 21:12 | 0:00 | nginx: master process nginx -g daemon off; |

Recall that the debian Container created the index.html file in the nginx root directory. Use curl to send a GET request to the nginx server:

```
root@two-containers:/# curl localhost
```

The output shows that nginx serves a web page written by the debian container:

```
Hello from the debian container
```

Discussion

The primary reason that Pods can have multiple containers is to support helper applications that assist a primary application. Typical examples of helper applications are data pullers, data pushers, and proxies. Helper and primary applications often need to communicate with each other. Typically this is done through a shared filesystem, as shown in this exercise, or through the loopback network interface, localhost. An example of this pattern is a web server along with a helper program that polls a Git repository for new updates.

The Volume in this exercise provides a way for Containers to communicate during the life of the Pod. If the Pod is deleted and recreated, any data stored in the shared Volume is lost.

Configure DNS for a Cluster

Kubernetes offers a DNS cluster addon, which most of the supported environments enable by default. In Kubernetes version 1.11 and later, CoreDNS is recommended and is installed by default with kubeadm.

For more information on how to configure CoreDNS for a Kubernetes cluster, see the [Customizing DNS Service](#). An example demonstrating how to use Kubernetes DNS with kube-dns, see the [Kubernetes DNS sample plugin](#).

Access Services Running on Clusters

This page shows how to connect to services running on the Kubernetes cluster.

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at

least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

Accessing services running on the cluster

In Kubernetes, [nodes](#), [pods](#) and [services](#) all have their own IPs. In many cases, the node IPs, pod IPs, and some service IPs on a cluster will not be routable, so they will not be reachable from a machine outside the cluster, such as your desktop machine.

Ways to connect

You have several options for connecting to nodes, pods and services from outside the cluster:

- Access services through public IPs.
 - Use a service with type NodePort or LoadBalancer to make the service reachable outside the cluster. See the [services](#) and [kubectl expose](#) documentation.
 - Depending on your cluster environment, this may only expose the service to your corporate network, or it may expose it to the internet. Think about whether the service being exposed is secure. Does it do its own authentication?
 - Place pods behind services. To access one specific pod from a set of replicas, such as for debugging, place a unique label on the pod and create a new service which selects this label.
 - In most cases, it should not be necessary for application developer to directly access nodes via their nodeIPs.
- Access services, nodes, or pods using the Proxy Verb.
 - Does apiserver authentication and authorization prior to accessing the remote service. Use this if the services are not secure enough to expose to the internet, or to gain access to ports on the node IP, or for debugging.
 - Proxies may cause problems for some web applications.
 - Only works for HTTP/HTTPS.
 - Described [here](#).
- Access from a node or pod in the cluster.
 - Run a pod, and then connect to a shell in it using [kubectl exec](#). Connect to other nodes, pods, and services from that shell.
 - Some clusters may allow you to ssh to a node in the cluster. From there you may be able to access cluster services. This is a non-standard method, and will work on some clusters but not others. Browsers and other tools may or may not be installed. Cluster DNS may not work.

Discovering builtin services

Typically, there are several services which are started on a cluster by kube-system. Get a list of these with the `kubectl cluster-info` command:

```
kubectl cluster-info
```

The output is similar to this:

Kubernetes master is running at `https://192.0.2.1`
elasticsearch-logging is running at `https://192.0.2.1/api/v1/namespaces/kube-system/services/elasticsearch-logging/proxy`
kibana-logging is running at `https://192.0.2.1/api/v1/namespaces/kube-system/services/kibana-logging/proxy`
kube-dns is running at `https://192.0.2.1/api/v1/namespaces/kube-system/services/kube-dns/proxy`
grafana is running at `https://192.0.2.1/api/v1/namespaces/kube-system/services/monitoring-grafana/proxy`
heapster is running at `https://192.0.2.1/api/v1/namespaces/kube-system/services/monitoring-heapster/proxy`

This shows the proxy-verb URL for accessing each service. For example, this cluster has cluster-level logging enabled (using Elasticsearch), which can be reached at `https://192.0.2.1/api/v1/namespaces/kube-system/services/elasticsearch-logging/proxy/` if suitable credentials are passed, or through a kubectl proxy at, for example: `http://localhost:8080/api/v1/namespaces/kube-system/services/elasticsearch-logging/proxy/`.

Note:

See [Access Clusters Using the Kubernetes API](#) for how to pass credentials or use kubectl proxy.

Manually constructing apiserver proxy URLs

As mentioned above, you use the `kubectl cluster-info` command to retrieve the service's proxy URL. To create proxy URLs that include service endpoints, suffixes, and parameters, you append to the service's proxy URL: `http://<kubernetes_master_address>/api/v1/namespaces/<namespace_name>/services/[<https>]<service_name>[:<port_name>]/proxy`

If you haven't specified a name for your port, you don't have to specify `port_name` in the URL. You can also use the port number in place of the `port_name` for both named and unnamed ports.

By default, the API server proxies to your service using HTTP. To use HTTPS, prefix the service name with `https::`: `http://<kubernetes_master_address>/api/v1/namespaces/<namespace_name>/services/<service_name>/proxy`

The supported formats for the `<service_name>` segment of the URL are:

- `<service_name>` - proxies to the default or unnamed port using http
- `<service_name>:<port_name>` - proxies to the specified port name or port number using http
- `https:<service_name>:` - proxies to the default or unnamed port using https (note the trailing colon)
- `https:<service_name>:<port_name>` - proxies to the specified port name or port number using https

Examples

- To access the Elasticsearch service endpoint `_search?q=user:kimchy`, you would use:

```
http://192.0.2.1/api/v1/namespaces/kube-system/services/elasticsearch-logging/proxy/_search?q=user:kimchy
```

- To access the Elasticsearch cluster health information `_cluster/health?pretty=true`, you
- would use:

```
https://192.0.2.1/api/v1/namespaces/kube-system/services/elasticsearch-logging/proxy/_cluster/health?pretty=true
```

The health information is similar to this:

```
{
  "cluster_name" : "kubernetes_logging",
  "status" : "yellow",
  "timed_out" : false,
  "number_of_nodes" : 1,
  "number_of_data_nodes" : 1,
  "active_primary_shards" : 5,
  "active_shards" : 5,
  "relocating_shards" : 0,
  "initializing_shards" : 0,
  "unassigned_shards" : 5
}
```

- To access the *https* Elasticsearch service health information `_cluster/health?pretty=true`, you would use:

```
https://192.0.2.1/api/v1/namespaces/kube-system/services/https:elasticsearch-logging:/proxy/_cluster/health?pretty=true
```

Using web browsers to access services running on the cluster

You may be able to put an apiserver proxy URL into the address bar of a browser. However:

- Web browsers cannot usually pass tokens, so you may need to use basic (password) auth. Apiserver can be configured to accept basic auth, but your cluster may not be configured to accept basic auth.
- Some web apps may not work, particularly those with client side javascript that construct URLs in a way that is unaware of the proxy path prefix.

Extend Kubernetes

Understand advanced ways to adapt your Kubernetes cluster to the needs of your work environment.

[Configure the Aggregation Layer](#)

[Use Custom Resources](#)

[Set up an Extension API Server](#)

[Configure Multiple Schedulers](#)

[Use an HTTP Proxy to Access the Kubernetes API](#)

Configure the Aggregation Layer

Configuring the [aggregation layer](#) allows the Kubernetes apiserver to be extended with additional APIs, which are not part of the core Kubernetes APIs.

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

Note:

There are a few setup requirements for getting the aggregation layer working in your environment to support mutual TLS auth between the proxy and extension apiservers. Kubernetes and the kube-apiserver have multiple CAs, so make sure that the proxy is signed by the aggregation layer CA and not by something else, like the Kubernetes general CA.

Caution:

Reusing the same CA for different client types can negatively impact the cluster's ability to function. For more information, see [CA Reusage and Conflicts](#).

Authentication Flow

Unlike Custom Resource Definitions (CRDs), the Aggregation API involves another server - your Extension apiserver - in addition to the standard Kubernetes apiserver. The Kubernetes apiserver will need to communicate with your extension apiserver, and your extension apiserver will need to communicate with the Kubernetes apiserver. In order for this communication to be secured, the Kubernetes apiserver uses x509 certificates to authenticate itself to the extension apiserver.

This section describes how the authentication and authorization flows work, and how to configure them.

The high-level flow is as follows:

1. Kubernetes apiserver: authenticate the requesting user and authorize their rights to the requested API path.
2. Kubernetes apiserver: proxy the request to the extension apiserver

3. Extension apiserver: authenticate the request from the Kubernetes apiserver
4. Extension apiserver: authorize the request from the original user
5. Extension apiserver: execute

The rest of this section describes these steps in detail.

The flow can be seen in the following diagram.

aggregation auth flows

The source for the above swimlanes can be found in the source of this document.

Kubernetes Apiserver Authentication and Authorization

A request to an API path that is served by an extension apiserver begins the same way as all API requests: communication to the Kubernetes apiserver. This path already has been registered with the Kubernetes apiserver by the extension apiserver.

The user communicates with the Kubernetes apiserver, requesting access to the path. The Kubernetes apiserver uses standard authentication and authorization configured with the Kubernetes apiserver to authenticate the user and authorize access to the specific path.

For an overview of authenticating to a Kubernetes cluster, see ["Authenticating to a Cluster"](#). For an overview of authorization of access to Kubernetes cluster resources, see ["Authorization Overview"](#).

Everything to this point has been standard Kubernetes API requests, authentication and authorization.

The Kubernetes apiserver now is prepared to send the request to the extension apiserver.

Kubernetes Apiserver Proxies the Request

The Kubernetes apiserver now will send, or proxy, the request to the extension apiserver that registered to handle the request. In order to do so, it needs to know several things:

1. How should the Kubernetes apiserver authenticate to the extension apiserver, informing the extension apiserver that the request, which comes over the network, is coming from a valid Kubernetes apiserver?
2. How should the Kubernetes apiserver inform the extension apiserver of the username and group for which the original request was authenticated?

In order to provide for these two, you must configure the Kubernetes apiserver using several flags.

Kubernetes Apiserver Client Authentication

The Kubernetes apiserver connects to the extension apiserver over TLS, authenticating itself using a client certificate. You must provide the following to the Kubernetes apiserver upon startup, using the provided flags:

- private key file via `--proxy-client-key-file`
- signed client certificate file via `--proxy-client-cert-file`

- certificate of the CA that signed the client certificate file via `--requestheader-client-ca-file`
- valid Common Name values (CNs) in the signed client certificate via `--requestheader-allowed-names`

The Kubernetes apiserver will use the files indicated by `--proxy-client-*file` to authenticate to the extension apiserver. In order for the request to be considered valid by a compliant extension apiserver, the following conditions must be met:

1. The connection must be made using a client certificate that is signed by the CA whose certificate is in `--requestheader-client-ca-file`.
2. The connection must be made using a client certificate whose CN is one of those listed in `--requestheader-allowed-names`.

Note:

You can set this option to blank as `--requestheader-allowed-names=""`. This will indicate to an extension apiserver that *any* CN is acceptable.

When started with these options, the Kubernetes apiserver will:

1. Use them to authenticate to the extension apiserver.
2. Create a configmap in the kube-system namespace called `extension-apiserver-authentication`, in which it will place the CA certificate and the allowed CNs. These in turn can be retrieved by extension apiservers to validate requests.

Note that the same client certificate is used by the Kubernetes apiserver to authenticate against *all* extension apiservers. It does not create a client certificate per extension apiserver, but rather a single one to authenticate as the Kubernetes apiserver. This same one is reused for all extension apiserver requests.

Original Request Username and Group

When the Kubernetes apiserver proxies the request to the extension apiserver, it informs the extension apiserver of the username and group with which the original request successfully authenticated. It provides these in http headers of its proxied request. You must inform the Kubernetes apiserver of the names of the headers to be used.

- the header in which to store the username via `--requestheader-username-headers`
- the header in which to store the group via `--requestheader-group-headers`
- the prefix to append to all extra headers via `--requestheader-extra-headers-prefix`

These header names are also placed in the `extension-apiserver-authentication` configmap, so they can be retrieved and used by extension apiservers.

Extension Apiserver Authenticates the Request

The extension apiserver, upon receiving a proxied request from the Kubernetes apiserver, must validate that the request actually did come from a valid authenticating proxy, which role the Kubernetes apiserver is fulfilling. The extension apiserver validates it via:

1. Retrieve the following from the configmap in kube-system, as described above:
 - Client CA certificate
 - List of allowed names (CNs)

- Header names for username, group and extra info
- 2. Check that the TLS connection was authenticated using a client certificate which:
 - Was signed by the CA whose certificate matches the retrieved CA certificate.
 - Has a CN in the list of allowed CNs, unless the list is blank, in which case all CNs are allowed.
 - Extract the username and group from the appropriate headers

If the above passes, then the request is a valid proxied request from a legitimate authenticating proxy, in this case the Kubernetes apiserver.

Note that it is the responsibility of the extension apiserver implementation to provide the above. Many do it by default, leveraging the `k8s.io/apiserver/` package. Others may provide options to override it using command-line options.

In order to have permission to retrieve the configmap, an extension apiserver requires the appropriate role. There is a default role named `extension-apiserver-authentication-reader` in the `kube-system` namespace which can be assigned.

Extension Apiserver Authorizes the Request

The extension apiserver now can validate that the user/group retrieved from the headers are authorized to execute the given request. It does so by sending a standard [SubjectAccessReview](#) request to the Kubernetes apiserver.

In order for the extension apiserver to be authorized itself to submit the `SubjectAccessReview` request to the Kubernetes apiserver, it needs the correct permissions. Kubernetes includes a default `ClusterRole` named `system:auth-delegator` that has the appropriate permissions. It can be granted to the extension apiserver's service account.

Extension Apiserver Executes

If the `SubjectAccessReview` passes, the extension apiserver executes the request.

Enable Kubernetes Apiserver flags

Enable the aggregation layer via the following kube-apiserver flags. They may have already been taken care of by your provider.

```
--requestheader-client-ca-file=<path to aggregator CA cert>
--requestheader-allowed-names=front-proxy-client
--requestheader-extra-headers-prefix=X-Remote-Extra-
--requestheader-group-headers=X-Remote-Group
--requestheader-username-headers=X-Remote-User
--proxy-client-cert-file=<path to aggregator proxy cert>
--proxy-client-key-file=<path to aggregator proxy key>
```

CA Reusage and Conflicts

The Kubernetes apiserver has two client CA options:

- `--client-ca-file`
- `--requestheader-client-ca-file`

Each of these functions independently and can conflict with each other, if not used correctly.

- `--client-ca-file`: When a request arrives to the Kubernetes apiserver, if this option is enabled, the Kubernetes apiserver checks the certificate of the request. If it is signed by one of the CA certificates in the file referenced by `--client-ca-file`, then the request is treated as a legitimate request, and the user is the value of the common name `CN=`, while the group is the organization `O=`. See the [documentation on TLS authentication](#).
- `--requestheader-client-ca-file`: When a request arrives to the Kubernetes apiserver, if this option is enabled, the Kubernetes apiserver checks the certificate of the request. If it is signed by one of the CA certificates in the file reference by `--requestheader-client-ca-file`, then the request is treated as a potentially legitimate request. The Kubernetes apiserver then checks if the common name `CN=` is one of the names in the list provided by `--requestheader-allowed-names`. If the name is allowed, the request is approved; if it is not, the request is not.

If *both* `--client-ca-file` and `--requestheader-client-ca-file` are provided, then the request first checks the `--requestheader-client-ca-file` CA and then the `--client-ca-file`. Normally, different CAs, either root CAs or intermediate CAs, are used for each of these options; regular client requests match against `--client-ca-file`, while aggregation requests match against `--requestheader-client-ca-file`. However, if both use the *same* CA, then client requests that normally would pass via `--client-ca-file` will fail, because the CA will match the CA in `--requestheader-client-ca-file`, but the common name `CN=` will **not** match one of the acceptable common names in `--requestheader-allowed-names`. This can cause your kubelets and other control plane components, as well as end-users, to be unable to authenticate to the Kubernetes apiserver.

For this reason, use different CA certs for the `--client-ca-file` option - to authorize control plane components and end-users - and the `--requestheader-client-ca-file` option - to authorize aggregation apiserver requests.

Warning:

Do **not** reuse a CA that is used in a different context unless you understand the risks and the mechanisms to protect the CA's usage.

If you are not running kube-proxy on a host running the API server, then you must make sure that the system is enabled with the following kube-apiserver flag:

```
--enable-aggregator-routing=true
```

Register APIService objects

You can dynamically configure what client requests are proxied to extension apiserver. The following is an example registration:

```
apiVersion: apiregistration.k8s.io/v1
kind: APIService
metadata:
  name: <name of the registration object>
spec:
  group: <API group name this extension apiserver hosts>
  version: <API version this extension apiserver hosts>
```

```
groupPriorityMinimum: <priority this APIService for this group, see API documentation>
versionPriority: <prioritizes ordering of this version within a group, see API documentation>
service:
  namespace: <namespace of the extension apiserver service>
  name: <name of the extension apiserver service>
caBundle: <pem encoded ca cert that signs the server cert used by the webhook>
```

The name of an APIService object must be a valid [path segment name](#).

Contacting the extension apiserver

Once the Kubernetes apiserver has determined a request should be sent to an extension apiserver, it needs to know how to contact it.

The service stanza is a reference to the service for an extension apiserver. The service namespace and name are required. The port is optional and defaults to 443.

Here is an example of an extension apiserver that is configured to be called on port "1234", and to verify the TLS connection against the ServerName my-service-name.my-service-namespace.svc using a custom CA bundle.

```
apiVersion: apiregistration.k8s.io/v1
kind: APIService
...
spec:
  ...
  service:
    namespace: my-service-namespace
    name: my-service-name
    port: 1234
  caBundle: "Ci0tLS0tQk...<base64-encoded PEM bundle>...tLS0K"
...
```

What's next

- [Set up an extension api-server](#) to work with the aggregation layer.
- For a high level overview, see [Extending the Kubernetes API with the aggregation layer](#).
- Learn how to [Extend the Kubernetes API Using Custom Resource Definitions](#).

Use Custom Resources

[Extend the Kubernetes API with CustomResourceDefinitions](#)

[Versions in CustomResourceDefinitions](#)

Extend the Kubernetes API with CustomResourceDefinitions

This page shows how to install a [custom resource](#) into the Kubernetes API by creating a [CustomResourceDefinition](#).

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version 1.16. To check the version, enter `kubectl version`. If you are using an older version of Kubernetes that is still supported, switch to the documentation for that version to see advice that is relevant for your cluster.

Create a CustomResourceDefinition

When you create a new CustomResourceDefinition (CRD), the Kubernetes API Server creates a new RESTful resource path for each version you specify. The custom resource created from a CRD object can be either namespaced or cluster-scoped, as specified in the CRD's `spec.scope` field. As with existing built-in objects, deleting a namespace deletes all custom objects in that namespace. CustomResourceDefinitions themselves are non-namespaced and are available to all namespaces.

For example, if you save the following CustomResourceDefinition to `resourcedefinition.yaml`:

```
apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
metadata:
  # name must match the spec fields below, and be in the form: <plural>.<group>
  name: crontabs.stable.example.com
spec:
  # group name to use for REST API: /apis/<group>/<version>
  group: stable.example.com
  # list of versions supported by this CustomResourceDefinition
  versions:
    - name: v1
      # Each version can be enabled/disabled by Served flag.
      served: true
      # One and only one version must be marked as the storage version.
      storage: true
    schema:
      openAPIV3Schema:
        type: object
        properties:
```

```

spec:
  type: object
  properties:
    cronSpec:
      type: string
    image:
      type: string
    replicas:
      type: integer
# either Namespaced or Cluster
scope: Namespaced
names:
  # plural name to be used in the URL: /apis/<group>/<version>/<plural>
  plural: crontabs
  # singular name to be used as an alias on the CLI and for display
  singular: crontab
  # kind is normally the CamelCased singular type. Your resource manifests use this.
  kind: CronTab
  # shortNames allow shorter string to match your resource on the CLI
  shortNames:
    - ct

```

and create it:

```
kubectl apply -f resourcedefinition.yaml
```

Then a new namespaced RESTful API endpoint is created at:

```
/apis/stable.example.com/v1/namespaces/*/crontabs/...
```

This endpoint URL can then be used to create and manage custom objects. The kind of these objects will be CronTab from the spec of the CustomResourceDefinition object you created above.

It might take a few seconds for the endpoint to be created. You can watch the Established condition of your CustomResourceDefinition to be true or watch the discovery information of the API server for your resource to show up.

Create custom objects

After the CustomResourceDefinition object has been created, you can create custom objects. Custom objects can contain custom fields. These fields can contain arbitrary JSON. In the following example, the cronSpec and image custom fields are set in a custom object of kind CronTab. The kind CronTab comes from the spec of the CustomResourceDefinition object you created above.

If you save the following YAML to my-crontab.yaml:

```

apiVersion: "stable.example.com/v1"
kind: CronTab
metadata:
  name: my-new-cron-object
spec:

```

```
cronSpec: "* * * * */5"
image: my-awesome-cron-image
```

and create it:

```
kubectl apply -f my-crontab.yaml
```

You can then manage your CronTab objects using kubectl. For example:

```
kubectl get crontab
```

Should print a list like this:

| NAME | AGE |
|--------------------|-----|
| my-new-cron-object | 6s |

Resource names are not case-sensitive when using kubectl, and you can use either the singular or plural forms defined in the CRD, as well as any short names.

You can also view the raw YAML data:

```
kubectl get ct -o yaml
```

You should see that it contains the custom cronSpec and image fields from the YAML you used to create it:

```
apiVersion: v1
items:
- apiVersion: stable.example.com/v1
  kind: CronTab
  metadata:
    annotations:
      kubectl.kubernetes.io/last-applied-configuration: |
        {"apiVersion":"stable.example.com/v1","kind":"CronTab","metadata":{"annotations":
{"name":"my-new-cron-object","namespace":"default"},"spec":{"cronSpec":"* * * * */
5","image":"my-awesome-cron-image"}}
    creationTimestamp: "2021-06-20T07:35:27Z"
    generation: 1
    name: my-new-cron-object
    namespace: default
    resourceVersion: "1326"
    uid: 9aab1d66-628e-41bb-a422-57b8b3b1f5a9
  spec:
    cronSpec: '* * * * */5'
    image: my-awesome-cron-image
kind: List
metadata:
  resourceVersion: ""
  selfLink: ""
```

Delete a CustomResourceDefinition

When you delete a CustomResourceDefinition, the server will uninstall the RESTful API endpoint and delete all custom objects stored in it.

```
kubectl delete -f resourcedefinition.yaml
kubectl get crontabs
```

Error from server (NotFound): Unable to list {"stable.example.com" "v1" "crontabs"}: the server could not find the requested resource (get crontabs.stable.example.com)

If you later recreate the same CustomResourceDefinition, it will start out empty.

Specifying a structural schema

CustomResources store structured data in custom fields (alongside the built-in fields `apiVersion`, `kind` and `metadata`, which the API server validates implicitly). With [OpenAPI v3.0 validation](#) a schema can be specified, which is validated during creation and updates, compare below for details and limits of such a schema.

With `apiextensions.k8s.io/v1` the definition of a structural schema is mandatory for CustomResourceDefinitions. In the beta version of CustomResourceDefinition, the structural schema was optional.

A structural schema is an [OpenAPI v3.0 validation schema](#) which:

1. specifies a non-empty type (via `type` in OpenAPI) for the root, for each specified field of an object node (via `properties` or `additionalProperties` in OpenAPI) and for each item in an array node (via `items` in OpenAPI), with the exception of:
 - a node with `x-kubernetes-int-or-string: true`
 - a node with `x-kubernetes-preserve-unknown-fields: true`
2. for each field in an object and each item in an array which is specified within any of `allOf`, `anyOf`, `oneOf` or `not`, the schema also specifies the field/item outside of those logical junctors (compare example 1 and 2).
3. does not set `description`, `type`, `default`, `additionalProperties`, `nullable` within an `allOf`, `anyOf`, `oneOf` or `not`, with the exception of the two pattern for `x-kubernetes-int-or-string: true` (see below).
4. if `metadata` is specified, then only restrictions on `metadata.name` and `metadata.generateName` are allowed.

Non-structural example 1:

```
allOf:
- properties:
  foo:
  ...
```

conflicts with rule 2. The following would be correct:

```
properties:
  foo:
  ...
```

```
allOf:  
- properties:  
  foo:  
  ...
```

Non-structural example 2:

```
allOf:  
- items:  
  properties:  
  foo:  
  ...
```

conflicts with rule 2. The following would be correct:

```
items:  
  properties:  
  foo:  
  ...  
allOf:  
- items:  
  properties:  
  foo:  
  ...
```

Non-structural example 3:

```
properties:  
  foo:  
    pattern: "abc"  
  metadata:  
    type: object  
    properties:  
      name:  
        type: string  
        pattern: "^a"  
      finalizers:  
        type: array  
        items:  
          type: string  
          pattern: "my-finalizer"  
anyOf:  
- properties:  
  bar:  
    type: integer  
    minimum: 42  
required: ["bar"]  
description: "foo bar object"
```

is not a structural schema because of the following violations:

- the type at the root is missing (rule 1).
- the type of foo is missing (rule 1).
- bar inside of anyOf is not specified outside (rule 2).

- bar's type is within anyOf (rule 3).
- the description is set within anyOf (rule 3).
- metadata.finalizers might not be restricted (rule 4).

In contrast, the following, corresponding schema is structural:

```

type: object
description: "foo bar object"
properties:
  foo:
    type: string
    pattern: "abc"
  bar:
    type: integer
  metadata:
    type: object
    properties:
      name:
        type: string
        pattern: "^a"
anyOf:
- properties:
  bar:
    minimum: 42
    required: ["bar"]

```

Violations of the structural schema rules are reported in the NonStructural condition in the CustomResourceDefinition.

Field pruning

CustomResourceDefinitions store validated resource data in the cluster's persistence store, [etcd](#). As with native Kubernetes resources such as [ConfigMap](#), if you specify a field that the API server does not recognize, the unknown field is *pruned* (removed) before being persisted.

CRDs converted from `apiextensions.k8s.io/v1beta1` to `apiextensions.k8s.io/v1` might lack structural schemas, and `spec.preserveUnknownFields` might be true.

For legacy CustomResourceDefinition objects created as `apiextensions.k8s.io/v1beta1` with `spec.preserveUnknownFields` set to true, the following is also true:

- Pruning is not enabled.
- You can store arbitrary data.

For compatibility with `apiextensions.k8s.io/v1`, update your custom resource definitions to:

1. Use a structural OpenAPI schema.
2. Set `spec.preserveUnknownFields` to false.

If you save the following YAML to `my-crontab.yaml`:

```

apiVersion: "stable.example.com/v1"
kind: CronTab
metadata:

```

```
name: my-new-cron-object
spec:
  cronSpec: "* * * * */5"
  image: my-awesome-cron-image
  someRandomField: 42
```

and create it:

```
kubectl create --validate=false -f my-crontab.yaml -o yaml
```

Your output is similar to:

```
apiVersion: stable.example.com/v1
kind: CronTab
metadata:
  creationTimestamp: 2017-05-31T12:56:35Z
  generation: 1
  name: my-new-cron-object
  namespace: default
  resourceVersion: "285"
  uid: 9423255b-4600-11e7-af6a-28d2447dc82b
spec:
  cronSpec: '* * * * */5'
  image: my-awesome-cron-image
```

Notice that the field `someRandomField` was pruned.

This example turned off client-side validation to demonstrate the API server's behavior, by adding the `--validate=false` command line option. Because the [OpenAPI validation schemas are also published](#) to clients, `kubectl` also checks for unknown fields and rejects those objects well before they would be sent to the API server.

Controlling pruning

By default, all unspecified fields for a custom resource, across all versions, are pruned. It is possible though to opt-out of that for specific sub-trees of fields by adding `x-kubernetes-preserve-unknown-fields: true` in the [structural OpenAPI v3 validation schema](#).

For example:

```
type: object
properties:
  json:
    x-kubernetes-preserve-unknown-fields: true
```

The field `json` can store any JSON value, without anything being pruned.

You can also partially specify the permitted JSON; for example:

```
type: object
properties:
  json:
    x-kubernetes-preserve-unknown-fields: true
```

```
type: object
description: this is arbitrary JSON
```

With this, only object type values are allowed.

Pruning is enabled again for each specified property (or `additionalProperties`):

```
type: object
properties:
  json:
    x-kubernetes-preserve-unknown-fields: true
    type: object
    properties:
      spec:
        type: object
        properties:
          foo:
            type: string
          bar:
            type: string
```

With this, the value:

```
json:
  spec:
    foo: abc
    bar: def
    something: x
  status:
    something: x
```

is pruned to:

```
json:
  spec:
    foo: abc
    bar: def
  status:
    something: x
```

This means that the `something` field in the specified `spec` object is pruned, but everything outside is not.

IntOrString

Nodes in a schema with `x-kubernetes-int-or-string: true` are excluded from rule 1, such that the following is structural:

```
type: object
properties:
  foo:
    x-kubernetes-int-or-string: true
```

Also those nodes are partially excluded from rule 3 in the sense that the following two patterns are allowed (exactly those, without variations in order to additional fields):

```
x-kubernetes-int-or-string: true
anyOf:
  - type: integer
  - type: string
...
```

and

```
x-kubernetes-int-or-string: true
allOf:
  - anyOf:
    - type: integer
    - type: string
  - ... # zero or more
...
```

With one of those specification, both an integer and a string validate.

In [Validation Schema Publishing](#), `x-kubernetes-int-or-string: true` is unfolded to one of the two patterns shown above.

RawExtension

RawExtensions (as in [runtime.RawExtension](#)) holds complete Kubernetes objects, i.e. with `apiVersion` and `kind` fields.

It is possible to specify those embedded objects (both completely without constraints or partially specified) by setting `x-kubernetes-embedded-resource: true`. For example:

```
type: object
properties:
  foo:
    x-kubernetes-embedded-resource: true
    x-kubernetes-preserve-unknown-fields: true
```

Here, the field `foo` holds a complete object, e.g.:

```
foo:
  apiVersion: v1
  kind: Pod
  spec:
  ...
```

Because `x-kubernetes-preserve-unknown-fields: true` is specified alongside, nothing is pruned. The use of `x-kubernetes-preserve-unknown-fields: true` is optional though.

With `x-kubernetes-embedded-resource: true`, the `apiVersion`, `kind` and `metadata` are implicitly specified and validated.

Serving multiple versions of a CRD

See [Custom resource definition versioning](#) for more information about serving multiple versions of your CustomResourceDefinition and migrating your objects from one version to another.

Advanced topics

Finalizers

Finalizers allow controllers to implement asynchronous pre-delete hooks. Custom objects support finalizers similar to built-in objects.

You can add a finalizer to a custom object like this:

```
apiVersion: "stable.example.com/v1"
kind: CronTab
metadata:
  finalizers:
    - stable.example.com/finalizer
```

Identifiers of custom finalizers consist of a domain name, a forward slash and the name of the finalizer. Any controller can add a finalizer to any object's list of finalizers.

The first delete request on an object with finalizers sets a value for the `metadata.deletionTimestamp` field but does not delete it. Once this value is set, entries in the finalizers list can only be removed. While any finalizers remain it is also impossible to force the deletion of an object.

When the `metadata.deletionTimestamp` field is set, controllers watching the object execute any finalizers they handle and remove the finalizer from the list after they are done. It is the responsibility of each controller to remove its finalizer from the list.

The value of `metadata.deletionGracePeriodSeconds` controls the interval between polling updates.

Once the list of finalizers is empty, meaning all finalizers have been executed, the resource is deleted by Kubernetes.

Validation

Custom resources are validated via [OpenAPI v3 schemas](#), by x-kubernetes-validations when the [Validation Rules feature](#) is enabled, and you can add additional validation using [admission webhooks](#).

Additionally, the following restrictions are applied to the schema:

- These fields cannot be set:
 - definitions,
 - dependencies,
 - deprecated,

- discriminator,
 - id,
 - patternProperties,
 - readOnly,
 - writeOnly,
 - xml,
 - \$ref.
- The field `uniqueItems` cannot be set to `true`.
 - The field `additionalProperties` cannot be set to `false`.
 - The field `additionalProperties` is mutually exclusive with `properties`.

The `x-kubernetes-validations` extension can be used to validate custom resources using [Common Expression Language \(CEL\)](#) expressions when the [Validation rules](#) feature is enabled and the `CustomResourceDefinition` schema is a [structural schema](#).

Refer to the [structural schemas](#) section for other restrictions and `CustomResourceDefinition` features.

The schema is defined in the `CustomResourceDefinition`. In the following example, the `CustomResourceDefinition` applies the following validations on the custom object:

- `spec.cronSpec` must be a string and must be of the form described by the regular expression.
- `spec.replicas` must be an integer and must have a minimum value of 1 and a maximum value of 10.

Save the `CustomResourceDefinition` to `resourcedefinition.yaml`:

```
apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
metadata:
  name: crontabs.stable.example.com
spec:
  group: stable.example.com
  versions:
    - name: v1
      served: true
      storage: true
      schema:
        # openAPIV3Schema is the schema for validating custom objects.
        openAPIV3Schema:
          type: object
          properties:
            spec:
              type: object
              properties:
                cronSpec:
                  type: string
                  pattern: '^(\\d+|\\*)(\\/\\d+)?(\\s+(\\d+|\\*)(\\/\\d+)?){4}$'
            image:
              type: string
```

```
    replicas:
      type: integer
      minimum: 1
      maximum: 10
  scope: Namespaced
  names:
    plural: crontabs
    singular: crontab
    kind: CronTab
    shortNames:
    - ct
```

and create it:

```
kubectl apply -f resourcedefinition.yaml
```

A request to create a custom object of kind CronTab is rejected if there are invalid values in its fields. In the following example, the custom object contains fields with invalid values:

- spec.cronSpec does not match the regular expression.
- spec.replicas is greater than 10.

If you save the following YAML to my-crontab.yaml:

```
apiVersion: "stable.example.com/v1"
kind: CronTab
metadata:
  name: my-new-cron-object
spec:
  cronSpec: "* * * *"
  image: my-awesome-cron-image
  replicas: 15
```

and attempt to create it:

```
kubectl apply -f my-crontab.yaml
```

then you get an error:

```
The CronTab "my-new-cron-object" is invalid: [: Invalid value: map[string]interface {}
{"apiVersion":"stable.example.com/v1", "kind":"CronTab", "metadata":map[string]interface {}
{"name":"my-new-cron-object", "namespace":"default", "deletionTimestamp":interface {}(nil),
"deletionGracePeriodSeconds":(*int64)(nil), "creationTimestamp":"2017-09-05T05:20:07Z",
"uid":"e14d79e7-91f9-11e7-a598-f0761cb232d1", "clusterName":""}, "spec":map[string]interface {}
{"cronSpec":"* * * *", "image":"my-awesome-cron-image", "replicas":15}}:
validation failure list:
spec.cronSpec in body should match '^(\\d+|\\*)(\\d+)?(\\s+(\\d+|\\*)(\\d+)?){4}$'
spec.replicas in body should be less than or equal to 10
```

If the fields contain valid values, the object creation request is accepted.

Save the following YAML to my-crontab.yaml:

```
apiVersion: "stable.example.com/v1"
kind: CronTab
metadata:
  name: my-new-cron-object
spec:
  cronSpec: "* * * * */5"
  image: my-awesome-cron-image
  replicas: 5
```

And create it:

```
kubectl apply -f my-crontab.yaml
crontab "my-new-cron-object" created
```

Validation ratcheting

FEATURE STATE: Kubernetes v1.30 [beta]

If you are using a version of Kubernetes older than v1.30, you need to explicitly enable the `CRDValidationRatcheting` [feature gate](#) to use this behavior, which then applies to all `CustomResourceDefinitions` in your cluster.

Provided you enabled the feature gate, Kubernetes implements *validation ratcheting* for `CustomResourceDefinitions`. The API server is willing to accept updates to resources that are not valid after the update, provided that each part of the resource that failed to validate was not changed by the update operation. In other words, any invalid part of the resource that remains invalid must have already been wrong. You cannot use this mechanism to update a valid resource so that it becomes invalid.

This feature allows authors of CRDs to confidently add new validations to the OpenAPIV3 schema under certain conditions. Users can update to the new schema safely without bumping the version of the object or breaking workflows.

While most validations placed in the OpenAPIV3 schema of a CRD support ratcheting, there are a few exceptions. The following OpenAPIV3 schema validations are not supported by ratcheting under the implementation in Kubernetes 1.30 and if violated will continue to throw an error as normally:

- Quantors
 - `allOf`
 - `oneOf`
 - `anyOf`
 - `not`
 - any validations in a descendent of one of these fields
- `x-kubernetes-validations` For Kubernetes 1.28, CRD validation rules][`#validation-rules`) are ignored by ratcheting. Starting with Alpha 2 in Kubernetes 1.29, `x-kubernetes-validations` are ratcheted only if they do not refer to `oldSelf`.

Transition Rules are never ratcheted: only errors raised by rules that do not use `oldSelf` will be automatically ratcheted if their values are unchanged.

To write custom ratcheting logic for CEL expressions, check out [optionalOldSelf](#).

- **x-kubernetes-list-type** Errors arising from changing the list type of a subschema will not be ratcheted. For example adding set onto a list with duplicates will always result in an error.
- **x-kubernetes-map-keys** Errors arising from changing the map keys of a list schema will not be ratcheted.
- **required** Errors arising from changing the list of required fields will not be ratcheted.
- **properties** Adding/removing/modifying the names of properties is not ratcheted, but changes to validations in each properties' schemas and subschemas may be ratcheted if the name of the property stays the same.
- **additionalProperties** To remove a previously specified additionalProperties validation will not be ratcheted.
- **metadata** Errors that come from Kubernetes' built-in validation of an object's metadata are not ratcheted (such as object name, or characters in a label value). If you specify your own additional rules for the metadata of a custom resource, that additional validation will be ratcheted.

Validation rules

FEATURE STATE: Kubernetes v1.29 [stable]

Validation rules use the [Common Expression Language \(CEL\)](#) to validate custom resource values. Validation rules are included in CustomResourceDefinition schemas using the x-kubernetes-validations extension.

The Rule is scoped to the location of the x-kubernetes-validations extension in the schema. And self variable in the CEL expression is bound to the scoped value.

All validation rules are scoped to the current object: no cross-object or stateful validation rules are supported.

For example:

```
...
openAPIV3Schema:
  type: object
  properties:
    spec:
      type: object
      x-kubernetes-validations:
        - rule: "self.minReplicas <= self.replicas"
          message: "replicas should be greater than or equal to minReplicas."
        - rule: "self.replicas <= self.maxReplicas"
          message: "replicas should be smaller than or equal to maxReplicas."
      properties:
        ...
        minReplicas:
          type: integer
        replicas:
          type: integer
```

```
maxReplicas:
  type: integer
required:
- minReplicas
- replicas
- maxReplicas
```

will reject a request to create this custom resource:

```
apiVersion: "stable.example.com/v1"
kind: CronTab
metadata:
  name: my-new-cron-object
spec:
  minReplicas: 0
  replicas: 20
  maxReplicas: 10
```

with the response:

The CronTab "my-new-cron-object" is invalid:

* spec: Invalid value: map[string]interface {}{"maxReplicas":10, "minReplicas":0, "replicas":20}: replicas should be smaller than or equal to maxReplicas.

x-kubernetes-validations could have multiple rules. The rule under x-kubernetes-validations represents the expression which will be evaluated by CEL. The message represents the message displayed when validation fails. If message is unset, the above response would be:

The CronTab "my-new-cron-object" is invalid:

* spec: Invalid value: map[string]interface {}{"maxReplicas":10, "minReplicas":0, "replicas":20}: failed rule: self.replicas <= self.maxReplicas

Note:

You can quickly test CEL expressions in [CEL Playground](#).

Validation rules are compiled when CRDs are created/updated. The request of CRDs create/update will fail if compilation of validation rules fail. Compilation process includes type checking as well.

The compilation failure:

- `no_matching_overload`: this function has no overload for the types of the arguments.

For example, a rule like `self == true` against a field of integer type will get error:

```
Invalid value: apiextensions.ValidationRule{Rule:"self == true", Message:"": compilation
failed: ERROR: \<input>:1:6: found no matching overload for '_==' applied to '(int, bool)'
```

- `no_such_field`: does not contain the desired field.

For example, a rule like `self.nonExistingField > 0` against a non-existing field will return the following error:

```
Invalid value: apiextensions.ValidationRule{Rule:"self.nonExistingField > 0", Message:""}:
compilation failed: ERROR: \<input>:1:5: undefined field 'nonExistingField'
```

- invalid argument: invalid argument to macros.

For example, a rule like `has(self)` will return error:

```
Invalid value: apiextensions.ValidationRule{Rule:"has(self)", Message:""}: compilation
failed: ERROR: <input>:1:4: invalid argument to has() macro
```

Validation Rules Examples:

| Rule | Purpose |
|---|--|
| <code>self.minReplicas <= self.replicas && self.replicas <= self.maxReplicas</code> | Validate that the three fields defining replicas are ordered appropriately |
| <code>'Available' in self.stateCounts</code> | Validate that an entry with the 'Available' key exists in a map |
| <code>(size(self.list1) == 0) != (size(self.list2) == 0)</code> | Validate that one of two lists is non-empty, but not both |
| <code>!('MY_KEY' in self.map1) self['MY_KEY'].matches('^ [a-zA-Z]*\$')</code> | Validate the value of a map for a specific key, if it is in the map |
| <code>self.envvars.filter(e, e.name == 'MY_ENV').all(e, e.value.matches('^ [a-zA-Z]*\$'))</code> | Validate the 'value' field of a listMap entry where key field 'name' is 'MY_ENV' |
| <code>has(self.expired) && self.created + self.ttl < self.expired</code> | Validate that 'expired' date is after a 'create' date plus a 'ttl' duration |
| <code>self.health.startsWith('ok')</code> | Validate a 'health' string field has the prefix 'ok' |
| <code>self.widgets.exists(w, w.key == 'x' && w.foo < 10)</code> | Validate that the 'foo' property of a listMap item with a key 'x' is less than 10 |
| <code>type(self) == string ? self == '100%' : self == 1000</code> | Validate an int-or-string field for both the int and string cases |
| <code>self.metadata.name.startsWith(self.prefix)</code> | Validate that an object's name has the prefix of another field value |
| <code>self.set1.all(e, !(e in self.set2))</code> | Validate that two listSets are disjoint |
| <code>size(self.names) == size(self.details) && self.names.all(n, n in self.details)</code> | Validate the 'details' map is keyed by the items in the 'names' listSet |
| <code>size(self.clusters.filter(c, c.name == self.primary)) == 1</code> | Validate that the 'primary' property has one and only one occurrence in the 'clusters' listMap |

Xref: [Supported evaluation on CEL](#)

- If the Rule is scoped to the root of a resource, it may make field selection into any fields declared in the OpenAPIv3 schema of the CRD as well as `apiVersion`, `kind`, `metadata.name` and `metadata.generateName`. This includes selection of fields in both the spec and status in the same expression:

```
...
openAPIV3Schema:
  type: object
```

```

x-kubernetes-validations:
  - rule: "self.status.availableReplicas >= self.spec.minReplicas"
properties:
  spec:
    type: object
    properties:
      minReplicas:
        type: integer
    ...
  status:
    type: object
    properties:
      availableReplicas:
        type: integer

```

- If the Rule is scoped to an object with properties, the accessible properties of the object are field selectable via `self.field` and field presence can be checked via `has(self.field)`. Null valued fields are treated as absent fields in CEL expressions.

```

...
openAPIV3Schema:
  type: object
  properties:
    spec:
      type: object
      x-kubernetes-validations:
        - rule: "has(self.foo)"
      properties:
        ...
        foo:
          type: integer

```

- If the Rule is scoped to an object with `additionalProperties` (i.e. a map) the value of the map are accessible via `self[mapKey]`, map containment can be checked via `mapKey` in `self` and all entries of the map are accessible via CEL macros and functions such as `self.all(...)`.

```

...
openAPIV3Schema:
  type: object
  properties:
    spec:
      type: object
      x-kubernetes-validations:
        - rule: "self['xyz'].foo > 0"
      additionalProperties:
        ...
        type: object
        properties:
          foo:
            type: integer

```

- If the Rule is scoped to an array, the elements of the array are accessible via `self[i]` and also by macros and functions.

```

...
openAPIV3Schema:
  type: object
  properties:
    ...
    foo:
      type: array
      x-kubernetes-validations:
        - rule: "size(self) == 1"
      items:
        type: string

```

- If the Rule is scoped to a scalar, `self` is bound to the scalar value.

```

...
openAPIV3Schema:
  type: object
  properties:
    spec:
      type: object
      properties:
        ...
        foo:
          type: integer
          x-kubernetes-validations:
            - rule: "self > 0"

```

Examples:

| type of the field rule scoped to | Rule example |
|----------------------------------|--|
| root object | <code>self.status.actual <= self.spec.maxDesired</code> |
| map of objects | <code>self.components['Widget'].priority < 10</code> |
| list of integers | <code>self.values.all(value, value >= 0 && value < 100)</code> |
| string | <code>self.startsWith('kube')</code> |

The `apiVersion`, `kind`, `metadata.name` and `metadata.generateName` are always accessible from the root of the object and from any x-kubernetes-embedded-resource annotated objects. No other metadata properties are accessible.

Unknown data preserved in custom resources via `x-kubernetes-preserve-unknown-fields` is not accessible in CEL expressions. This includes:

- Unknown field values that are preserved by object schemas with `x-kubernetes-preserve-unknown-fields`.
- Object properties where the property schema is of an "unknown type". An "unknown type" is recursively defined as:
 - A schema with no type and `x-kubernetes-preserve-unknown-fields` set to true
 - An array where the items schema is of an "unknown type"
 - An object where the `additionalProperties` schema is of an "unknown type"

Only property names of the form `[a-zA-Z_.-][a-zA-Z0-9_.-]*` are accessible. Accessible property names are escaped according to the following rules when accessed in the expression:

| escape sequence | property name equivalent |
|------------------------------|--------------------------------------|
| <code>__underscores__</code> | <code>__</code> |
| <code>__dot__</code> | <code>.</code> |
| <code>__dash__</code> | <code>-</code> |
| <code>__slash__</code> | <code>/</code> |
| <code>__keyword__</code> | CEL RESERVED keyword |

Note: CEL RESERVED keyword needs to match the exact property name to be escaped (e.g. `int` in the word `sprint` would not be escaped).

Examples on escaping:

| property name | rule with escaped property name |
|------------------------|---|
| <code>namespace</code> | <code>self.__namespace__ > 0</code> |
| <code>x-prop</code> | <code>self.x__dash__prop > 0</code> |
| <code>redact__d</code> | <code>self.redact__underscores__d > 0</code> |
| <code>string</code> | <code>self.startsWith('kube')</code> |

Equality on arrays with `x-kubernetes-list-type` of `set` or `map` ignores element order, i.e., `[1, 2] == [2, 1]`. Concatenation on arrays with `x-kubernetes-list-type` use the semantics of the list type:

- `set`: `X + Y` performs a union where the array positions of all elements in `X` are preserved and non-intersecting elements in `Y` are appended, retaining their partial order.
- `map`: `X + Y` performs a merge where the array positions of all keys in `X` are preserved but the values are overwritten by values in `Y` when the key sets of `X` and `Y` intersect. Elements in `Y` with non-intersecting keys are appended, retaining their partial order.

Here is the declarations type mapping between OpenAPIv3 and CEL type:

| OpenAPIv3 type | CEL type |
|--|--|
| 'object' with Properties | object / "message type" |
| 'object' with AdditionalProperties | map |
| 'object' with x-kubernetes-embedded-type | object / "message type", 'apiVersion', 'kind', 'metadata.name' and 'metadata.generateName' are implicitly included in schema |
| 'object' with x-kubernetes-preserve-unknown-fields | object / "message type", unknown fields are NOT accessible in CEL expression |
| x-kubernetes-int-or-string | dynamic object that is either an int or a string, <code>type(value)</code> can be used to check the type |
| 'array' | list |
| 'array' with x-kubernetes-list-type=map | list with map based Equality & unique key guarantees |
| 'array' with x-kubernetes-list-type=set | list with set based Equality & unique entry guarantees |

| OpenAPIv3 type | CEL type |
|--|---------------------------------------|
| 'boolean' | boolean |
| 'number' (all formats) | double |
| 'integer' (all formats) | int (64) |
| 'null' | null_type |
| 'string' | string |
| 'string' with format=byte (base64 encoded) | bytes |
| 'string' with format=date | timestamp (google.protobuf.Timestamp) |
| 'string' with format=datetime | timestamp (google.protobuf.Timestamp) |
| 'string' with format=duration | duration (google.protobuf.Duration) |

xref: [CEL types](#), [OpenAPI types](#), [Kubernetes Structural Schemas](#).

The messageExpression field

Similar to the message field, which defines the string reported for a validation rule failure, messageExpression allows you to use a CEL expression to construct the message string. This allows you to insert more descriptive information into the validation failure message. messageExpression must evaluate a string and may use the same variables that are available to the rule field. For example:

```
x-kubernetes-validations:
- rule: "self.x <= self.maxLimit"
  messageExpression: "'x exceeded max limit of ' + string(self.maxLimit)'
```

Keep in mind that CEL string concatenation (+ operator) does not auto-cast to string. If you have a non-string scalar, use the string(<value>) function to cast the scalar to a string like shown in the above example.

messageExpression must evaluate to a string, and this is checked while the CRD is being written. Note that it is possible to set message and messageExpression on the same rule, and if both are present, messageExpression will be used. However, if messageExpression evaluates to an error, the string defined in message will be used instead, and the messageExpression error will be logged. This fallback will also occur if the CEL expression defined in messageExpression generates an empty string, or a string containing line breaks.

If one of the above conditions are met and no message has been set, then the default validation failure message will be used instead.

messageExpression is a CEL expression, so the restrictions listed in [Resource use by validation functions](#) apply. If evaluation halts due to resource constraints during messageExpression execution, then no further validation rules will be executed.

Setting messageExpression is optional.

The message field

If you want to set a static message, you can supply message rather than messageExpression. The value of message is used as an opaque error string if validation fails.

Setting message is optional.

The reason field

You can add a machine-readable validation failure reason within a validation, to be returned whenever a request fails this validation rule.

For example:

```
x-kubernetes-validations:  
- rule: "self.x <= self.maxLimit"  
  reason: "FieldValueInvalid"
```

The HTTP status code returned to the caller will match the reason of the first failed validation rule. The currently supported reasons are: "FieldValueInvalid", "FieldValueForbidden", "FieldValueRequired", "FieldValueDuplicate". If not set or unknown reasons, default to use "FieldValueInvalid".

Setting reason is optional.

The fieldPath field

You can specify the field path returned when the validation fails.

For example:

```
x-kubernetes-validations:  
- rule: "self.foo.test.x <= self.maxLimit"  
  fieldPath: ".foo.test.x"
```

In the example above, the validation checks the value of field x should be less than the value of maxLimit. If no fieldPath specified, when validation fails, the fieldPath would be default to wherever self scoped. With fieldPath specified, the returned error will have fieldPath properly refer to the location of field x.

The fieldPath value must be a relative JSON path that is scoped to the location of this x-kubernetes-validations extension in the schema. Additionally, it should refer to an existing field within the schema. For example when validation checks if a specific attribute foo under a map testMap, you could set fieldPath to ".testMap.foo" or ".testMap['foo']". If the validation requires checking for unique attributes in two lists, the fieldPath can be set to either of the lists. For example, it can be set to .testList1 or .testList2. It supports child operation to refer to an existing field currently. Refer to [JSONPath support in Kubernetes](#) for more info. The fieldPath field does not support indexing arrays numerically.

Setting fieldPath is optional.

The optionalOldSelf field

FEATURE STATE: Kubernetes v1.30 [beta]

If your cluster does not have [CRD validation ratcheting](#) enabled, the CustomResourceDefinition API doesn't include this field, and trying to set it may result in an error.

The optionalOldSelf field is a boolean field that alters the behavior of [Transition Rules](#) described below. Normally, a transition rule will not evaluate if oldSelf cannot be determined: during object creation or when a new value is introduced in an update.

If optionalOldSelf is set to true, then transition rules will always be evaluated and the type of oldSelf be changed to a CEL [Optional](#) type.

optionalOldSelf is useful in cases where schema authors would like a more control tool [than provided by the default equality based behavior of](#) to introduce newer, usually stricter constraints on new values, while still allowing old values to be "grandfathered" or ratcheted using the older validation.

Example Usage:

| CEL | Description |
|---|-------------|
| <code>`self.foo == "foo"</code> | |
| <code>[oldSelf.orValue(""), self].all(x, ["OldCase1", "OldCase2"].exists(case, x == case))</code> | |
| <code>oldSelf.optMap(o, o.size()).orValue(0) < 4</code> | |

Validation functions

Functions available include:

- CEL standard functions, defined in the [list of standard definitions](#)
- CEL standard [macros](#)
- CEL [extended string function library](#)
- Kubernetes [CEL extension library](#)

Transition rules

A rule that contains an expression referencing the identifier oldSelf is implicitly considered a *transition rule*. Transition rules allow schema authors to prevent certain transitions between two otherwise valid states. For example:

```
type: string
enum: ["low", "medium", "high"]
x-kubernetes-validations:
- rule: "!(self == 'high' && oldSelf == 'low') && !(self == 'low' && oldSelf == 'high')"
  message: cannot transition directly between 'low' and 'high'
```

Unlike other rules, transition rules apply only to operations meeting the following criteria:

- The operation updates an existing object. Transition rules never apply to create operations.
- Both an old and a new value exist. It remains possible to check if a value has been added or removed by placing a transition rule on the parent node. Transition rules are never applied to custom resource creation. When placed on an optional field, a transition rule will not apply to update operations that set or unset the field.
- The path to the schema node being validated by a transition rule must resolve to a node that is comparable between the old object and the new object. For example, list items and

their descendants (spec.foo[10].bar) can't necessarily be correlated between an existing object and a later update to the same object.

Errors will be generated on CRD writes if a schema node contains a transition rule that can never be applied, e.g. "*path*: update rule *rule* cannot be set on schema because the schema or its parent schema is not mergeable".

Transition rules are only allowed on *correlatable portions* of a schema. A portion of the schema is correlatable if all array parent schemas are of type x-kubernetes-list-type=map; any set or atomicarray parent schemas make it impossible to unambiguously correlate a self with oldSelf.

Here are some examples for transition rules:

Transition rules examples

| Use Case | Rule |
|---|---|
| Immutability | self.foo == oldSelf.foo |
| Prevent modification/removal once assigned | oldSelf != 'bar' self == 'bar' or !has(oldSelf.field) has(self.field) |
| Append-only set | self.all(element, element in oldSelf) |
| If previous value was X, new value can only be A or B, not Y or Z | oldSelf != 'X' self in ['A', 'B'] |
| Monotonic (non-decreasing) counters | self >= oldSelf |

Resource use by validation functions

When you create or update a CustomResourceDefinition that uses validation rules, the API server checks the likely impact of running those validation rules. If a rule is estimated to be prohibitively expensive to execute, the API server rejects the create or update operation, and returns an error message. A similar system is used at runtime that observes the actions the interpreter takes. If the interpreter executes too many instructions, execution of the rule will be halted, and an error will result. Each CustomResourceDefinition is also allowed a certain amount of resources to finish executing all of its validation rules. If the sum total of its rules are estimated at creation time to go over that limit, then a validation error will also occur.

You are unlikely to encounter issues with the resource budget for validation if you only specify rules that always take the same amount of time regardless of how large their input is. For example, a rule that asserts that self.foo == 1 does not by itself have any risk of rejection on validation resource budget groups. But if foo is a string and you define a validation rule self.foo.contains("someString"), that rule takes longer to execute depending on how long foo is. Another example would be if foo were an array, and you specified a validation rule self.foo.all(x, x > 5). The cost system always assumes the worst-case scenario if a limit on the length of foo is not given, and this will happen for anything that can be iterated over (lists, maps, etc.).

Because of this, it is considered best practice to put a limit via maxItems, maxProperties, and maxLength for anything that will be processed in a validation rule in order to prevent validation errors during cost estimation. For example, given this schema with one rule:

```
openAPIV3Schema:
  type: object
  properties:
    foo:
```

```
type: array
items:
  type: string
x-kubernetes-validations:
  - rule: "self.all(x, x.contains('a string'))"
```

then the API server rejects this rule on validation budget grounds with error:

```
spec.validation.openAPIV3Schema.properties[spec].properties[foo].x-kubernetes-
validations[0].rule: Forbidden:
CEL rule exceeded budget by more than 100x (try simplifying the rule, or adding maxItems,
maxProperties, and
maxLength where arrays, maps, and strings are used)
```

The rejection happens because `self.all` implies calling `contains()` on every string in `foo`, which in turn will check the given string to see if it contains 'a string'. Without limits, this is a very expensive rule.

If you do not specify any validation limit, the estimated cost of this rule will exceed the per-rule cost limit. But if you add limits in the appropriate places, the rule will be allowed:

```
openAPIV3Schema:
  type: object
  properties:
    foo:
      type: array
      maxItems: 25
      items:
        type: string
        maxLength: 10
      x-kubernetes-validations:
        - rule: "self.all(x, x.contains('a string'))"
```

The cost estimation system takes into account how many times the rule will be executed in addition to the estimated cost of the rule itself. For instance, the following rule will have the same estimated cost as the previous example (despite the rule now being defined on the individual array items):

```
openAPIV3Schema:
  type: object
  properties:
    foo:
      type: array
      maxItems: 25
      items:
        type: string
        x-kubernetes-validations:
          - rule: "self.contains('a string')"
```

If a list inside of a list has a validation rule that uses `self.all`, that is significantly more expensive than a non-nested list with the same rule. A rule that would have been allowed on a non-nested list might need lower limits set on both nested lists in order to be allowed. For example, even without having limits set, the following rule is allowed:

```
openAPIV3Schema:
  type: object
  properties:
    foo:
      type: array
      items:
        type: integer
      x-kubernetes-validations:
        - rule: "self.all(x, x == 5)"
```

But the same rule on the following schema (with a nested array added) produces a validation error:

```
openAPIV3Schema:
  type: object
  properties:
    foo:
      type: array
      items:
        type: array
        items:
          type: integer
      x-kubernetes-validations:
        - rule: "self.all(x, x == 5)"
```

This is because each item of `foo` is itself an array, and each subarray in turn calls `self.all`. Avoid nested lists and maps if possible where validation rules are used.

Defaulting

Note:

To use defaulting, your CustomResourceDefinition must use API version `apiextensions.k8s.io/v1`.

Defaulting allows to specify default values in the [OpenAPI v3 validation schema](#):

```
apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
metadata:
  name: crontabs.stable.example.com
spec:
  group: stable.example.com
  versions:
    - name: v1
      served: true
      storage: true
      schema:
        # openAPIV3Schema is the schema for validating custom objects.
        openAPIV3Schema:
          type: object
          properties:
            spec:
```

```
type: object
properties:
  cronSpec:
    type: string
    pattern: '^(\\d+|\\*)(\\/\\d+)?(\\s+(\\d+|\\*)(\\/\\d+)?){4}$'
    default: "5 0 * * *"
  image:
    type: string
  replicas:
    type: integer
    minimum: 1
    maximum: 10
    default: 1
scope: Namespaced
names:
  plural: crontabs
  singular: crontab
  kind: CronTab
  shortNames:
  - ct
```

With this both cronSpec and replicas are defaulted:

```
apiVersion: "stable.example.com/v1"
kind: CronTab
metadata:
  name: my-new-cron-object
spec:
  image: my-awesome-cron-image
```

leads to

```
apiVersion: "stable.example.com/v1"
kind: CronTab
metadata:
  name: my-new-cron-object
spec:
  cronSpec: "5 0 * * *"
  image: my-awesome-cron-image
  replicas: 1
```

Defaulting happens on the object

- in the request to the API server using the request version defaults,
- when reading from etcd using the storage version defaults,
- after mutating admission plugins with non-empty patches using the admission webhook object version defaults.

Defaults applied when reading data from etcd are not automatically written back to etcd. An update request via the API is required to persist those defaults back into etcd.

Default values must be pruned (with the exception of defaults for metadata fields) and must validate against a provided schema.

Default values for metadata fields of x-kubernetes-embedded-resources: true nodes (or parts of a default value covering metadata) are not pruned during CustomResourceDefinition creation, but through the pruning step during handling of requests.

Defaulting and Nullable

Null values for fields that either don't specify the nullable flag, or give it a false value, will be pruned before defaulting happens. If a default is present, it will be applied. When nullable is true, null values will be conserved and won't be defaulted.

For example, given the OpenAPI schema below:

```
type: object
properties:
  spec:
    type: object
    properties:
      foo:
        type: string
        nullable: false
        default: "default"
      bar:
        type: string
        nullable: true
      baz:
        type: string
```

creating an object with null values for foo and bar and baz

```
spec:
  foo: null
  bar: null
  baz: null
```

leads to

```
spec:
  foo: "default"
  bar: null
```

with foo pruned and defaulted because the field is non-nullable, bar maintaining the null value due to nullable: true, and baz pruned because the field is non-nullable and has no default.

Publish Validation Schema in OpenAPI

CustomResourceDefinition [OpenAPI v3 validation schemas](#) which are [structural](#) and [enable pruning](#) are published as [OpenAPI v3](#) and OpenAPI v2 from Kubernetes API server. It is recommended to use the OpenAPI v3 document as it is a lossless representation of the CustomResourceDefinition OpenAPI v3 validation schema while OpenAPI v2 represents a lossy conversion.

The [kubectrl](#) command-line tool consumes the published schema to perform client-side validation (kubectrl create and kubectrl apply), schema explanation (kubectrl explain) on custom

resources. The published schema can be consumed for other purposes as well, like client generation or documentation.

Compatibility with OpenAPI V2

For compatibility with OpenAPI V2, the OpenAPI v3 validation schema performs a lossy conversion to the OpenAPI v2 schema. The schema show up in definitions and paths fields in the [OpenAPI v2 spec](#).

The following modifications are applied during the conversion to keep backwards compatibility with kubectl in previous 1.13 version. These modifications prevent kubectl from being over-strict and rejecting valid OpenAPI schemas that it doesn't understand. The conversion won't modify the validation schema defined in CRD, and therefore won't affect [validation](#) in the API server.

1. The following fields are removed as they aren't supported by OpenAPI v2.
 - The fields allOf, anyOf, oneOf and not are removed
2. If nullable: true is set, we drop type, nullable, items and properties because OpenAPI v2 is not able to express nullable. To avoid kubectl to reject good objects, this is necessary.

Additional printer columns

The kubectl tool relies on server-side output formatting. Your cluster's API server decides which columns are shown by the kubectl get command. You can customize these columns for a CustomResourceDefinition. The following example adds the Spec, Replicas, and Age columns.

Save the CustomResourceDefinition to resourcedefinition.yaml:

```
apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
metadata:
  name: crontabs.stable.example.com
spec:
  group: stable.example.com
  scope: Namespaced
  names:
    plural: crontabs
    singular: crontab
    kind: CronTab
    shortNames:
      - ct
  versions:
    - name: v1
      served: true
      storage: true
      schema:
        openAPIV3Schema:
          type: object
          properties:
            spec:
              type: object
```

```

    properties:
      cronSpec:
        type: string
      image:
        type: string
      replicas:
        type: integer
    additionalPrinterColumns:
    - name: Spec
      type: string
      description: The cron spec defining the interval a CronJob is run
      jsonPath: .spec.cronSpec
    - name: Replicas
      type: integer
      description: The number of jobs launched by the CronJob
      jsonPath: .spec.replicas
    - name: Age
      type: date
      jsonPath: .metadata.creationTimestamp

```

Create the CustomResourceDefinition:

```
kubectl apply -f resourcedefinition.yaml
```

Create an instance using the my-crontab.yaml from the previous section.

Invoke the server-side printing:

```
kubectl get crontab my-new-cron-object
```

Notice the NAME, SPEC, REPLICAS, and AGE columns in the output:

```

NAME          SPEC      REPLICAS  AGE
my-new-cron-object  * * * * * 1      7s

```

Note:

The NAME column is implicit and does not need to be defined in the CustomResourceDefinition.

Field selectors

[Field Selectors](#) let clients select custom resources based on the value of one or more resource fields.

All custom resources support the `metadata.name` and `metadata.namespace` field selectors.

Fields declared in a [CustomResourceDefinition](#) may also be used with field selectors when included in the `spec.versions[*].selectableFields` field of the [CustomResourceDefinition](#).

Selectable fields for custom resources

FEATURE STATE: Kubernetes v1.30 [alpha]

FEATURE STATE: Kubernetes v1.30 [alpha]

You need to enable the CustomResourceFieldSelectors [feature gate](#) to use this behavior, which then applies to all CustomResourceDefinitions in your cluster.

The spec.versions[*].selectableFields field of a [CustomResourceDefinition](#) may be used to declare which other fields in a custom resource may be used in field selectors. The following example adds the .spec.color and .spec.size fields as selectable fields.

Save the CustomResourceDefinition to shirt-resource-definition.yaml:

[customresourcedefinition/shirt-resource-definition.yaml](#)

```
apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
metadata:
  name: shirts.stable.example.com
spec:
  group: stable.example.com
  scope: Namespaced
  names:
    plural: shirts
    singular: shirt
    kind: Shirt
  versions:
    - name: v1
      served: true
      storage: true
      schema:
        openAPIV3Schema:
          type: object
          properties:
            spec:
              type: object
              properties:
                color:
                  type: string
                size:
                  type: string
            selectableFields:
              - jsonPath: .spec.color
              - jsonPath: .spec.size
          additionalPrinterColumns:
            - jsonPath: .spec.color
              name: Color
              type: string
            - jsonPath: .spec.size
              name: Size
              type: string
```

Create the CustomResourceDefinition:

```
kubectl apply -f https://k8s.io/examples/customresourcedefinition/shirt-resource-
definition.yaml
```

Define some Shirts by editing `shirt-resources.yaml`; for example:

[customresourcedefinition/shirt-resources.yaml](#)

```
---
apiVersion: stable.example.com/v1
kind: Shirt
metadata:
  name: example1
spec:
  color: blue
  size: S
---
apiVersion: stable.example.com/v1
kind: Shirt
metadata:
  name: example2
spec:
  color: blue
  size: M
---
apiVersion: stable.example.com/v1
kind: Shirt
metadata:
  name: example3
spec:
  color: green
  size: M
```

Create the custom resources:

```
kubectl apply -f https://k8s.io/examples/customresourcedefinition/shirt-resources.yaml
```

Get all the resources:

```
kubectl get shirts.stable.example.com
```

The output is:

| NAME | COLOR | SIZE |
|----------|-------|------|
| example1 | blue | S |
| example2 | blue | M |
| example3 | green | M |

Fetch blue shirts (retrieve Shirts with a color of blue):

```
kubectl get shirts.stable.example.com --field-selector spec.color=blue
```

Should output:

| NAME | COLOR | SIZE |
|----------|-------|------|
| example1 | blue | S |
| example2 | blue | M |

Get only resources with a color of green and a size of M:

```
kubectl get shirts.stable.example.com --field-selector spec.color=green,spec.size=M
```

Should output:

| NAME | COLOR | SIZE |
|----------|-------|------|
| example2 | blue | M |

Priority

Each column includes a priority field. Currently, the priority differentiates between columns shown in standard view or wide view (using the `-o wide` flag).

- Columns with priority 0 are shown in standard view.
- Columns with priority greater than 0 are shown only in wide view.

Type

A column's type field can be any of the following (compare [OpenAPI v3 data types](#)):

- integer – non-floating-point numbers
- number – floating point numbers
- string – strings
- boolean – true or false
- date – rendered differentially as time since this timestamp.

If the value inside a CustomResource does not match the type specified for the column, the value is omitted. Use CustomResource validation to ensure that the value types are correct.

Format

A column's format field can be any of the following:

- int32
- int64
- float
- double
- byte
- date
- date-time
- password

The column's format controls the style used when kubectl prints the value.

Subresources

Custom resources support `/status` and `/scale` subresources.

The status and scale subresources can be optionally enabled by defining them in the CustomResourceDefinition.

Status subresource

When the status subresource is enabled, the `/status` subresource for the custom resource is exposed.

- The status and the spec stanzas are represented by the `.status` and `.spec` JSONPaths respectively inside of a custom resource.
- PUT requests to the `/status` subresource take a custom resource object and ignore changes to anything except the status stanza.
- PUT requests to the `/status` subresource only validate the status stanza of the custom resource.
- PUT/POST/PATCH requests to the custom resource ignore changes to the status stanza.
- The `.metadata.generation` value is incremented for all changes, except for changes to `.metadata` or `.status`.
- Only the following constructs are allowed at the root of the CRD OpenAPI validation schema:
 - `description`
 - `example`
 - `exclusiveMaximum`
 - `exclusiveMinimum`
 - `externalDocs`
 - `format`
 - `items`
 - `maximum`
 - `maxItems`
 - `maxLength`
 - `minimum`
 - `minItems`
 - `minLength`
 - `multipleOf`
 - `pattern`
 - `properties`
 - `required`
 - `title`
 - `type`
 - `uniqueItems`

Scale subresource

When the scale subresource is enabled, the `/scale` subresource for the custom resource is exposed. The `autoscaling/v1.Scale` object is sent as the payload for `/scale`.

To enable the scale subresource, the following fields are defined in the CustomResourceDefinition.

- `specReplicasPath` defines the JSONPath inside of a custom resource that corresponds to `scale.spec.replicas`.
 - It is a required value.
 - Only JSONPaths under `.spec` and with the dot notation are allowed.
 - If there is no value under the `specReplicasPath` in the custom resource, the `/scale` subresource will return an error on GET.
- `statusReplicasPath` defines the JSONPath inside of a custom resource that corresponds to `scale.status.replicas`.
 - It is a required value.
 - Only JSONPaths under `.status` and with the dot notation are allowed.
 - If there is no value under the `statusReplicasPath` in the custom resource, the status replica value in the `/scale` subresource will default to 0.
- `labelSelectorPath` defines the JSONPath inside of a custom resource that corresponds to `Scale.Status.Selector`.
 - It is an optional value.
 - It must be set to work with HPA and VPA.
 - Only JSONPaths under `.status` or `.spec` and with the dot notation are allowed.
 - If there is no value under the `labelSelectorPath` in the custom resource, the status selector value in the `/scale` subresource will default to the empty string.
 - The field pointed by this JSON path must be a string field (not a complex selector struct) which contains a serialized label selector in string form.

In the following example, both status and scale subresources are enabled.

Save the CustomResourceDefinition to `resourcedefinition.yaml`:

```
apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
metadata:
  name: crontabs.stable.example.com
spec:
  group: stable.example.com
  versions:
    - name: v1
      served: true
      storage: true
      schema:
        openAPIV3Schema:
          type: object
          properties:
            spec:
              type: object
              properties:
                cronSpec:
                  type: string
                image:
```

```

    type: string
  replicas:
    type: integer
  status:
    type: object
  properties:
    replicas:
      type: integer
    labelSelector:
      type: string
# subresources describes the subresources for custom resources.
subresources:
# status enables the status subresource.
  status: {}
# scale enables the scale subresource.
  scale:
# specReplicasPath defines the JSONPath inside of a custom resource that corresponds to
Scale.Spec.Replicas.
    specReplicasPath: .spec.replicas
# statusReplicasPath defines the JSONPath inside of a custom resource that corresponds
to Scale.Status.Replicas.
    statusReplicasPath: .status.replicas
# labelSelectorPath defines the JSONPath inside of a custom resource that corresponds to
Scale.Status.Selector.
    labelSelectorPath: .status.labelSelector
scope: Namespaced
names:
  plural: crontabs
  singular: crontab
  kind: CronTab
  shortNames:
  - ct

```

And create it:

```
kubectl apply -f resourcedefinition.yaml
```

After the CustomResourceDefinition object has been created, you can create custom objects.

If you save the following YAML to my-crontab.yaml:

```

apiVersion: "stable.example.com/v1"
kind: CronTab
metadata:
  name: my-new-cron-object
spec:
  cronSpec: "* * * * */5"
  image: my-awesome-cron-image
  replicas: 3

```

and create it:

```
kubectl apply -f my-crontab.yaml
```

Then new namespaced RESTful API endpoints are created at:

```
/apis/stable.example.com/v1/namespaces/*/crontabs/status
```

and

```
/apis/stable.example.com/v1/namespaces/*/crontabs/scale
```

A custom resource can be scaled using the `kubectl scale` command. For example, the following command sets `.spec.replicas` of the custom resource created above to 5:

```
kubectl scale --replicas=5 crontabs/my-new-cron-object
crontabs "my-new-cron-object" scaled

kubectl get crontabs my-new-cron-object -o jsonpath='{.spec.replicas}'
5
```

You can use a [PodDisruptionBudget](#) to protect custom resources that have the scale subresource enabled.

Categories

Categories is a list of grouped resources the custom resource belongs to (eg. all). You can use `kubectl get <category-name>` to list the resources belonging to the category.

The following example adds all in the list of categories in the CustomResourceDefinition and illustrates how to output the custom resource using `kubectl get all`.

Save the following CustomResourceDefinition to `resourcedefinition.yaml`:

```
apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
metadata:
  name: crontabs.stable.example.com
spec:
  group: stable.example.com
  versions:
    - name: v1
      served: true
      storage: true
      schema:
        openAPIV3Schema:
          type: object
          properties:
            spec:
              type: object
              properties:
                cronSpec:
                  type: string
                image:
                  type: string
                replicas:
                  type: integer
  scope: Namespaced
```

```
names:
  plural: crontabs
  singular: crontab
  kind: CronTab
  shortNames:
  - ct
  # categories is a list of grouped resources the custom resource belongs to.
  categories:
  - all
```

and create it:

```
kubectl apply -f resourcedefinition.yaml
```

After the CustomResourceDefinition object has been created, you can create custom objects.

Save the following YAML to `my-crontab.yaml`:

```
apiVersion: "stable.example.com/v1"
kind: CronTab
metadata:
  name: my-new-cron-object
spec:
  cronSpec: "** * * * */5"
  image: my-awesome-cron-image
```

and create it:

```
kubectl apply -f my-crontab.yaml
```

You can specify the category when using `kubectl get`:

```
kubectl get all
```

and it will include the custom resources of kind CronTab:

| NAME | AGE |
|-----------------------------|-----|
| crontabs/my-new-cron-object | 3s |

What's next

- Read about [custom resources](#).
- See [CustomResourceDefinition](#).
- Serve [multiple versions](#) of a CustomResourceDefinition.

Versions in CustomResourceDefinitions

This page explains how to add versioning information to [CustomResourceDefinitions](#), to indicate the stability level of your CustomResourceDefinitions or advance your API to a new

version with conversion between API representations. It also describes how to upgrade an object from one version to another.

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

You should have an initial understanding of [custom resources](#).

Your Kubernetes server must be at or later than version v1.16. To check the version, enter kubectl version.

Overview

The CustomResourceDefinition API provides a workflow for introducing and upgrading to new versions of a CustomResourceDefinition.

When a CustomResourceDefinition is created, the first version is set in the CustomResourceDefinition spec.versions list to an appropriate stability level and a version number. For example v1beta1 would indicate that the first version is not yet stable. All custom resource objects will initially be stored at this version.

Once the CustomResourceDefinition is created, clients may begin using the v1beta1 API.

Later it might be necessary to add new version such as v1.

Adding a new version:

1. Pick a conversion strategy. Since custom resource objects need the ability to be served at both versions, that means they will sometimes be served in a different version than the one stored. To make this possible, the custom resource objects must sometimes be converted between the version they are stored at and the version they are served at. If the conversion involves schema changes and requires custom logic, a conversion webhook should be used. If there are no schema changes, the default None conversion strategy may be used and only the apiVersion field will be modified when serving different versions.
2. If using conversion webhooks, create and deploy the conversion webhook. See the [Webhook conversion](#) for more details.
3. Update the CustomResourceDefinition to include the new version in the spec.versions list with served:true. Also, set spec.conversion field to the selected conversion strategy. If using a conversion webhook, configure spec.conversion.webhookClientConfig field to call the webhook.

Once the new version is added, clients may incrementally migrate to the new version. It is perfectly safe for some clients to use the old version while others use the new version.

Migrate stored objects to the new version:

1. See the [upgrade existing objects to a new stored version](#) section.

It is safe for clients to use both the old and new version before, during and after upgrading the objects to a new stored version.

Removing an old version:

1. Ensure all clients are fully migrated to the new version. The kube-apiserver logs can be reviewed to help identify any clients that are still accessing via the old version.
2. Set served to false for the old version in the spec.versions list. If any clients are still unexpectedly using the old version they may begin reporting errors attempting to access the custom resource objects at the old version. If this occurs, switch back to using served:true on the old version, migrate the remaining clients to the new version and repeat this step.
3. Ensure the [upgrade of existing objects to the new stored version](#) step has been completed.
 1. Verify that the storage is set to true for the new version in the spec.versions list in the CustomResourceDefinition.
 2. Verify that the old version is no longer listed in the CustomResourceDefinition status.storedVersions.
4. Remove the old version from the CustomResourceDefinition spec.versions list.
5. Drop conversion support for the old version in conversion webhooks.

Specify multiple versions

The CustomResourceDefinition API versions field can be used to support multiple versions of custom resources that you have developed. Versions can have different schemas, and conversion webhooks can convert custom resources between versions. Webhook conversions should follow the [Kubernetes API conventions](#) wherever applicable. Specifically, See the [API change documentation](#) for a set of useful gotchas and suggestions.

Note:

In apiextensions.k8s.io/v1beta1, there was a version field instead of versions. The version field is deprecated and optional, but if it is not empty, it must match the first item in the versions field.

This example shows a CustomResourceDefinition with two versions. For the first example, the assumption is all versions share the same schema with no conversion between them. The comments in the YAML provide more context.

- [apiextensions.k8s.io/v1](#)
- [apiextensions.k8s.io/v1beta1](#)

```

- name: v1beta1
  # Each version can be enabled/disabled by Served flag.
  served: true
  # One and only one version must be marked as the storage version.
  storage: true
- name: v1
  served: true
  storage: false
validation:
  openAPIV3Schema:
    type: object
    properties:
      host:
        type: string
      port:
        type: string
# The conversion section is introduced in Kubernetes 1.13+ with a default value of
# None conversion (strategy sub-field set to None).
conversion:
  # None conversion assumes the same schema for all versions and only sets the apiVersion
  # field of custom resources to the proper value
  strategy: None
# either Namespaced or Cluster
scope: Namespaced
names:
  # plural name to be used in the URL: /apis/<group>/<version>/<plural>
  plural: crontabs
  # singular name to be used as an alias on the CLI and for display
  singular: crontab
  # kind is normally the PascalCased singular type. Your resource manifests use this.
  kind: CronTab
  # shortNames allow shorter string to match your resource on the CLI
  shortNames:
  - ct

```

You can save the CustomResourceDefinition in a YAML file, then use `kubectl apply` to create it.

```
kubectl apply -f my-versioned-crontab.yaml
```

After creation, the API server starts to serve each enabled version at an HTTP REST endpoint. In the above example, the API versions are available at `/apis/example.com/v1beta1` and `/apis/example.com/v1`.

Version priority

Regardless of the order in which versions are defined in a CustomResourceDefinition, the version with the highest priority is used by `kubectl` as the default version to access objects. The priority is determined by parsing the *name* field to determine the version number, the stability (GA, Beta, or Alpha), and the sequence within that stability level.

The algorithm used for sorting the versions is designed to sort versions in the same way that the Kubernetes project sorts Kubernetes versions. Versions start with a v followed by a number, an optional beta or alpha designation, and optional additional numeric versioning information. Broadly, a version string might look like v2 or v2beta1. Versions are sorted using the following algorithm:

- Entries that follow Kubernetes version patterns are sorted before those that do not.
- For entries that follow Kubernetes version patterns, the numeric portions of the version string is sorted largest to smallest.
- If the strings beta or alpha follow the first numeric portion, they sorted in that order, after the equivalent string without the beta or alpha suffix (which is presumed to be the GA version).
- If another number follows the beta, or alpha, those numbers are also sorted from largest to smallest.
- Strings that don't fit the above format are sorted alphabetically and the numeric portions are not treated specially. Notice that in the example below, foo1 is sorted above foo10. This is different from the sorting of the numeric portion of entries that do follow the Kubernetes version patterns.

This might make sense if you look at the following sorted version list:

```
- v10
- v2
- v1
- v11beta2
- v10beta3
- v3beta1
- v12alpha1
- v11alpha2
- foo1
- foo10
```

For the example in [Specify multiple versions](#), the version sort order is v1, followed by v1beta1. This causes the kubectl command to use v1 as the default version unless the provided object specifies the version.

Version deprecation

FEATURE STATE: Kubernetes v1.19 [stable]

Starting in v1.19, a CustomResourceDefinition can indicate a particular version of the resource it defines is deprecated. When API requests to a deprecated version of that resource are made, a warning message is returned in the API response as a header. The warning message for each deprecated version of the resource can be customized if desired.

A customized warning message should indicate the deprecated API group, version, and kind, and should indicate what API group, version, and kind should be used instead, if applicable.

- apiextensions.k8s.io/v1
- apiextensions.k8s.io/v1beta1

```
apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
name: crontabs.example.com
```

```

spec:
  group: example.com
  names:
    plural: crontabs
    singular: crontab
    kind: CronTab
  scope: Namespaced
  versions:
  - name: v1alpha1
    served: true
    storage: false
    # This indicates the v1alpha1 version of the custom resource is deprecated.
    # API requests to this version receive a warning header in the server response.
    deprecated: true
    # This overrides the default warning returned to API clients making v1alpha1 API requests.
    deprecationWarning: "example.com/v1alpha1 CronTab is deprecated; see http://example.com/
v1alpha1-v1 for instructions to migrate to example.com/v1 CronTab"

    schema: ...
  - name: v1beta1
    served: true
    # This indicates the v1beta1 version of the custom resource is deprecated.
    # API requests to this version receive a warning header in the server response.
    # A default warning message is returned for this version.
    deprecated: true
    schema: ...
  - name: v1
    served: true
    storage: true
    schema: ...

```

```

# Deprecated in v1.16 in favor of apiextensions.k8s.io/v1
apiVersion: apiextensions.k8s.io/v1beta1
kind: CustomResourceDefinition
metadata:
  name: crontabs.example.com
spec:
  group: example.com
  names:
    plural: crontabs
    singular: crontab
    kind: CronTab
  scope: Namespaced
  validation: ...
  versions:
  - name: v1alpha1
    served: true
    storage: false
    # This indicates the v1alpha1 version of the custom resource is deprecated.
    # API requests to this version receive a warning header in the server response.
    deprecated: true
    # This overrides the default warning returned to API clients making v1alpha1 API requests.
    deprecationWarning: "example.com/v1alpha1 CronTab is deprecated; see http://example.com/

```

```
v1alpha1-v1 for instructions to migrate to example.com/v1 CronTab"
- name: v1beta1
  served: true
  # This indicates the v1beta1 version of the custom resource is deprecated.
  # API requests to this version receive a warning header in the server response.
  # A default warning message is returned for this version.
  deprecated: true
- name: v1
  served: true
  storage: true
```

Version removal

An older API version cannot be dropped from a CustomResourceDefinition manifest until existing stored data has been migrated to the newer API version for all clusters that served the older version of the custom resource, and the old version is removed from the `status.storedVersions` of the CustomResourceDefinition.

```
apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
  name: crontabs.example.com
spec:
  group: example.com
  names:
    plural: crontabs
    singular: crontab
    kind: CronTab
  scope: Namespaced
  versions:
    - name: v1beta1
      # This indicates the v1beta1 version of the custom resource is no longer served.
      # API requests to this version receive a not found error in the server response.
      served: false
      schema: ...
    - name: v1
      served: true
      # The new served version should be set as the storage version
      storage: true
      schema: ...
```

Webhook conversion

FEATURE STATE: Kubernetes v1.16 [stable]

Note:

Webhook conversion is available as beta since 1.15, and as alpha since Kubernetes 1.13. The CustomResourceWebhookConversion feature must be enabled, which is the case automatically for many clusters for beta features. Please refer to the [feature gate](#) documentation for more information.

The above example has a None conversion between versions which only sets the `apiVersion` field on conversion and does not change the rest of the object. The API server also supports webhook conversions that call an external service in case a conversion is required. For example when:

- custom resource is requested in a different version than stored version.
- Watch is created in one version but the changed object is stored in another version.
- custom resource PUT request is in a different version than storage version.

To cover all of these cases and to optimize conversion by the API server, the conversion requests may contain multiple objects in order to minimize the external calls. The webhook should perform these conversions independently.

Write a conversion webhook server

Please refer to the implementation of the [custom resource conversion webhook server](#) that is validated in a Kubernetes e2e test. The webhook handles the `ConversionReview` requests sent by the API servers, and sends back conversion results wrapped in `ConversionResponse`. Note that the request contains a list of custom resources that need to be converted independently without changing the order of objects. The example server is organized in a way to be reused for other conversions. Most of the common code are located in the [framework file](#) that leaves only [one function](#) to be implemented for different conversions.

Note:

The example conversion webhook server leaves the `ClientAuth` field [empty](#), which defaults to `NoClientCert`. This means that the webhook server does not authenticate the identity of the clients, supposedly API servers. If you need mutual TLS or other ways to authenticate the clients, see how to [authenticate API servers](#).

Permissible mutations

A conversion webhook must not mutate anything inside of metadata of the converted object other than labels and annotations. Attempted changes to name, UID and namespace are rejected and fail the request which caused the conversion. All other changes are ignored.

Deploy the conversion webhook service

Documentation for deploying the conversion webhook is the same as for the [admission webhook example service](#). The assumption for next sections is that the conversion webhook server is deployed to a service named `example-conversion-webhook-server` in default namespace and serving traffic on path `/crdconvert`.

Note:

When the webhook server is deployed into the Kubernetes cluster as a service, it has to be exposed via a service on port 443 (The server itself can have an arbitrary port but the service object should map it to port 443). The communication between the API server and the webhook service may fail if a different port is used for the service.

Configure CustomResourceDefinition to use conversion webhooks

The None conversion example can be extended to use the conversion webhook by modifying conversion section of the spec:

- apiextensions.k8s.io/v1
- apiextensions.k8s.io/v1beta1

```
apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
metadata:
  # name must match the spec fields below, and be in the form: <plural>.<group>
  name: crontabs.example.com
spec:
  # group name to use for REST API: /apis/<group>/<version>
  group: example.com
  # list of versions supported by this CustomResourceDefinition
  versions:
    - name: v1beta1
      # Each version can be enabled/disabled by Served flag.
      served: true
      # One and only one version must be marked as the storage version.
      storage: true
      # Each version can define its own schema when there is no top-level
      # schema is defined.
      schema:
        openAPIV3Schema:
          type: object
          properties:
            hostPort:
              type: string
    - name: v1
      served: true
      storage: false
      schema:
        openAPIV3Schema:
          type: object
          properties:
            host:
              type: string
            port:
              type: string
  conversion:
    # the Webhook strategy instructs the API server to call an external webhook for any
    # conversion between custom resources.
    strategy: Webhook
    # webhook is required when strategy is `Webhook` and it configures the webhook endpoint
    # to be called by API server.
    webhook:
      # conversionReviewVersions indicates what ConversionReview versions are understood/
      # preferred by the webhook.
      # The first version in the list understood by the API server is sent to the webhook.
      # The webhook must respond with a ConversionReview object in the same version it
```

received.

```
conversionReviewVersions: ["v1","v1beta1"]
clientConfig:
  service:
    namespace: default
    name: example-conversion-webhook-server
    path: /crdconvert
    caBundle: "Ci0tLS0tQk...<base64-encoded PEM bundle>...tLS0K"
```

either Namespaced or Cluster

Deprecated in v1.16 in favor of apiextensions.k8s.io/v1

apiVersion: apiextensions.k8s.io/v1beta1

kind: CustomResourceDefinition

metadata:

name must match the spec fields below, and be in the form: <plural>.<group>

name: crontabs.example.com

spec:

group name to use for REST API: /apis/<group>/<version>

group: example.com

prunes object fields that are not specified in OpenAPI schemas below.

preserveUnknownFields: false

list of versions supported by this CustomResourceDefinition

versions:

- name: v1beta1

Each version can be enabled/disabled by Served flag.

served: true

One and only one version must be marked as the storage version.

storage: true

Each version can define its own schema when there is no top-level

schema is defined.

schema:

openAPIV3Schema:

type: object

properties:

hostPort:

type: string

- name: v1

served: true

storage: false

schema:

openAPIV3Schema:

type: object

```

properties:
  host:
    type: string
  port:
    type: string
conversion:
  # the Webhook strategy instructs the API server to call an external webhook for any
  # conversion between custom resources.
  strategy: Webhook
  # webhookClientConfig is required when strategy is `Webhook` and it configures the
  # webhook endpoint to be called by API server.
  webhookClientConfig:
    service:
      namespace: default
      name: example-conversion-webhook-server
      path: /crdconvert
      caBundle: "Ci0tLS0tQk...<base64-encoded PEM bundle>...tLS0K"
  # either Namespaced or Cluster
  scope: Namespaced
  names:
    # plural name to be used in the URL: /apis/<group>/<version>/<plural>
    plural: crontabs
    # singular name to be used as an alias on the CLI and for display
    singular: crontab
    # kind is normally the CamelCased singular type. Your resource manifests use this.
    kind: CronTab
    # shortNames allow shorter string to match your resource on the CLI
  shortNames:
    - ct

```

You can save the CustomResourceDefinition in a YAML file, then use `kubectl apply` to apply it.

```
kubectl apply -f my-versioned-crontab-with-conversion.yaml
```

Make sure the conversion service is up and running before applying new changes.

Contacting the webhook

Once the API server has determined a request should be sent to a conversion webhook, it needs to know how to contact the webhook. This is specified in the `webhookClientConfig` stanza of the webhook configuration.

Conversion webhooks can either be called via a URL or a service reference, and can optionally include a custom CA bundle to use to verify the TLS connection.

URL

`url` gives the location of the webhook, in standard URL form (`scheme://host:port/path`).

The host should not refer to a service running in the cluster; use a service reference by specifying the `service` field instead. The host might be resolved via external DNS in some apiservers (i.e., kube-apiserver cannot resolve in-cluster DNS as that would be a layering violation). host may also be an IP address.

Please note that using localhost or 127.0.0.1 as a host is risky unless you take great care to run this webhook on all hosts which run an apiserver which might need to make calls to this webhook. Such installations are likely to be non-portable or not readily run in a new cluster.

The scheme must be "https"; the URL must begin with "https://".

Attempting to use a user or basic auth (for example "user:password@") is not allowed. Fragments ("#...") and query parameters ("?...") are also not allowed.

Here is an example of a conversion webhook configured to call a URL (and expects the TLS certificate to be verified using system trust roots, so does not specify a caBundle):

- apiextensions.k8s.io/v1
- apiextensions.k8s.io/v1beta1

```
apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
...
spec:
  ...
  conversion:
    strategy: Webhook
    webhook:
      clientConfig:
        url: "https://my-webhook.example.com:9443/my-webhook-path"
  ...
```

```
# Deprecated in v1.16 in favor of apiextensions.k8s.io/v1
apiVersion: apiextensions.k8s.io/v1beta1
kind: CustomResourceDefinition
...
spec:
  ...
  conversion:
    strategy: Webhook
    webhookClientConfig:
      url: "https://my-webhook.example.com:9443/my-webhook-path"
  ...
```

Service Reference

The service stanza inside `webhookClientConfig` is a reference to the service for a conversion webhook. If the webhook is running within the cluster, then you should use service instead of url. The service namespace and name are required. The port is optional and defaults to 443. The path is optional and defaults to "/".

Here is an example of a webhook that is configured to call a service on port "1234" at the subpath "/my-path", and to verify the TLS connection against the ServerName my-service-name.my-service-namespace.svc using a custom CA bundle.

- apiextensions.k8s.io/v1
- apiextensions.k8s.io/v1beta1

```

apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
...
spec:
  ...
  conversion:
    strategy: Webhook
    webhook:
      clientConfig:
        service:
          namespace: my-service-namespace
          name: my-service-name
          path: /my-path
          port: 1234
      caBundle: "Ci0tLS0tQk...<base64-encoded PEM bundle>...tLS0K"
  ...

```

```

# Deprecated in v1.16 in favor of apiextensions.k8s.io/v1
apiVersion: apiextensions.k8s.io/v1beta1
kind: CustomResourceDefinition
...
spec:
  ...
  conversion:
    strategy: Webhook
    webhookClientConfig:
      service:
        namespace: my-service-namespace
        name: my-service-name
        path: /my-path
        port: 1234
      caBundle: "Ci0tLS0tQk...<base64-encoded PEM bundle>...tLS0K"
  ...

```

Webhook request and response

Request

Webhooks are sent a POST request, with Content-Type: application/json, with a ConversionReview API object in the apiextensions.k8s.io API group serialized to JSON as the body.

Webhooks can specify what versions of ConversionReview objects they accept with the conversionReviewVersions field in their CustomResourceDefinition:

- apiextensions.k8s.io/v1
- apiextensions.k8s.io/v1beta1

```

apiVersion: apiextensions.k8s.io/v1
kind: CustomResourceDefinition
...
spec:

```

```
...
conversion:
  strategy: Webhook
  webhook:
    conversionReviewVersions: ["v1", "v1beta1"]
...
```

conversionReviewVersions is a required field when creating apiextensions.k8s.io/v1 custom resource definitions. Webhooks are required to support at least one ConversionReview version understood by the current and previous API server.

```
# Deprecated in v1.16 in favor of apiextensions.k8s.io/v1
apiVersion: apiextensions.k8s.io/v1beta1
kind: CustomResourceDefinition
...
spec:
  ...
  conversion:
    strategy: Webhook
    conversionReviewVersions: ["v1", "v1beta1"]
  ...
```

If no conversionReviewVersions are specified, the default when creating apiextensions.k8s.io/v1beta1 custom resource definitions is v1beta1.

API servers send the first ConversionReview version in the conversionReviewVersions list they support. If none of the versions in the list are supported by the API server, the custom resource definition will not be allowed to be created. If an API server encounters a conversion webhook configuration that was previously created and does not support any of the ConversionReview versions the API server knows how to send, attempts to call to the webhook will fail.

This example shows the data contained in an ConversionReview object for a request to convert CronTab objects to example.com/v1:

- [apiextensions.k8s.io/v1](#)
- [apiextensions.k8s.io/v1beta1](#)

```
{
  "apiVersion": "apiextensions.k8s.io/v1",
  "kind": "ConversionReview",
  "request": {
    # Random uid uniquely identifying this conversion call
    "uid": "705ab4f5-6393-11e8-b7cc-42010a800002",

    # The API group and version the objects should be converted to
    "desiredAPIVersion": "example.com/v1",

    # The list of objects to convert.
    # May contain one or more objects, in one or more versions.

  },
  "hostPort": "example.com:2345"
}
]
}
}

```

Response

Webhooks respond with a 200 HTTP status code, Content-Type: application/json, and a body containing a ConversionReview object (in the same version they were sent), with the response stanza populated, serialized to JSON.

If conversion succeeds, a webhook should return a response stanza containing the following fields:

- uid, copied from the request.uid sent to the webhook
- result, set to {"status": "Success"}
- convertedObjects, containing all of the objects from request.objects, converted to request.desiredVersion

Example of a minimal successful response from a webhook:

- apiextensions.k8s.io/v1
- apiextensions.k8s.io/v1beta1

```

{
  "apiVersion": "apiextensions.k8s.io/v1",
  "kind": "ConversionReview",
  "response": {
    # must match <request.uid>
    "uid": "705ab4f5-6393-11e8-b7cc-42010a800002",
    "result": {
      "status": "Success"
    },
    # Objects must match the order of request.objects, and have apiVersion set to
    <request.desiredAPIVersion>.
  }
}

```

kind, metadata.uid, metadata.name, and metadata.namespace fields must not be changed by the webhook.

metadata.labels and metadata.annotations fields may be changed by the webhook.

All other changes to metadata fields by the webhook are ignored.

```

"convertedObjects": [
  {
    "kind": "CronTab",
    "apiVersion": "example.com/v1",
    "metadata": {
      "creationTimestamp": "2019-09-04T14:03:02Z",
      "name": "local-crontab",

```

```

    "namespace": "default",
    "resourceVersion": "143",
    "uid": "3415a7fc-162b-4300-b5da-fd6083580d66"
  },
  "host": "localhost",
  "port": "1234"
},
{
  "kind": "CronTab",
  "apiVersion": "example.com/v1",
  "metadata": {
    "creationTimestamp": "2019-09-03T13:02:01Z",
    "name": "remote-crontab",
    "resourceVersion": "12893",
    "uid": "359a83ec-b575-460d-b553-d859cedde8a0"
  },
  "host": "example.com",
  "port": "2345"
}
]
}
}

```

```

{
  # Deprecated in v1.16 in favor of apiextensions.k8s.io/v1
  "apiVersion": "apiextensions.k8s.io/v1beta1",
  "kind": "ConversionReview",
  "response": {
    # must match <request.uid>
    "uid": "705ab4f5-6393-11e8-b7cc-42010a800002",
    "result": {
      "status": "Failed"
    }
  },
  # Objects must match the order of request.objects, and have apiVersion set to
  <request.desiredAPIVersion>.

```

kind, metadata.uid, metadata.name, and metadata.namespace fields must not be changed by the webhook.

metadata.labels and metadata.annotations fields may be changed by the webhook.

All other changes to metadata fields by the webhook are ignored.

```

"convertedObjects": [
  {
    "kind": "CronTab",
    "apiVersion": "example.com/v1",
    "metadata": {
      "creationTimestamp": "2019-09-04T14:03:02Z",
      "name": "local-crontab",
      "namespace": "default",
      "resourceVersion": "143",
      "uid": "3415a7fc-162b-4300-b5da-fd6083580d66"
    },
    "host": "localhost",
    "port": "1234"
  }
]

```

```

    },
    {
      "kind": "CronTab",
      "apiVersion": "example.com/v1",
      "metadata": {
        "creationTimestamp": "2019-09-03T13:02:01Z",
        "name": "remote-crontab",
        "resourceVersion": "12893",
        "uid": "359a83ec-b575-460d-b553-d859cedde8a0"
      },
      "host": "example.com",
      "port": "2345"
    }
  ]
}

```

If conversion fails, a webhook should return a response stanza containing the following fields:

- uid, copied from the request.uid sent to the webhook
- result, set to {"status":"Failed"}

Warning:

Failing conversion can disrupt read and write access to the custom resources, including the ability to update or delete the resources. Conversion failures should be avoided whenever possible, and should not be used to enforce validation constraints (use validation schemas or webhook admission instead).

Example of a response from a webhook indicating a conversion request failed, with an optional message:

- apiextensions.k8s.io/v1
- apiextensions.k8s.io/v1beta1

```

{
  "apiVersion": "apiextensions.k8s.io/v1",
  "kind": "ConversionReview",
  "response": {
    "uid": "<value from request.uid>",
    "result": {
      "status": "Failed",
      "message": "hostPort could not be parsed into a separate host and port"
    }
  }
}

```

```

{
  # Deprecated in v1.16 in favor of apiextensions.k8s.io/v1
  "apiVersion": "apiextensions.k8s.io/v1beta1",
  "kind": "ConversionReview",
  "response": {
    "uid": "<value from request.uid>",

```

```
"result": {
  "status": "Failed",
  "message": "hostPort could not be parsed into a separate host and port"
}
}
```

Writing, reading, and updating versioned CustomResourceDefinition objects

When an object is written, it is stored at the version designated as the storage version at the time of the write. If the storage version changes, existing objects are never converted automatically. However, newly-created or updated objects are written at the new storage version. It is possible for an object to have been written at a version that is no longer served.

When you read an object, you specify the version as part of the path. You can request an object at any version that is currently served. If you specify a version that is different from the object's stored version, Kubernetes returns the object to you at the version you requested, but the stored object is not changed on disk.

What happens to the object that is being returned while serving the read request depends on what is specified in the CRD's `spec.conversion`:

- if the default strategy value `None` is specified, the only modifications to the object are changing the `apiVersion` string and perhaps [pruning unknown fields](#) (depending on the configuration). Note that this is unlikely to lead to good results if the schemas differ between the storage and requested version. In particular, you should not use this strategy if the same data is represented in different fields between versions.
- if [webhook conversion](#) is specified, then this mechanism controls the conversion.

If you update an existing object, it is rewritten at the version that is currently the storage version. This is the only way that objects can change from one version to another.

To illustrate this, consider the following hypothetical series of events:

1. The storage version is `v1beta1`. You create an object. It is stored at version `v1beta1`
2. You add version `v1` to your CustomResourceDefinition and designate it as the storage version. Here the schemas for `v1` and `v1beta1` are identical, which is typically the case when promoting an API to stable in the Kubernetes ecosystem.
3. You read your object at version `v1beta1`, then you read the object again at version `v1`. Both returned objects are identical except for the `apiVersion` field.
4. You create a new object. It is stored at version `v1`. You now have two objects, one of which is at `v1beta1`, and the other of which is at `v1`.
5. You update the first object. It is now stored at version `v1` since that is the current storage version.

Previous storage versions

The API server records each version which has ever been marked as the storage version in the status field `storedVersions`. Objects may have been stored at any version that has ever been designated as a storage version. No objects can exist in storage at a version that has never been a storage version.

Upgrade existing objects to a new stored version

When deprecating versions and dropping support, select a storage upgrade procedure.

Option 1: Use the Storage Version Migrator

1. Run the [storage Version migrator](#)
2. Remove the old version from the CustomResourceDefinition status.storedVersions field.

Option 2: Manually upgrade the existing objects to a new stored version

The following is an example procedure to upgrade from v1beta1 to v1.

1. Set v1 as the storage in the CustomResourceDefinition file and apply it using kubectl. The storedVersions is now v1beta1, v1.
2. Write an upgrade procedure to list all existing objects and write them with the same content. This forces the backend to write objects in the current storage version, which is v1.
3. Remove v1beta1 from the CustomResourceDefinition status.storedVersions field.

Note:

The flag `--subresource` is used with the kubectl get, patch, edit, and replace commands to fetch and update the subresources, status and scale, for all the API resources that support them. This flag is available starting from kubectl version v1.24. Previously, reading subresources (like status) via kubectl involved using `kubectl --raw`, and updating subresources using kubectl was not possible at all. Starting from v1.24, the kubectl tool can be used to edit or patch the status subresource on a CRD object. See [How to patch a Deployment using the subresource flag](#).

This page is part of the documentation for Kubernetes v1.30. If you are running a different version of Kubernetes, consult the documentation for that release.

Here is an example of how to patch the status subresource for a CRD object using kubectl:

```
kubectl patch customresourcedefinitions <CRD_Name> --subresource='status' --type='merge' -p '{"status":{"storedVersions":["v1"]}}'
```

Set up an Extension API Server

Setting up an extension API server to work with the aggregation layer allows the Kubernetes apiserver to be extended with additional APIs, which are not part of the core Kubernetes APIs.

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

- You must [configure the aggregation layer](#) and enable the apiserver flags.

Set up an extension api-server to work with the aggregation layer

The following steps describe how to set up an extension-apiserver *at a high level*. These steps apply regardless if you're using YAML configs or using APIs. An attempt is made to specifically identify any differences between the two. For a concrete example of how they can be implemented using YAML configs, you can look at the [sample-apiserver](#) in the Kubernetes repo.

Alternatively, you can use an existing 3rd party solution, such as [apiserver-builder](#), which should generate a skeleton and automate all of the following steps for you.

1. Make sure the APIService API is enabled (check `--runtime-config`). It should be on by default, unless it's been deliberately turned off in your cluster.
2. You may need to make an RBAC rule allowing you to add APIService objects, or get your cluster administrator to make one. (Since API extensions affect the entire cluster, it is not recommended to do testing/development/debug of an API extension in a live cluster.)
3. Create the Kubernetes namespace you want to run your extension api-service in.
4. Create/get a CA cert to be used to sign the server cert the extension api-server uses for HTTPS.
5. Create a server cert/key for the api-server to use for HTTPS. This cert should be signed by the above CA. It should also have a CN of the Kube DNS name. This is derived from the Kubernetes service and be of the form `<service name>.<service name namespace>.svc`
6. Create a Kubernetes secret with the server cert/key in your namespace.
7. Create a Kubernetes deployment for the extension api-server and make sure you are loading the secret as a volume. It should contain a reference to a working image of your extension api-server. The deployment should also be in your namespace.
8. Make sure that your extension-apiserver loads those certs from that volume and that they are used in the HTTPS handshake.
9. Create a Kubernetes service account in your namespace.
10. Create a Kubernetes cluster role for the operations you want to allow on your resources.
11. Create a Kubernetes cluster role binding from the service account in your namespace to the cluster role you created.
12. Create a Kubernetes cluster role binding from the service account in your namespace to the `system:auth-delegator` cluster role to delegate auth decisions to the Kubernetes core API server.
13. Create a Kubernetes role binding from the service account in your namespace to the `extension-apiserver-authentication-reader` role. This allows your extension api-server to access the `extension-apiserver-authentication` configmap.
14. Create a Kubernetes apiservice. The CA cert above should be base64 encoded, stripped of new lines and used as the `spec.caBundle` in the apiservice. This should not be namespaced. If using the [kube-aggregator API](#), only pass in the PEM encoded CA bundle because the base 64 encoding is done for you.
15. Use `kubectl` to get your resource. When run, `kubectl` should return "No resources found.". This message indicates that everything worked but you currently have no objects of that resource type created.

What's next

- Walk through the steps to [configure the API aggregation layer](#) and enable the apiserver flags.
- For a high level overview, see [Extending the Kubernetes API with the aggregation layer](#).
- Learn how to [Extend the Kubernetes API using Custom Resource Definitions](#).

Configure Multiple Schedulers

Kubernetes ships with a default scheduler that is described [here](#). If the default scheduler does not suit your needs you can implement your own scheduler. Moreover, you can even run multiple schedulers simultaneously alongside the default scheduler and instruct Kubernetes what scheduler to use for each of your pods. Let's learn how to run multiple schedulers in Kubernetes with an example.

A detailed description of how to implement a scheduler is outside the scope of this document. Please refer to the kube-scheduler implementation in [pkg/scheduler](#) in the Kubernetes source directory for a canonical example.

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

Package the scheduler

Package your scheduler binary into a container image. For the purposes of this example, you can use the default scheduler (kube-scheduler) as your second scheduler. Clone the [Kubernetes source code from GitHub](#) and build the source.

```
git clone https://github.com/kubernetes/kubernetes.git
cd kubernetes
make
```

Create a container image containing the kube-scheduler binary. Here is the Dockerfile to build the image:

```
FROM busybox
ADD ./_output/local/bin/linux/amd64/kube-scheduler /usr/local/bin/kube-scheduler
```

Save the file as Dockerfile, build the image and push it to a registry. This example pushes the image to [Google Container Registry \(GCR\)](#). For more details, please read the GCR

[documentation](#). Alternatively you can also use the [docker hub](#). For more details refer to the docker hub [documentation](#).

```
docker build -t gcr.io/my-gcp-project/my-kube-scheduler:1.0 .    # The image name and the repository
gcloud docker -- push gcr.io/my-gcp-project/my-kube-scheduler:1.0 # used in here is just an example
```

Define a Kubernetes Deployment for the scheduler

Now that you have your scheduler in a container image, create a pod configuration for it and run it in your Kubernetes cluster. But instead of creating a pod directly in the cluster, you can use a [Deployment](#) for this example. A [Deployment](#) manages a [Replica Set](#) which in turn manages the pods, thereby making the scheduler resilient to failures. Here is the deployment config. Save it as my-scheduler.yaml:

[admin/sched/my-scheduler.yaml](#)

```
apiVersion: v1
kind: ServiceAccount
metadata:
  name: my-scheduler
  namespace: kube-system
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: my-scheduler-as-kube-scheduler
subjects:
- kind: ServiceAccount
  name: my-scheduler
  namespace: kube-system
roleRef:
  kind: ClusterRole
  name: system:kube-scheduler
  apiGroup: rbac.authorization.k8s.io
---
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: my-scheduler-as-volume-scheduler
subjects:
- kind: ServiceAccount
  name: my-scheduler
  namespace: kube-system
roleRef:
  kind: ClusterRole
  name: system:volume-scheduler
  apiGroup: rbac.authorization.k8s.io
---
apiVersion: rbac.authorization.k8s.io/v1
kind: RoleBinding
```

```

metadata:
  name: my-scheduler-extension-apiserver-authentication-reader
  namespace: kube-system
roleRef:
  kind: Role
  name: extension-apiserver-authentication-reader
  apiGroup: rbac.authorization.k8s.io
subjects:
- kind: ServiceAccount
  name: my-scheduler
  namespace: kube-system
---
apiVersion: v1
kind: ConfigMap
metadata:
  name: my-scheduler-config
  namespace: kube-system
data:
  my-scheduler-config.yaml: |
    apiVersion: kubescheduler.config.k8s.io/v1beta2
    kind: KubeSchedulerConfiguration
    profiles:
      - schedulerName: my-scheduler
    leaderElection:
      leaderElect: false
---
apiVersion: apps/v1
kind: Deployment
metadata:
  labels:
    component: scheduler
    tier: control-plane
  name: my-scheduler
  namespace: kube-system
spec:
  selector:
    matchLabels:
      component: scheduler
      tier: control-plane

        version: second
    spec:
      serviceAccountName: my-scheduler
      containers:
      - command:
        - /usr/local/bin/kube-scheduler
        - --config=/etc/kubernetes/my-scheduler/my-scheduler-config.yaml
        image: gcr.io/my-gcp-project/my-kube-scheduler:1.0

```

```
livenessProbe:
  httpGet:
    path: /healthz
    port: 10259
    scheme: HTTPS
  initialDelaySeconds: 15
name: kube-second-scheduler
readinessProbe:
  httpGet:
    path: /healthz
    port: 10259
    scheme: HTTPS
resources:
  requests:
    cpu: '0.1'
securityContext:
  privileged: false
volumeMounts:
  - name: config-volume
    mountPath: /etc/kubernetes/my-scheduler
hostNetwork: false
hostPID: false
volumes:
  - name: config-volume
    configMap:
      name: my-scheduler-config
```

In the above manifest, you use a [KubeSchedulerConfiguration](#) to customize the behavior of your scheduler implementation. This configuration has been passed to the kube-scheduler during initialization with the `--config` option. The `my-scheduler-config` ConfigMap stores the configuration file. The Pod of the `my-scheduler` Deployment mounts the `my-scheduler-config` ConfigMap as a volume.

In the aforementioned Scheduler Configuration, your scheduler implementation is represented via a [KubeSchedulerProfile](#).

Note:

To determine if a scheduler is responsible for scheduling a specific Pod, the `spec.schedulerName` field in a PodTemplate or Pod manifest must match the `schedulerName` field of the `KubeSchedulerProfile`. All schedulers running in the cluster must have unique names.

Also, note that you create a dedicated service account `my-scheduler` and bind the `ClusterRole` `system:kube-scheduler` to it so that it can acquire the same privileges as `kube-scheduler`.

Please see the [kube-scheduler documentation](#) for detailed description of other command line arguments and [Scheduler Configuration reference](#) for detailed description of other customizable kube-scheduler configurations.

Run the second scheduler in the cluster

In order to run your scheduler in a Kubernetes cluster, create the deployment specified in the config above in a Kubernetes cluster:

```
kubectl create -f my-scheduler.yaml
```

Verify that the scheduler pod is running:

```
kubectl get pods --namespace=kube-system
```

| NAME | READY | STATUS | RESTARTS | AGE |
|--------------------------|-------|---------|----------|-----|
| | | | | |
| my-scheduler-lnf4s-4744f | 1/1 | Running | 0 | 2m |
| ... | | | | |

You should see a "Running" my-scheduler pod, in addition to the default kube-scheduler pod in this list.

Enable leader election

To run multiple-scheduler with leader election enabled, you must do the following:

Update the following fields for the KubeSchedulerConfiguration in the my-scheduler-config ConfigMap in your YAML file:

- leaderElection.leaderElect to true
- leaderElection.resourceNamespace to <lock-object-namespace>
- leaderElection.resourceName to <lock-object-name>

Note:

The control plane creates the lock objects for you, but the namespace must already exist. You can use the kube-system namespace.

If RBAC is enabled on your cluster, you must update the system:kube-scheduler cluster role. Add your scheduler name to the resourceNames of the rule applied for endpoints and leases resources, as in the following example:

```
kubectl edit clusterrole system:kube-scheduler
```

[admin/sched/clusterrole.yaml](#)

```
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRole
metadata:
  annotations:
    rbac.authorization.kubernetes.io/autoupdate: "true"
  labels:
    kubernetes.io/bootstrapping: rbac-defaults
  name: system:kube-scheduler
rules:
- apiGroups:
```

```

- coordination.k8s.io
resources:
- leases
verbs:
- create
- apiGroups:
- coordination.k8s.io
resourceNames:
- kube-scheduler
- my-scheduler
resources:
- leases
verbs:
- get
- update
- apiGroups:
- ""
resourceNames:
- kube-scheduler
- my-scheduler
resources:
- endpoints
verbs:
- delete
- get
- patch
- update

```

Specify schedulers for pods

Now that your second scheduler is running, create some pods, and direct them to be scheduled by either the default scheduler or the one you deployed. In order to schedule a given pod using a specific scheduler, specify the name of the scheduler in that pod spec. Let's look at three examples.

- Pod spec without any scheduler name

[admin/sched/pod1.yaml](#)

```

apiVersion: v1
kind: Pod
metadata:
  name: no-annotation
  labels:
    name: multischeduler-example
spec:
  containers:
  - name: pod-with-no-annotation-container
    image: registry.k8s.io/pause:2.0

```

When no scheduler name is supplied, the pod is automatically scheduled using the default-scheduler.

Save this file as `pod1.yaml` and submit it to the Kubernetes cluster.

```
kubectrl create -f pod1.yaml
```

- Pod spec with default-scheduler

[admin/sched/pod2.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
  name: annotation-default-scheduler
  labels:
    name: multischeduler-example
spec:
  schedulerName: default-scheduler
  containers:
  - name: pod-with-default-annotation-container
    image: registry.k8s.io/pause:2.0
```

A scheduler is specified by supplying the scheduler name as a value to `spec.schedulerName`. In this case, we supply the name of the default scheduler which is `default-scheduler`.

Save this file as `pod2.yaml` and submit it to the Kubernetes cluster.

```
kubectrl create -f pod2.yaml
```

- Pod spec with my-scheduler

[admin/sched/pod3.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
  name: annotation-second-scheduler
  labels:
    name: multischeduler-example
spec:
  schedulerName: my-scheduler
  containers:
  - name: pod-with-second-annotation-container
    image: registry.k8s.io/pause:2.0
```

In this case, we specify that this pod should be scheduled using the scheduler that we deployed - `my-scheduler`. Note that the value of `spec.schedulerName` should match the name supplied for the scheduler in the `schedulerName` field of the mapping `KubeSchedulerProfile`.

Save this file as `pod3.yaml` and submit it to the Kubernetes cluster.

```
kubectrl create -f pod3.yaml
```

Verify that all three pods are running.

```
kubectrl get pods
```

Verifying that the pods were scheduled using the desired schedulers

In order to make it easier to work through these examples, we did not verify that the pods were actually scheduled using the desired schedulers. We can verify that by changing the order of pod and deployment config submissions above. If we submit all the pod configs to a Kubernetes cluster before submitting the scheduler deployment config, we see that the pod annotation-second-scheduler remains in "Pending" state forever while the other two pods get scheduled. Once we submit the scheduler deployment config and our new scheduler starts running, the annotation-second-scheduler pod gets scheduled as well.

Alternatively, you can look at the "Scheduled" entries in the event logs to verify that the pods were scheduled by the desired schedulers.

```
kubectrl get events
```

You can also use a [custom scheduler configuration](#) or a custom container image for the cluster's main scheduler by modifying its static pod manifest on the relevant control plane nodes.

Use an HTTP Proxy to Access the Kubernetes API

This page shows how to use an HTTP proxy to access the Kubernetes API.

Before you begin

You need to have a Kubernetes cluster, and the kubectrl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter kubectrl version.

If you do not already have an application running in your cluster, start a Hello world application by entering this command:

```
kubectrl create deployment node-hello --image=gcr.io/google-samples/node-hello:1.0 --port=8080
```

Using kubectrl to start a proxy server

This command starts a proxy to the Kubernetes API server:

```
kubectrl proxy --port=8080
```

Exploring the Kubernetes API

When the proxy server is running, you can explore the API using `curl`, `wget`, or a browser.

Get the API versions:

```
curl http://localhost:8080/api/
```

The output should look similar to this:

```
{
  "kind": "APIVersions",
  "versions": [
    "v1"
  ],
  "serverAddressByClientCIDRs": [
    {
      "clientCIDR": "0.0.0.0/0",
      "serverAddress": "10.0.2.15:8443"
    }
  ]
}
```

Get a list of pods:

```
curl http://localhost:8080/api/v1/namespaces/default/pods
```

The output should look similar to this:

```
{
  "kind": "PodList",
  "apiVersion": "v1",
  "metadata": {
    "resourceVersion": "33074"
  },
  "items": [
    {
      "metadata": {
        "name": "kubernetes-bootcamp-2321272333-ix8pt",
        "generateName": "kubernetes-bootcamp-2321272333-",
        "namespace": "default",
        "uid": "ba21457c-6b1d-11e6-85f7-1ef9f1dab92b",
        "resourceVersion": "33003",
        "creationTimestamp": "2016-08-25T23:43:30Z",
        "labels": {
          "pod-template-hash": "2321272333",
          "run": "kubernetes-bootcamp"
        }
      },
      ...
    }
  ]
}
```

What's next

Learn more about [kubect proxy](#).

Use a SOCKS5 Proxy to Access the Kubernetes API

FEATURE STATE: Kubernetes v1.24 [stable]

This page shows how to use a SOCKS5 proxy to access the API of a remote Kubernetes cluster. This is useful when the cluster you want to access does not expose its API directly on the public internet.

Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version v1.24. To check the version, enter `kubectl version`.

You need SSH client software (the `ssh` tool), and an SSH service running on the remote server. You must be able to log in to the SSH service on the remote server.

Task context

Note:

This example tunnels traffic using SSH, with the SSH client and server acting as a SOCKS proxy. You can instead use any other kind of [SOCKS5](#) proxies.

Figure 1 represents what you're going to achieve in this task.

- You have a client computer, referred to as local in the steps ahead, from where you're going to create requests to talk to the Kubernetes API.
- The Kubernetes server/API is hosted on a remote server.
- You will use SSH client and server software to create a secure SOCKS5 tunnel between the local and the remote server. The HTTPS traffic between the client and the Kubernetes API will flow over the SOCKS5 tunnel, which is itself tunnelled over SSH.

```
graph LR; subgraph local[Local client machine] client([client])-. local traffic .-> local_ssh[Local SSH SOCKS5 proxy]; end local_ssh[SSH SOCKS5
```

```

proxy]-- SSH Tunnel -->sshd subgraph remote[Remote server] sshd[SSH
server]-- local traffic -->service1; end client([client])-. proxied HTTPs traffic
going through the proxy .->service1[Kubernetes API]; classDef plain
fill:#ddd,stroke:#fff,stroke-width:4px,color:#000; classDef k8s
fill:#326ce5,stroke:#fff,stroke-width:4px,color:#fff; classDef cluster
fill:#fff,stroke:#bbb,stroke-width:2px,color:#326ce5; class
ingress,service1,service2,pod1,pod2,pod3,pod4 k8s; class client plain; class cluster
cluster;

```

JavaScript must be [enabled](#) to view this content

Figure 1. SOCKS5 tutorial components

Using ssh to create a SOCKS5 proxy

The following command starts a SOCKS5 proxy between your client machine and the remote SOCKS server:

```
# The SSH tunnel continues running in the foreground after you run this
ssh -D 1080 -q -N username@kubernetes-remote-server.example
```

The SOCKS5 proxy lets you connect to your cluster's API server based on the following configuration:

- `-D 1080`: opens a SOCKS proxy on local port `:1080`.
- `-q`: quiet mode. Causes most warning and diagnostic messages to be suppressed.
- `-N`: Do not execute a remote command. Useful for just forwarding ports.
- `username@kubernetes-remote-server.example`: the remote SSH server behind which the Kubernetes cluster is running (eg: a bastion host).

Client configuration

To access the Kubernetes API server through the proxy you must instruct `kubectl` to send queries through the SOCKS proxy we created earlier. Do this by either setting the appropriate environment variable, or via the `proxy-url` attribute in the `kubeconfig` file. Using an environment variable:

```
export HTTPS_PROXY=socks5://localhost:1080
```

To always use this setting on a specific `kubectl` context, specify the `proxy-url` attribute in the relevant cluster entry within the `~/.kube/config` file. For example:

```

apiVersion: v1
clusters:
- cluster:
  certificate-authority-data: LRMEMMW2 # shortened for readability
  server: https://<API_SERVER_IP_ADDRESS>:6443 # the "Kubernetes API" server, in other
words the IP address of kubernetes-remote-server.example
  proxy-url: socks5://localhost:1080 # the "SSH SOCKS5 proxy" in the diagram above
  name: default
contexts:
- context:
  cluster: default

```

```
user: default
name: default
current-context: default
kind: Config
preferences: {}
users:
- name: default
  user:
    client-certificate-data: LS0tLS1CR== # shortened for readability
    client-key-data: LS0tLS1CRUdJT= # shortened for readability
```

Once you have created the tunnel via the ssh command mentioned earlier, and defined either the environment variable or the proxy-url attribute, you can interact with your cluster through that proxy. For example:

```
kubectl get pods
```

| NAMESPACE | NAME | READY | STATUS | RESTARTS | AGE |
|-------------|-------------------------|-------|---------|----------|-------|
| kube-system | coredns-85cb69466-klwq8 | 1/1 | Running | 0 | 5m46s |

Note:

- Before kubectl 1.24, most kubectl commands worked when using a socks proxy, except kubectl exec.
- kubectl supports both HTTPS_PROXY and https_proxy environment variables. These are used by other programs that support SOCKS, such as curl. Therefore in some cases it will be better to define the environment variable on the command line:

```
HTTPS_PROXY=socks5://localhost:1080 kubectl get pods
```

- When using proxy-url, the proxy is used only for the relevant kubectl context, whereas the environment variable will affect all contexts.
- The k8s API server hostname can be further protected from DNS leakage by using the socks5h protocol name instead of the more commonly known socks5 protocol shown above. In this case, kubectl will ask the proxy server (such as an ssh bastion) to resolve the k8s API server domain name, instead of resolving it on the system running kubectl. Note also that with socks5h, a k8s API server URL like https://localhost:6443/api does not refer to your local client computer. Instead, it refers to localhost as known on the proxy server (eg the ssh bastion).

Clean up

Stop the ssh port-forwarding process by pressing CTRL+C on the terminal where it is running.

Type unset https_proxy in a terminal to stop forwarding http traffic through the proxy.

- [OpenSSH remote login client](#)

Set up Konnectivity service

The Konnectivity service provides a TCP level proxy for the control plane to cluster communication.

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#).

Configure the Konnectivity service

The following steps require an egress configuration, for example:

[admin/konnectivity/egress-selector-configuration.yaml](#)

```
apiVersion: apiserver.k8s.io/v1beta1
kind: EgressSelectorConfiguration
egressSelections:
# Since we want to control the egress traffic to the cluster, we use the
# "cluster" as the name. Other supported values are "etcd", and "controlplane".
- name: cluster
  connection:
    # This controls the protocol between the API Server and the Konnectivity
    # server. Supported values are "GRPC" and "HTTPConnect". There is no
    # end user visible difference between the two modes. You need to set the
    # Konnectivity server to work in the same mode.
    proxyProtocol: GRPC
  transport:
    # This controls what transport the API Server uses to communicate with the
    # Konnectivity server. UDS is recommended if the Konnectivity server
    # locates on the same machine as the API Server. You need to configure the
    # Konnectivity server to listen on the same UDS socket.
    # The other supported transport is "tcp". You will need to set up TLS
    # config to secure the TCP transport.
    uds:
      udsName: /etc/kubernetes/konnectivity-server/konnectivity-server.socket
```

You need to configure the API Server to use the Konnectivity service and direct the network traffic to the cluster nodes:

1. Make sure that [Service Account Token Volume Projection](#) feature enabled in your cluster. It is enabled by default since Kubernetes v1.20.
2. Create an egress configuration file such as `admin/konnectivity/egress-selector-configuration.yaml`.
3. Set the `--egress-selector-config-file` flag of the API Server to the path of your API Server egress configuration file.
4. If you use UDS connection, add volumes config to the kube-apiserver:

```
spec:
  containers:
    volumeMounts:
      - name: konnectivity-uds
        mountPath: /etc/kubernetes/konnectivity-server
        readOnly: false
  volumes:
    - name: konnectivity-uds
      hostPath:
        path: /etc/kubernetes/konnectivity-server
        type: DirectoryOrCreate
```

Generate or obtain a certificate and kubeconfig for konnectivity-server. For example, you can use the OpenSSL command line tool to issue a X.509 certificate, using the cluster CA certificate /etc/kubernetes/pki/ca.crt from a control-plane host.

```
openssl req -subj "/CN=system:konnectivity-server" -new -newkey rsa:2048 -nodes -out
konnectivity.csr -keyout konnectivity.key
openssl x509 -req -in konnectivity.csr -CA /etc/kubernetes/pki/ca.crt -CAkey /etc/kubernetes/
pki/ca.key -CAcreateserial -out konnectivity.crt -days 375 -sha256
SERVER=$(kubectl config view -o jsonpath='{.clusters..server}')
kubectl --kubeconfig /etc/kubernetes/konnectivity-server.conf config set-credentials
system:konnectivity-server --client-certificate konnectivity.crt --client-key konnectivity.key --
embed-certs=true
kubectl --kubeconfig /etc/kubernetes/konnectivity-server.conf config set-cluster kubernet
es --server "$SERVER" --certificate-authority /etc/kubernetes/pki/ca.crt --embed-certs=true
kubectl --kubeconfig /etc/kubernetes/konnectivity-server.conf config set-context
system:konnectivity-server@kubernetes --cluster kubernet
es --user system:konnectivity-server
kubectl --kubeconfig /etc/kubernetes/konnectivity-server.conf config use-context
system:konnectivity-server@kubernetes
rm -f konnectivity.crt konnectivity.key konnectivity.csr
```

Next, you need to deploy the Konnectivity server and agents. [kubernetes-sigs/apiserver-network-proxy](#) is a reference implementation.

Deploy the Konnectivity server on your control plane node. The provided konnectivity-server.yaml manifest assumes that the Kubernetes components are deployed as a [static Pod](#) in your cluster. If not, you can deploy the Konnectivity server as a DaemonSet.

[admin/konnectivity/konnectivity-server.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
  name: konnectivity-server
  namespace: kube-system
spec:
  priorityClassName: system-cluster-critical
  hostNetwork: true
  containers:
    - name: konnectivity-server-container
      image: registry.k8s.io/kas-network-proxy/proxy-server:v0.0.37
      command: ["/proxy-server"]
      args: [
```

```

"--logtostderr=true",
# This needs to be consistent with the value set in egressSelectorConfiguration.
"--uds-name=/etc/kubernetes/konnectivity-server/konnectivity-server.socket",
"--delete-existing-uds-file",
# The following two lines assume the Konnectivity server is
# deployed on the same machine as the apiserver, and the certs and
# key of the API Server are at the specified location.
"--cluster-cert=/etc/kubernetes/pki/apiserver.crt",
"--cluster-key=/etc/kubernetes/pki/apiserver.key",
# This needs to be consistent with the value set in egressSelectorConfiguration.
"--mode=grpc",
"--server-port=0",
"--agent-port=8132",
"--admin-port=8133",
"--health-port=8134",
"--agent-namespace=kube-system",
"--agent-service-account=konnectivity-agent",
"--kubeconfig=/etc/kubernetes/konnectivity-server.conf",
"--authentication-audience=system:konnectivity-server"
]

```

livenessProbe:

httpGet:

scheme: HTTP

host: 127.0.0.1

port: 8134

path: /healthz

initialDelaySeconds: 30

timeoutSeconds: 60

ports:

- name: agentport

containerPort: 8132

hostPort: 8132

- name: adminport

containerPort: 8133

hostPort: 8133

- name: healthport

containerPort: 8134

hostPort: 8134

volumeMounts:

- name: k8s-certs

mountPath: /etc/kubernetes/pki

readOnly: true

- name: kubeconfig

mountPath: /etc/kubernetes/konnectivity-server.conf

readOnly: true

- name: konnectivity-uds

mountPath: /etc/kubernetes/konnectivity-server

readOnly: false

volumes:

- name: k8s-certs

hostPath:

path: /etc/kubernetes/pki

- name: kubeconfig

```
hostPath:
  path: /etc/kubernetes/konnectivity-server.conf
  type: FileOrCreate
- name: konnectivity-uds
  hostPath:
    path: /etc/kubernetes/konnectivity-server
    type: DirectoryOrCreate
```

Then deploy the Konnectivity agents in your cluster:

[admin/konnectivity/konnectivity-agent.yaml](#)

```
apiVersion: apps/v1
# Alternatively, you can deploy the agents as Deployments. It is not necessary
# to have an agent on each node.
kind: DaemonSet
metadata:
  labels:
    addonmanager.kubernetes.io/mode: Reconcile
    k8s-app: konnectivity-agent
  namespace: kube-system
  name: konnectivity-agent
spec:
  selector:
    matchLabels:
      k8s-app: konnectivity-agent
  template:
    metadata:
      labels:
        k8s-app: konnectivity-agent
    spec:
      priorityClassName: system-cluster-critical
      tolerations:
        - key: "CriticalAddonsOnly"
          operator: "Exists"
      containers:
        - image: us.gcr.io/k8s-artifacts-prod/kas-network-proxy/proxy-agent:v0.0.37
          name: konnectivity-agent
          command: ["/proxy-agent"]
          args: [
            "--logtostderr=true",
            "--ca-cert=/var/run/secrets/kubernetes.io/serviceaccount/ca.crt",
            # Since the konnectivity server runs with hostNetwork=true,
            # this is the IP address of the master machine.
            "--proxy-server-host=35.225.206.7",
            "--proxy-server-port=8132",
            "--admin-server-port=8133",
            "--health-server-port=8134",
            "--service-account-token-path=/var/run/secrets/tokens/konnectivity-agent-token"
          ]
      volumeMounts:
        - mountPath: /var/run/secrets/tokens
          name: konnectivity-agent-token
```

```
livenessProbe:
  httpGet:
    port: 8134
    path: /healthz
  initialDelaySeconds: 15
  timeoutSeconds: 15
serviceAccountName: konnectivity-agent
volumes:
- name: konnectivity-agent-token
  projected:
    sources:
    - serviceAccountToken:
        path: konnectivity-agent-token
        audience: system:konnectivity-server
```

Last, if RBAC is enabled in your cluster, create the relevant RBAC rules:

[admin/konnectivity/konnectivity-rbac.yaml](#)

```
apiVersion: rbac.authorization.k8s.io/v1
kind: ClusterRoleBinding
metadata:
  name: system:konnectivity-server

apiVersion: v1
kind: ServiceAccount
metadata:
  name: konnectivity-agent
  namespace: kube-system
  labels:
    kubernetes.io/cluster-service: "true"
    addonmanager.kubernetes.io/mode: Reconcile
```

TLS

Understand how to protect traffic within your cluster using Transport Layer Security (TLS).

[Configure Certificate Rotation for the Kubelet](#)

[Manage TLS Certificates in a Cluster](#)

Configure Certificate Rotation for the Kubelet

This page shows how to enable and configure certificate rotation for the kubelet.

FEATURE STATE: [Kubernetes v1.19](#) [stable]

Before you begin

- Kubernetes version 1.8.0 or later is required

Overview

The kubelet uses certificates for authenticating to the Kubernetes API. By default, these certificates are issued with one year expiration so that they do not need to be renewed too frequently.

Kubernetes contains [kubelet certificate rotation](#), that will automatically generate a new key and request a new certificate from the Kubernetes API as the current certificate approaches expiration. Once the new certificate is available, it will be used for authenticating connections to the Kubernetes API.

Enabling client certificate rotation

The kubelet process accepts an argument `--rotate-certificates` that controls if the kubelet will automatically request a new certificate as the expiration of the certificate currently in use approaches.

The kube-controller-manager process accepts an argument `--cluster-signing-duration` (`--experimental-cluster-signing-duration` prior to 1.19) that controls how long certificates will be issued for.

Understanding the certificate rotation configuration

When a kubelet starts up, if it is configured to bootstrap (using the `--bootstrap-kubeconfig` flag), it will use its initial certificate to connect to the Kubernetes API and issue a certificate signing request. You can view the status of certificate signing requests using:

```
kubectl get csr
```

Initially a certificate signing request from the kubelet on a node will have a status of `Pending`. If the certificate signing requests meets specific criteria, it will be auto approved by the controller manager, then it will have a status of `Approved`. Next, the controller manager will sign a certificate, issued for the duration specified by the `--cluster-signing-duration` parameter, and the signed certificate will be attached to the certificate signing request.

The kubelet will retrieve the signed certificate from the Kubernetes API and write that to disk, in the location specified by `--cert-dir`. Then the kubelet will use the new certificate to connect to the Kubernetes API.

As the expiration of the signed certificate approaches, the kubelet will automatically issue a new certificate signing request, using the Kubernetes API. This can happen at any point between 30% and 10% of the time remaining on the certificate. Again, the controller manager will automatically approve the certificate request and attach a signed certificate to the certificate signing request. The kubelet will retrieve the new signed certificate from the Kubernetes API and write that to disk. Then it will update the connections it has to the Kubernetes API to reconnect using the new certificate.

Manage TLS Certificates in a Cluster

Kubernetes provides a `certificates.k8s.io` API, which lets you provision TLS certificates signed by a Certificate Authority (CA) that you control. These CA and certificates can be used by your workloads to establish trust.

`certificates.k8s.io` API uses a protocol that is similar to the [ACME draft](#).

Note:

Certificates created using the `certificates.k8s.io` API are signed by a [dedicated CA](#). It is possible to configure your cluster to use the cluster root CA for this purpose, but you should never rely on this. Do not assume that these certificates will validate against the cluster root CA.

Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercode](#)
- [Play with Kubernetes](#)

You need the `cfssl` tool. You can download `cfssl` from <https://github.com/cloudflare/cfssl/releases>.

Some steps in this page use the `jq` tool. If you don't have `jq`, you can install it via your operating system's software sources, or fetch it from <https://jqlang.github.io/jq/>.

Trusting TLS in a cluster

Trusting the [custom CA](#) from an application running as a pod usually requires some extra application configuration. You will need to add the CA certificate bundle to the list of CA certificates that the TLS client or server trusts. For example, you would do this with a `golang` TLS config by parsing the certificate chain and adding the parsed certificates to the `RootCAs` field in the [tls.Config](#) struct.

Note:

Even though the custom CA certificate may be included in the filesystem (in the ConfigMap `kube-root-ca.crt`), you should not use that certificate authority for any purpose other than to verify internal Kubernetes endpoints. An example of an internal Kubernetes endpoint is the Service named `kubernetes` in the default namespace.

If you want to use a custom certificate authority for your workloads, you should generate that CA separately, and distribute its CA certificate using a [ConfigMap](#) that your pods have access to read.

Requesting a certificate

The following section demonstrates how to create a TLS certificate for a Kubernetes service accessed through DNS.

Note:

This tutorial uses CFSSL: Cloudflare's PKI and TLS toolkit [click here](#) to know more.

Create a certificate signing request

Generate a private key and certificate signing request (or CSR) by running the following command:

```
cat <<EOF | cfssl genkey - | cfssljson -bare server
{
  "hosts": [
    "my-svc.my-namespace.svc.cluster.local",
    "my-pod.my-namespace.pod.cluster.local",
    "192.0.2.24",
    "10.0.34.2"
  ],
  "CN": "my-pod.my-namespace.pod.cluster.local",
  "key": {
    "algo": "ecdsa",
    "size": 256
  }
}
EOF
```

Where `192.0.2.24` is the service's cluster IP, `my-svc.my-namespace.svc.cluster.local` is the service's DNS name, `10.0.34.2` is the pod's IP and `my-pod.my-namespace.pod.cluster.local` is the pod's DNS name. You should see the output similar to:

```
2022/02/01 11:45:32 [INFO] generate received request
2022/02/01 11:45:32 [INFO] received CSR
2022/02/01 11:45:32 [INFO] generating key: ecdsa-256
2022/02/01 11:45:32 [INFO] encoded CSR
```

This command generates two files; it generates `server.csr` containing the PEM encoded [PKCS#10](#) certification request, and `server-key.pem` containing the PEM encoded key to the certificate that is still to be created.

Create a CertificateSigningRequest object to send to the Kubernetes API

Generate a CSR manifest (in YAML), and send it to the API server. You can do that by running the following command:

```
cat <<EOF | kubectl apply -f -
apiVersion: certificates.k8s.io/v1
kind: CertificateSigningRequest
metadata:
  name: my-svc.my-namespace
spec:
  request: $(cat server.csr | base64 | tr -d '\n')
  signerName: example.com/serving
  usages:
    - digital signature
    - key encipherment
    - server auth
EOF
```

Notice that the `server.csr` file created in step 1 is base64 encoded and stashed in the `.spec.request` field. You are also requesting a certificate with the "digital signature", "key encipherment", and "server auth" key usages, signed by an example `example.com/serving` signer. A specific `signerName` must be requested. View documentation for [supported signer names](#) for more information.

The CSR should now be visible from the API in a Pending state. You can see it by running:

```
kubectl describe csr my-svc.my-namespace
```

```
Name:          my-svc.my-namespace
Labels:        <none>
Annotations:   <none>
CreationTimestamp:  Tue, 01 Feb 2022 11:49:15 -0500
Requesting User:  yourname@example.com
Signer:         example.com/serving
Status:        Pending
Subject:
  Common Name:  my-pod.my-namespace.pod.cluster.local
  Serial Number:
Subject Alternative Names:
  DNS Names:   my-pod.my-namespace.pod.cluster.local
               my-svc.my-namespace.svc.cluster.local
  IP Addresses: 192.0.2.24
               10.0.34.2
Events: <none>
```

Get the CertificateSigningRequest approved

Approving the [certificate signing request](#) is either done by an automated approval process or on a one off basis by a cluster administrator. If you're authorized to approve a certificate request, you can do that manually using kubectl; for example:

```
kubectl certificate approve my-svc.my-namespace
```

```
certificatesigningrequest.certificates.k8s.io/my-svc.my-namespace approved
```

You should now see the following:

```
kubectl get csr
```

| NAME | AGE | SIGNERNAME | REQUESTOR | REQUESTEDDURATION | CONDITION |
|---------------------|----------|---------------------|----------------------|-------------------|-----------|
| my-svc.my-namespace | 10m | example.com/serving | yourname@example.com | | |
| <none> | Approved | | | | |

This means the certificate request has been approved and is waiting for the requested signer to sign it.

Sign the CertificateSigningRequest

Next, you'll play the part of a certificate signer, issue the certificate, and upload it to the API.

A signer would typically watch the CertificateSigningRequest API for objects with its signerName, check that they have been approved, sign certificates for those requests, and update the API object status with the issued certificate.

Create a Certificate Authority

You need an authority to provide the digital signature on the new certificate.

First, create a signing certificate by running the following:

```
cat <<EOF | cfssl gencert -initca - | cfssljson -bare ca
{
  "CN": "My Example Signer",
  "key": {
    "algo": "rsa",
    "size": 2048
  }
}
EOF
```

You should see output similar to:

```
2022/02/01 11:50:39 [INFO] generating a new CA key and certificate from CSR
2022/02/01 11:50:39 [INFO] generate received request
2022/02/01 11:50:39 [INFO] received CSR
2022/02/01 11:50:39 [INFO] generating key: rsa-2048
2022/02/01 11:50:39 [INFO] encoded CSR
```

```
2022/02/01 11:50:39 [INFO] signed certificate with serial number
263983151013686720899716354349605500797834580472
```

This produces a certificate authority key file (ca-key.pem) and certificate (ca.pem).

Issue a certificate

[tls/server-signing-config.json](#)

```
{
  "signing": {
    "default": {
      "usages": [
        "digital signature",
        "key encipherment",
        "server auth"
      ],
      "expiry": "876000h",
      "ca_constraint": {
        "is_ca": false
      }
    }
  }
}
```

Use a server-signing-config.json signing configuration and the certificate authority key file and certificate to sign the certificate request:

```
kubectl get csr my-svc.my-namespace -o jsonpath='{.spec.request}' | \
base64 --decode | \
cfssl sign -ca ca.pem -ca-key ca-key.pem -config server-signing-config.json - | \
cfssljson -bare ca-signed-server
```

You should see the output similar to:

```
2022/02/01 11:52:26 [INFO] signed certificate with serial number
576048928624926584381415936700914530534472870337
```

This produces a signed serving certificate file, ca-signed-server.pem.

Upload the signed certificate

Finally, populate the signed certificate in the API object's status:

```
kubectl get csr my-svc.my-namespace -o json | \
jq '.status.certificate = "$(base64 ca-signed-server.pem | tr -d '\n')"' | \
kubectl replace --raw /apis/certificates.k8s.io/v1/certificatesigningrequests/my-svc.my-namespace/status -f -
```

Note:

This uses the command line tool [jq](#) to populate the base64-encoded content in the `.status.certificate` field. If you do not have `jq`, you can also save the JSON output to a file, populate this field manually, and upload the resulting file.

Once the CSR is approved and the signed certificate is uploaded, run:

```
kubectl get csr
```

The output is similar to:

| NAME | AGE | SIGNERNAME | REQUESTOR | REQUESTEDDURATION | CONDITION |
|---------------------|-----|---------------------|----------------------|-------------------|-----------|
| my-svc.my-namespace | 20m | example.com/serving | yourname@example.com | | |
| <none> | | Approved,Issued | | | |

Download the certificate and use it

Now, as the requesting user, you can download the issued certificate and save it to a `server.crt` file by running the following:

```
kubectl get csr my-svc.my-namespace -o jsonpath='{.status.certificate}' \
| base64 --decode > server.crt
```

Now you can populate `server.crt` and `server-key.pem` in a [Secret](#) that you could later mount into a Pod (for example, to use with a webserver that serves HTTPS).

```
kubectl create secret tls server --cert server.crt --key server-key.pem
```

```
secret/server created
```

Finally, you can populate `ca.pem` into a [ConfigMap](#) and use it as the trust root to verify the serving certificate:

```
kubectl create configmap example-serving-ca --from-file ca.crt=ca.pem
```

```
configmap/example-serving-ca created
```

Approving CertificateSigningRequests

A Kubernetes administrator (with appropriate permissions) can manually approve (or deny) `CertificateSigningRequests` by using the `kubectl certificate approve` and `kubectl certificate deny` commands. However if you intend to make heavy usage of this API, you might consider writing an automated certificates controller.

Caution:

The ability to approve CSRs decides who trusts whom within your environment. The ability to approve CSRs should not be granted broadly or lightly.

You should make sure that you confidently understand both the verification requirements that fall on the approver **and** the repercussions of issuing a specific certificate before you grant the approve permission.

Whether a machine or a human using `kubectl` as above, the role of the *approver* is to verify that the CSR satisfies two requirements:

1. The subject of the CSR controls the private key used to sign the CSR. This addresses the threat of a third party masquerading as an authorized subject. In the above example, this step would be to verify that the pod controls the private key used to generate the CSR.
2. The subject of the CSR is authorized to act in the requested context. This addresses the threat of an undesired subject joining the cluster. In the above example, this step would be to verify that the pod is allowed to participate in the requested service.

If and only if these two requirements are met, the approver should approve the CSR and otherwise should deny the CSR.

For more information on certificate approval and access control, read the [Certificate Signing Requests](#) reference page.

Configuring your cluster to provide signing

This page assumes that a signer is set up to serve the certificates API. The Kubernetes controller manager provides a default implementation of a signer. To enable it, pass the `--cluster-signing-cert-file` and `--cluster-signing-key-file` parameters to the controller manager with paths to your Certificate Authority's keypair.

Manual Rotation of CA Certificates

This page shows how to manually rotate the certificate authority (CA) certificates.

Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)
- For more information about authentication in Kubernetes, see [Authenticating](#).
- For more information about best practices for CA certificates, see [Single root CA](#).

Rotate the CA certificates manually

Caution:

Make sure to back up your certificate directory along with configuration files and any other necessary files.

This approach assumes operation of the Kubernetes control plane in a HA configuration with multiple API servers. Graceful termination of the API server is also assumed so clients can cleanly disconnect from one API server and reconnect to another.

Configurations with a single API server will experience unavailability while the API server is being restarted.

1. Distribute the new CA certificates and private keys (for example: `ca.crt`, `ca.key`, `front-proxy-ca.crt`, and `front-proxy-ca.key`) to all your control plane nodes in the Kubernetes certificates directory.
2. Update the `--root-ca-file` flag for the [kube-controller-manager](#) to include both old and new CA, then restart the kube-controller-manager.

Any [ServiceAccount](#) created after this point will get Secrets that include both old and new CAs.

Note:

The files specified by the kube-controller-manager flags `--client-ca-file` and `--cluster-signing-cert-file` cannot be CA bundles. If these flags and `--root-ca-file` point to the same `ca.crt` file which is now a bundle (includes both old and new CA) you will face an error. To workaround this problem you can copy the new CA to a separate file and make the flags `--client-ca-file` and `--cluster-signing-cert-file` point to the copy. Once `ca.crt` is no longer a bundle you can restore the problem flags to point to `ca.crt` and delete the copy.

[Issue 1350](#) for kubeadm tracks a bug with the kube-controller-manager being unable to accept a CA bundle.

3. Wait for the controller manager to update `ca.crt` in the service account Secrets to include both old and new CA certificates.

If any Pods are started before new CA is used by API servers, the new Pods get this update and will trust both old and new CAs.

4. Restart all pods using in-cluster configurations (for example: kube-proxy, CoreDNS, etc) so they can use the updated certificate authority data from Secrets that link to ServiceAccounts.

- Make sure CoreDNS, kube-proxy and other Pods using in-cluster configurations are working as expected.

5. Append the both old and new CA to the file against `--client-ca-file` and `--kubelet-certificate-authority` flag in the kube-apiserver configuration.
6. Append the both old and new CA to the file against `--client-ca-file` flag in the kube-scheduler configuration.
7. Update certificates for user accounts by replacing the content of `client-certificate-data` and `client-key-data` respectively.

For information about creating certificates for individual user accounts, see [Configure certificates for user accounts](#).

Additionally, update the `certificate-authority-data` section in the kubeconfig files, respectively with Base64-encoded old and new certificate authority data

8. Update the `--root-ca-file` flag for the [Cloud Controller Manager](#) to include both old and new CA, then restart the cloud-controller-manager.

Note:

If your cluster does not have a cloud-controller-manager, you can skip this step.

9. Follow the steps below in a rolling fashion.

1. Restart any other [aggregated API servers](#) or webhook handlers to trust the new CA certificates.
2. Restart the kubelet by update the file against `clientCAFile` in kubelet configuration and `certificate-authority-data` in `kubelet.conf` to use both the old and new CA on all nodes.

If your kubelet is not using client certificate rotation, update `client-certificate-data` and `client-key-data` in `kubelet.conf` on all nodes along with the kubelet client certificate file usually found in `/var/lib/kubelet/pki`.

3. Restart API servers with the certificates (`apiserver.crt`, `apiserver-kubelet-client.crt` and `front-proxy-client.crt`) signed by new CA. You can use the existing private keys or new private keys. If you changed the private keys then update these in the Kubernetes certificates directory as well.

Since the Pods in your cluster trust both old and new CAs, there will be a momentarily disconnection after which pods' Kubernetes clients reconnect to the new API server. The new API server uses a certificate signed by the new CA.

- Restart the [kube-scheduler](#) to use and trust the new CAs.
- Make sure control plane components logs no TLS errors.

Note:

To generate certificates and private keys for your cluster using the `openssl` command line tool, see [\[Certificates \('openssl'\)\]\(/docs/tasks/administer-cluster/certificates/#openssl\)](#). You can also use [\['cfssl'\]\(/docs/tasks/administer-cluster/certificates/#cfssl\)](#).

4. Annotate any DaemonSets and Deployments to trigger pod replacement in a safer rolling fashion.

```
for namespace in $(kubectl get namespace -o jsonpath='{.items[*].metadata.name}'); do
  for name in $(kubectl get deployments -n $namespace -o jsonpath='{.items[*].metadata.name}'); do
    kubectl patch deployment -n ${namespace} ${name} -p '{"spec":{"template":{"metadata":{"annotations":{"ca-rotation": "1"}}}}}'
  done
  for name in $(kubectl get daemonset -n $namespace -o jsonpath='{.items[*].metadata.name}'); do
```

```
kubectl patch daemonset -n ${namespace} ${name} -p '{"spec":{"template":{"metadata":{"annotations":{"ca-rotation": "1"}}}}}'  
done  
done
```

Note:

To limit the number of concurrent disruptions that your application experiences, see [\[configure pod disruption budget\]\(/docs/tasks/run-application/configure-pdb/\)](#).

Depending on how you use StatefulSets you may also need to perform similar rolling replacement.

10. If your cluster is using bootstrap tokens to join nodes, update the ConfigMap `cluster-info` in the `kube-public` namespace with new CA.

```
base64_encoded_ca="$(base64 -w0 /etc/kubernetes/pki/ca.crt)"  
  
kubectl get cm/cluster-info --namespace kube-public -o yaml | \  
/bin/sed "s/\\(certificate-authority-data:\\).*/\\1 ${base64_encoded_ca}/" | \  
kubectl apply -f -
```

11. Verify the cluster functionality.

1. Check the logs from control plane components, along with the kubelet and the kube-proxy. Ensure those components are not reporting any TLS errors; see [looking at the logs](#) for more details.
2. Validate logs from any aggregated api servers and pods using in-cluster config.

12. Once the cluster functionality is successfully verified:

1. Update all service account tokens to include new CA certificate only.
 - All pods using an in-cluster kubeconfig will eventually need to be restarted to pick up the new Secret, so that no Pods are relying on the old cluster CA.
2. Restart the control plane components by removing the old CA from the kubeconfig files and the files against `--client-ca-file`, `--root-ca-file` flags resp.
3. On each node, restart the kubelet by removing the old CA from file against the `clientCAFile` flag and from the kubelet kubeconfig file. You should carry this out as a rolling update.

If your cluster lets you make this change, you can also roll it out by replacing nodes rather than reconfiguring them.

Manage Cluster Daemons

Perform common tasks for managing a DaemonSet, such as performing a rolling update.

[Perform a Rolling Update on a DaemonSet](#)

[Perform a Rollback on a DaemonSet](#)

[Running Pods on Only Some Nodes](#)

Perform a Rolling Update on a DaemonSet

This page shows how to perform a rolling update on a DaemonSet.

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

DaemonSet Update Strategy

DaemonSet has two update strategy types:

- OnDelete: With OnDelete update strategy, after you update a DaemonSet template, new DaemonSet pods will *only* be created when you manually delete old DaemonSet pods. This is the same behavior of DaemonSet in Kubernetes version 1.5 or before.
- RollingUpdate: This is the default update strategy.
With RollingUpdate update strategy, after you update a DaemonSet template, old DaemonSet pods will be killed, and new DaemonSet pods will be created automatically, in a controlled fashion. At most one pod of the DaemonSet will be running on each node during the whole update process.

Performing a Rolling Update

To enable the rolling update feature of a DaemonSet, you must set its `.spec.updateStrategy.type` to RollingUpdate.

You may want to set `.spec.updateStrategy.rollingUpdate.maxUnavailable` (default to 1), `.spec.minReadySeconds` (default to 0) and `.spec.updateStrategy.rollingUpdate.maxSurge` (defaults to 0) as well.

Creating a DaemonSet with RollingUpdate update strategy

This YAML file specifies a DaemonSet with an update strategy as 'RollingUpdate'

[controllers/fluentd-daemonset.yaml](#)

```
apiVersion: apps/v1
kind: DaemonSet
metadata:
  name: fluentd-elasticsearch
```

```

namespace: kube-system
labels:
  k8s-app: fluentd-logging
spec:
  selector:
    matchLabels:
      name: fluentd-elasticsearch
  updateStrategy:
    type: RollingUpdate
    rollingUpdate:
      maxUnavailable: 1
  template:
    metadata:
      labels:
        name: fluentd-elasticsearch
    spec:
      tolerations:
        # these tolerations are to have the daemonset runnable on control plane nodes
        # remove them if your control plane nodes should not run pods
        - key: node-role.kubernetes.io/control-plane
          operator: Exists
          effect: NoSchedule
        - key: node-role.kubernetes.io/master
          operator: Exists
          effect: NoSchedule
      containers:
        - name: fluentd-elasticsearch
          image: quay.io/fluentd_elasticsearch/fluentd:v2.5.2
          volumeMounts:
            - name: varlog
              mountPath: /var/log
            - name: varlibdockercontainers
              mountPath: /var/lib/docker/containers
              readOnly: true
      terminationGracePeriodSeconds: 30
      volumes:
        - name: varlog
          hostPath:
            path: /var/log
        - name: varlibdockercontainers
          hostPath:
            path: /var/lib/docker/containers

```

After verifying the update strategy of the DaemonSet manifest, create the DaemonSet:

```
kubectl create -f https://k8s.io/examples/controllers/fluentd-daemonset.yaml
```

Alternatively, use `kubectl apply` to create the same DaemonSet if you plan to update the DaemonSet with `kubectl apply`.

```
kubectl apply -f https://k8s.io/examples/controllers/fluentd-daemonset.yaml
```

Checking DaemonSet RollingUpdate update strategy

Check the update strategy of your DaemonSet, and make sure it's set to RollingUpdate:

```
kubectl get ds/fluentd-elasticsearch -o go-template='{{.spec.updateStrategy.type}}{{"\n"}}' -n kube-system
```

If you haven't created the DaemonSet in the system, check your DaemonSet manifest with the following command instead:

```
kubectl apply -f https://k8s.io/examples/controllers/fluentd-daemonset.yaml --dry-run=client -o go-template='{{.spec.updateStrategy.type}}{{"\n"}}'
```

The output from both commands should be:

RollingUpdate

If the output isn't RollingUpdate, go back and modify the DaemonSet object or manifest accordingly.

Updating a DaemonSet template

Any updates to a RollingUpdate DaemonSet .spec.template will trigger a rolling update. Let's update the DaemonSet by applying a new YAML file. This can be done with several different kubectl commands.

[controllers/fluentd-daemonset-update.yaml](https://k8s.io/examples/controllers/fluentd-daemonset-update.yaml)

```
apiVersion: apps/v1
kind: DaemonSet
metadata:
  name: fluentd-elasticsearch
  namespace: kube-system
  labels:
    k8s-app: fluentd-logging
spec:
  selector:
    matchLabels:
      name: fluentd-elasticsearch
  updateStrategy:
    type: RollingUpdate
    rollingUpdate:
      maxUnavailable: 1
  template:
    metadata:
      labels:
        name: fluentd-elasticsearch
    spec:
      tolerations:
        # these tolerations are to have the daemonset runnable on control plane nodes
        # remove them if your control plane nodes should not run pods
        - key: node-role.kubernetes.io/control-plane
          operator: Exists
```

```

    effect: NoSchedule
  - key: node-role.kubernetes.io/master
    operator: Exists
    effect: NoSchedule
containers:
- name: fluentd-elasticsearch
  image: quay.io/fluentd_elasticsearch/fluentd:v2.5.2
resources:
  limits:
    memory: 200Mi
  requests:
    cpu: 100m
    memory: 200Mi
volumeMounts:
- name: varlog
  mountPath: /var/log
- name: varlibdockercontainers
  mountPath: /var/lib/docker/containers
  readOnly: true
terminationGracePeriodSeconds: 30
volumes:
- name: varlog
  hostPath:
    path: /var/log
- name: varlibdockercontainers
  hostPath:
    path: /var/lib/docker/containers

```

Declarative commands

If you update DaemonSets using [configuration files](#), use kubectl apply:

```
kubectl apply -f https://k8s.io/examples/controllers/fluentd-daemonset-update.yaml
```

Imperative commands

If you update DaemonSets using [imperative commands](#), use kubectl edit :

```
kubectl edit ds/fluentd-elasticsearch -n kube-system
```

Updating only the container image

If you only need to update the container image in the DaemonSet template, i.e. `.spec.template.spec.containers[*].image`, use kubectl set image:

```
kubectl set image ds/fluentd-elasticsearch fluentd-elasticsearch=quay.io/fluentd_elasticsearch/fluentd:v2.6.0 -n kube-system
```

Watching the rolling update status

Finally, watch the rollout status of the latest DaemonSet rolling update:

```
kubectl rollout status ds/fluentd-elasticsearch -n kube-system
```

When the rollout is complete, the output is similar to this:

```
daemonset "fluentd-elasticsearch" successfully rolled out
```

Troubleshooting

DaemonSet rolling update is stuck

Sometimes, a DaemonSet rolling update may be stuck. Here are some possible causes:

Some nodes run out of resources

The rollout is stuck because new DaemonSet pods can't be scheduled on at least one node. This is possible when the node is [running out of resources](#).

When this happens, find the nodes that don't have the DaemonSet pods scheduled on by comparing the output of `kubectl get nodes` and the output of:

```
kubectl get pods -l name=fluentd-elasticsearch -o wide -n kube-system
```

Once you've found those nodes, delete some non-DaemonSet pods from the node to make room for new DaemonSet pods.

Note:

This will cause service disruption when deleted pods are not controlled by any controllers or pods are not replicated. This does not respect [PodDisruptionBudget](#) either.

Broken rollout

If the recent DaemonSet template update is broken, for example, the container is crash looping, or the container image doesn't exist (often due to a typo), DaemonSet rollout won't progress.

To fix this, update the DaemonSet template again. New rollout won't be blocked by previous unhealthy rollouts.

Clock skew

If `.spec.minReadySeconds` is specified in the DaemonSet, clock skew between master and nodes will make DaemonSet unable to detect the right rollout progress.

Clean up

Delete DaemonSet from a namespace :

```
kubectl delete ds fluentd-elasticsearch -n kube-system
```

What's next

- See [Performing a rollback on a DaemonSet](#)
- See [Creating a DaemonSet to adopt existing DaemonSet pods](#)

Perform a Rollback on a DaemonSet

This page shows how to perform a rollback on a [DaemonSet](#).

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version 1.7. To check the version, enter kubectl version.

You should already know how to [perform a rolling update on a DaemonSet](#).

Performing a rollback on a DaemonSet

Step 1: Find the DaemonSet revision you want to roll back to

You can skip this step if you only want to roll back to the last revision.

List all revisions of a DaemonSet:

```
kubectl rollout history daemonset <daemonset-name>
```

This returns a list of DaemonSet revisions:

```
daemonsets "<daemonset-name>"
REVISION    CHANGE-CAUSE
1           ...
2           ...
...
```

- Change cause is copied from DaemonSet annotation `kubernetes.io/change-cause` to its revisions upon creation. You may specify `--record=true` in kubectl to record the command executed in the change cause annotation.

To see the details of a specific revision:

```
kubectl rollout history daemonset <daemonset-name> --revision=1
```

This returns the details of that revision:

```
daemonsets "<daemonset-name>" with revision #1
Pod Template:
Labels:    foo=bar
Containers:
app:
  Image:    ...
  Port:     ...
  Environment: ...
  Mounts:   ...
  Volumes:  ...
```

Step 2: Roll back to a specific revision

```
# Specify the revision number you get from Step 1 in --to-revision
kubectl rollout undo daemonset <daemonset-name> --to-revision=<revision>
```

If it succeeds, the command returns:

```
daemonset "<daemonset-name>" rolled back
```

Note:

If `--to-revision` flag is not specified, kubectl picks the most recent revision.

Step 3: Watch the progress of the DaemonSet rollback

kubectl rollout undo daemonset tells the server to start rolling back the DaemonSet. The real rollback is done asynchronously inside the cluster [control plane](#).

To watch the progress of the rollback:

```
kubectl rollout status ds/<daemonset-name>
```

When the rollback is complete, the output is similar to:

```
daemonset "<daemonset-name>" successfully rolled out
```

Understanding DaemonSet revisions

In the previous kubectl rollout history step, you got a list of DaemonSet revisions. Each revision is stored in a resource named ControllerRevision.

To see what is stored in each revision, find the DaemonSet revision raw resources:

```
kubectl get controllerrevision -l <daemonset-selector-key>=<daemonset-selector-value>
```

This returns a list of ControllerRevisions:

| NAME | CONTROLLER | REVISION | AGE |
|----------------------------------|----------------------------|----------|-----|
| <daemonset-name>-<revision-hash> | DaemonSet/<daemonset-name> | 1 | 1h |
| <daemonset-name>-<revision-hash> | DaemonSet/<daemonset-name> | 2 | 1h |

Each ControllerRevision stores the annotations and template of a DaemonSet revision.

kubectl rollout undo takes a specific ControllerRevision and replaces DaemonSet template with the template stored in the ControllerRevision. kubectl rollout undo is equivalent to updating DaemonSet template to a previous revision through other commands, such as kubectl edit or kubectl apply.

Note:

DaemonSet revisions only roll forward. That is to say, after a rollback completes, the revision number (.revision field) of the ControllerRevision being rolled back to will advance. For example, if you have revision 1 and 2 in the system, and roll back from revision 2 to revision 1, the ControllerRevision with .revision: 1 will become .revision: 3.

Troubleshooting

- See [troubleshooting DaemonSet rolling update](#).

Running Pods on Only Some Nodes

This page demonstrates how can you run [Pods](#) on only some [Nodes](#) as part of a [DaemonSet](#)

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Running Pods on only some Nodes

Imagine that you want to run a [DaemonSet](#), but you only need to run those daemon pods on nodes that have local solid state (SSD) storage. For example, the Pod might provide cache service to the node, and the cache is only useful when low-latency local storage is available.

Step 1: Add labels to your nodes

Add the label `ssd=true` to the nodes which have SSDs.

```
kubectl label nodes example-node-1 example-node-2 ssd=true
```

Step 2: Create the manifest

Let's create a [DaemonSet](#) which will provision the daemon pods on the SSD labeled [nodes](#) only.

Next, use a nodeSelector to ensure that the DaemonSet only runs Pods on nodes with the `ssd` label set to "true".

[controllers/daemonset-label-selector.yaml](#)

```
apiVersion: apps/v1
kind: DaemonSet
metadata:
  name: ssd-driver
  labels:
    app: nginx
spec:
  selector:
    matchLabels:
      app: ssd-driver-pod
  template:
    metadata:
      labels:
        app: ssd-driver-pod
    spec:
      nodeSelector:
        ssd: "true"
      containers:
        - name: example-container
          image: example-image
```

Step 3: Create the DaemonSet

Create the DaemonSet from the manifest by using `kubectl create` or `kubectl apply`

Let's label another node as `ssd=true`.

```
kubectl label nodes example-node-3 ssd=true
```

Labelling the node automatically triggers the control plane (specifically, the DaemonSet controller) to run a new daemon pod on that node.

```
kubectl get pods -o wide
```

The output is similar to:

| NAME | READY | STATUS | RESTARTS | AGE | IP | NODE |
|--------------------------------|-------|---------|----------|-----|-------|----------------|
| <daemonset-name><some-hash-01> | 1/1 | Running | 0 | 13s | | example-node-1 |
| <daemonset-name><some-hash-02> | 1/1 | Running | 0 | 13s | | example-node-2 |
| <daemonset-name><some-hash-03> | 1/1 | Running | 0 | 5s | | example-node-3 |

Networking

Learn how to configure networking for your cluster.

[Adding entries to Pod /etc/hosts with HostAliases](#)

[Extend Service IP Ranges](#)

Adding entries to Pod /etc/hosts with HostAliases

Adding entries to a Pod's /etc/hosts file provides Pod-level override of hostname resolution when DNS and other options are not applicable. You can add these custom entries with the HostAliases field in PodSpec.

Modification not using HostAliases is not suggested because the file is managed by the kubelet and can be overwritten on during Pod creation/restart.

Default hosts file content

Start an Nginx Pod which is assigned a Pod IP:

```
kubectl run nginx --image nginx
```

```
pod/nginx created
```

Examine a Pod IP:

```
kubectl get pods --output=wide
```

| NAME | READY | STATUS | RESTARTS | AGE | IP | NODE |
|-------|-------|---------|----------|-----|------------|---------|
| nginx | 1/1 | Running | 0 | 13s | 10.200.0.4 | worker0 |

The hosts file content would look like this:

```
kubectl exec nginx -- cat /etc/hosts
```

```
# Kubernetes-managed hosts file.
127.0.0.1 localhost
::1 localhost ip6-localhost ip6-loopback
fe00::0 ip6-localnet
fe00::0 ip6-mcastprefix
fe00::1 ip6-allnodes
fe00::2 ip6-allrouters
10.200.0.4nginx
```

By default, the hosts file only includes IPv4 and IPv6 boilerplates like localhost and its own hostname.

Adding additional entries with hostAliases

In addition to the default boilerplate, you can add additional entries to the hosts file. For example: to resolve foo.local, bar.local to 127.0.0.1 and foo.remote, bar.remote to 10.1.2.3, you can configure HostAliases for a Pod under .spec.hostAliases:

[service/networking/hostaliases-pod.yaml](#)

```

apiVersion: v1
kind: Pod
metadata:
  name: hostaliases-pod
spec:
  restartPolicy: Never
  hostAliases:
  - ip: "127.0.0.1"
    hostnames:
    - "foo.local"
    - "bar.local"
  - ip: "10.1.2.3"
    hostnames:
    - "foo.remote"
    - "bar.remote"
  containers:
  - name: cat-hosts
    image: busybox:1.28
    command:
    - cat
    args:
    - "/etc/hosts"

```

You can start a Pod with that configuration by running:

```
kubectl apply -f https://k8s.io/examples/service/networking/hostaliases-pod.yaml
```

```
pod/hostaliases-pod created
```

Examine a Pod's details to see its IPv4 address and its status:

```
kubectl get pod --output=wide
```

| NAME | READY | STATUS | RESTARTS | AGE | IP | NODE |
|-----------------|-------|-----------|----------|-----|------------|---------|
| hostaliases-pod | 0/1 | Completed | 0 | 6s | 10.200.0.5 | worker0 |

The hosts file content looks like this:

```
kubectl logs hostaliases-pod
```

```

# Kubernetes-managed hosts file.
127.0.0.1 localhost
::1 localhost ip6-localhost ip6-loopback
fe00::0 ip6-localnet
fe00::0 ip6-mcastprefix
fe00::1 ip6-allnodes
fe00::2 ip6-allrouters
10.200.0.5 hostaliases-pod

# Entries added by HostAliases.
127.0.0.1 foo.local bar.local
10.1.2.3 foo.remote bar.remote

```

with the additional entries specified at the bottom.

Why does the kubelet manage the hosts file?

The kubelet manages the hosts file for each container of the Pod to prevent the container runtime from modifying the file after the containers have already been started. Historically, Kubernetes always used Docker Engine as its container runtime, and Docker Engine would then modify the `/etc/hosts` file after each container had started.

Current Kubernetes can use a variety of container runtimes; even so, the kubelet manages the hosts file within each container so that the outcome is as intended regardless of which container runtime you use.

Caution:

Avoid making manual changes to the hosts file inside a container.

If you make manual changes to the hosts file, those changes are lost when the container exits.

Extend Service IP Ranges

FEATURE STATE: Kubernetes v1.27 [alpha]

This document shares how to extend the existing Service IP range assigned to a cluster.

Before you begin

You need to have a Kubernetes cluster, and the `kubectl` command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version v1.29. To check the version, enter `kubectl version`.

API

Kubernetes clusters with kube-apiservers that have enabled the `MultiCIDRServiceAllocator` [feature gate](#) and the `networking.k8s.io/v1alpha1` API, will create a new `ServiceCIDR` object that takes the well-known name `kubernetes`, and that uses an IP address range based on the value of the `--service-cluster-ip-range` command line argument to kube-apiserver.

```
kubectl get servicecidr
```

| NAME | CIDRS | AGE |
|------------|--------------|-----|
| kubernetes | 10.96.0.0/28 | 17d |

The well-known kubernetes Service, that exposes the kube-apiserver endpoint to the Pods, calculates the first IP address from the default ServiceCIDR range and uses that IP address as its cluster IP address.

```
kubectl get service kubernetes
```

| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE |
|------------|-----------|------------|-------------|---------|-----|
| kubernetes | ClusterIP | 10.96.0.1 | <none> | 443/TCP | 17d |

The default Service, in this case, uses the ClusterIP 10.96.0.1, that has the corresponding IPAddress object.

```
kubectl get ipaddress 10.96.0.1
```

| NAME | PARENTREF |
|-----------|-----------------------------|
| 10.96.0.1 | services/default/kubernetes |

The ServiceCIDRs are protected with [finalizers](#), to avoid leaving Service ClusterIPs orphans; the finalizer is only removed if there is another subnet that contains the existing IPAddresses or there are no IPAddresses belonging to the subnet.

Extend the number of available IPs for Services

There are cases that users will need to increase the number addresses available to Services, previously, increasing the Service range was a disruptive operation that could also cause data loss. With this new feature users only need to add a new ServiceCIDR to increase the number of available addresses.

Adding a new ServiceCIDR

On a cluster with a 10.96.0.0/28 range for Services, there is only $2^{(32-28)} - 2 = 14$ IP addresses available. The kubernetes.default Service is always created; for this example, that leaves you with only 13 possible Services.

```
for i in $(seq 1 13); do kubectl create service clusterip "test-$i" --tcp 80 -o json | jq -r .spec.clusterIP; done
```

```
10.96.0.11
10.96.0.5
10.96.0.12
10.96.0.13
10.96.0.14
10.96.0.2
10.96.0.3
10.96.0.4
10.96.0.6
10.96.0.7
10.96.0.8
10.96.0.9
```

```
error: failed to create ClusterIP service: Internal error occurred: failed to allocate a serviceIP: range is full
```

You can increase the number of IP addresses available for Services, by creating a new ServiceCIDR that extends or adds new IP address ranges.

```
cat <EOF | kubectl apply -f -
apiVersion: networking.k8s.io/v1alpha1
kind: ServiceCIDR
metadata:
  name: newcidr1
spec:
  cidrs:
  - 10.96.0.0/24
EOF
```

```
servicecidr.networking.k8s.io/newcidr1 created
```

and this will allow you to create new Services with ClusterIPs that will be picked from this new range.

```
for i in $(seq 13 16); do kubectl create service clusterip "test-$i" --tcp 80 -o json | jq -
r .spec.clusterIP; done
```

```
10.96.0.48
10.96.0.200
10.96.0.121
10.96.0.144
```

Deleting a ServiceCIDR

You cannot delete a ServiceCIDR if there are IPAddresses that depend on the ServiceCIDR.

```
kubectl delete servicecidr newcidr1
```

```
servicecidr.networking.k8s.io "newcidr1" deleted
```

Kubernetes uses a finalizer on the ServiceCIDR to track this dependent relationship.

```
kubectl get servicecidr newcidr1 -o yaml
```

```
apiVersion: networking.k8s.io/v1alpha1
kind: ServiceCIDR
metadata:
  creationTimestamp: "2023-10-12T15:11:07Z"
  deletionGracePeriodSeconds: 0
  deletionTimestamp: "2023-10-12T15:12:45Z"
  finalizers:
  - networking.k8s.io/service-cidr-finalizer
  name: newcidr1
  resourceVersion: "1133"
  uid: 5ffd8afe-c78f-4e60-ae76-cec448a8af40
spec:
  cidrs:
  - 10.96.0.0/24
status:
  conditions:
```

```
- lastTransitionTime: "2023-10-12T15:12:45Z"
  message: There are still IPAddresses referencing the ServiceCIDR, please remove
    them or create a new ServiceCIDR
  reason: OrphanIPAddress
  status: "False"
  type: Ready
```

By removing the Services containing the IP addresses that are blocking the deletion of the ServiceCIDR

```
for i in $(seq 13 16); do kubectl delete service "test-$i" ; done
```

```
service "test-13" deleted
service "test-14" deleted
service "test-15" deleted
service "test-16" deleted
```

the control plane notices the removal. The control plane then removes its finalizer, so that the ServiceCIDR that was pending deletion will actually be removed.

```
kubectl get servicecidr newcidr1
```

```
Error from server (NotFound): servicecidrs.networking.k8s.io "newcidr1" not found
```

Validate IPv4/IPv6 dual-stack

This document shares how to validate IPv4/IPv6 dual-stack enabled Kubernetes clusters.

Before you begin

- Provider support for dual-stack networking (Cloud provider or otherwise must be able to provide Kubernetes nodes with routable IPv4/IPv6 network interfaces)
- A [network plugin](#) that supports dual-stack networking.
- [Dual-stack enabled](#) cluster

Your Kubernetes server must be at or later than version v1.23. To check the version, enter `kubectl version`.

Note:

While you can validate with an earlier version, the feature is only GA and officially supported since v1.23.

Validate addressing

Validate node addressing

Each dual-stack Node should have a single IPv4 block and a single IPv6 block allocated. Validate that IPv4/IPv6 Pod address ranges are configured by running the following command. Replace

the sample node name with a valid dual-stack Node from your cluster. In this example, the Node's name is k8s-linuxpool1-34450317-0:

```
kubectl get nodes k8s-linuxpool1-34450317-0 -o go-template --template='{{range .spec.podCIDRs}}{{printf "%s\n" .}}{{end}}'
```

```
10.244.1.0/24
2001:db8::/64
```

There should be one IPv4 block and one IPv6 block allocated.

Validate that the node has an IPv4 and IPv6 interface detected. Replace node name with a valid node from the cluster. In this example the node name is k8s-linuxpool1-34450317-0:

```
kubectl get nodes k8s-linuxpool1-34450317-0 -o go-template --template='{{range .status.addresses}}{{printf "%s: %s\n" .type .address}}{{end}}'
```

```
Hostname: k8s-linuxpool1-34450317-0
InternalIP: 10.0.0.5
InternalIP: 2001:db8:10::5
```

Validate Pod addressing

Validate that a Pod has an IPv4 and IPv6 address assigned. Replace the Pod name with a valid Pod in your cluster. In this example the Pod name is pod01:

```
kubectl get pods pod01 -o go-template --template='{{range .status.podIPs}}{{printf "%s\n" .ip}}{{end}}'
```

```
10.244.1.4
2001:db8::4
```

You can also validate Pod IPs using the Downward API via the status.podIPs fieldPath. The following snippet demonstrates how you can expose the Pod IPs via an environment variable called MY_POD_IPS within a container.

```
env:
- name: MY_POD_IPS
  valueFrom:
    fieldRef:
      fieldPath: status.podIPs
```

The following command prints the value of the MY_POD_IPS environment variable from within a container. The value is a comma separated list that corresponds to the Pod's IPv4 and IPv6 addresses.

```
kubectl exec -it pod01 -- set | grep MY_POD_IPS
```

```
MY_POD_IPS=10.244.1.4,2001:db8::4
```

The Pod's IP addresses will also be written to /etc/hosts within a container. The following command executes a cat on /etc/hosts on a dual stack Pod. From the output you can verify both the IPv4 and IPv6 IP address for the Pod.

```
kubect exec -it pod01 -- cat /etc/hosts
```

```
# Kubernetes-managed hosts file.
127.0.0.1 localhost
::1 localhost ip6-localhost ip6-loopback
fe00::0 ip6-localnet
fe00::0 ip6-mcastprefix
fe00::1 ip6-allnodes
fe00::2 ip6-allrouters
10.244.1.4 pod01
2001:db8::4 pod01
```

Validate Services

Create the following Service that does not explicitly define `.spec.ipFamilyPolicy`. Kubernetes will assign a cluster IP for the Service from the first configured service-cluster-ip-range and set the `.spec.ipFamilyPolicy` to SingleStack.

[service/networking/dual-stack-default-svc.yaml](#)

```
apiVersion: v1
kind: Service
metadata:
  name: my-service
  labels:
    app.kubernetes.io/name: MyApp
spec:
  selector:
    app.kubernetes.io/name: MyApp
  ports:
    - protocol: TCP
      port: 80
```

Use `kubectl` to view the YAML for the Service.

```
kubectl get svc my-service -o yaml
```

The Service has `.spec.ipFamilyPolicy` set to SingleStack and `.spec.clusterIP` set to an IPv4 address from the first configured range set via `--service-cluster-ip-range` flag on kube-controller-manager.

```
apiVersion: v1
kind: Service
metadata:
  name: my-service
  namespace: default
spec:
  clusterIP: 10.0.217.164
  clusterIPs:
    - 10.0.217.164
  ipFamilies:
    - IPv4
  ipFamilyPolicy: SingleStack
```

```
ports:
- port: 80
  protocol: TCP
  targetPort: 9376
selector:
  app.kubernetes.io/name: MyApp
sessionAffinity: None
type: ClusterIP
status:
  loadBalancer: {}
```

Create the following Service that explicitly defines IPv6 as the first array element in `.spec.ipFamilies`. Kubernetes will assign a cluster IP for the Service from the IPv6 range configured `service-cluster-ip-range` and set the `.spec.ipFamilyPolicy` to `SingleStack`.

[service/networking/dual-stack-ipfamilies-ipv6.yaml](#)

```
apiVersion: v1
kind: Service
metadata:
  name: my-service
  labels:
    app.kubernetes.io/name: MyApp
spec:
  ipFamilies:
  - IPv6
  selector:
    app.kubernetes.io/name: MyApp
  ports:
  - protocol: TCP
    port: 80
```

Use `kubectl` to view the YAML for the Service.

```
kubectl get svc my-service -o yaml
```

The Service has `.spec.ipFamilyPolicy` set to `SingleStack` and `.spec.clusterIP` set to an IPv6 address from the IPv6 range set via `--service-cluster-ip-range` flag on `kube-controller-manager`.

```
apiVersion: v1
kind: Service
metadata:
  labels:
    app.kubernetes.io/name: MyApp
  name: my-service
spec:
  clusterIP: 2001:db8:fd00::5118
  clusterIPs:
  - 2001:db8:fd00::5118
  ipFamilies:
  - IPv6
  ipFamilyPolicy: SingleStack
  ports:
  - port: 80
```

```
protocol: TCP
targetPort: 80
selector:
  app.kubernetes.io/name: MyApp
sessionAffinity: None
type: ClusterIP
status:
  loadBalancer: {}
```

Create the following Service that explicitly defines `PreferDualStack` in `.spec.ipFamilyPolicy`. Kubernetes will assign both IPv4 and IPv6 addresses (as this cluster has dual-stack enabled) and select the `.spec.ClusterIP` from the list of `.spec.ClusterIPs` based on the address family of the first element in the `.spec.ipFamilies` array.

[service/networking/dual-stack-preferred-svc.yaml](#)

```
apiVersion: v1
kind: Service
metadata:
  name: my-service
  labels:
    app.kubernetes.io/name: MyApp
spec:
  ipFamilyPolicy: PreferDualStack
  selector:
    app.kubernetes.io/name: MyApp
  ports:
    - protocol: TCP
      port: 80
```

Note:

The `kubectl get svc` command will only show the primary IP in the `CLUSTER-IP` field.

```
kubectl get svc -l app.kubernetes.io/name=MyApp
```

| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE |
|------------|-----------|--------------|-------------|---------|-----|
| my-service | ClusterIP | 10.0.216.242 | <none> | 80/TCP | 5s |

Validate that the Service gets cluster IPs from the IPv4 and IPv6 address blocks using `kubectl describe`. You may then validate access to the service via the IPs and ports.

```
kubectl describe svc -l app.kubernetes.io/name=MyApp
```

```
Name:          my-service
Namespace:     default
Labels:        app.kubernetes.io/name=MyApp
Annotations:   <none>
Selector:      app.kubernetes.io/name=MyApp
Type:          ClusterIP
IP Family Policy: PreferDualStack
IP Families:   IPv4,IPv6
IP:            10.0.216.242
```

```
IPs:      10.0.216.242,2001:db8:fd00::af55
Port:      <unset> 80/TCP
TargetPort: 9376/TCP
Endpoints: <none>
Session Affinity: None
Events:    <none>
```

Create a dual-stack load balanced Service

If the cloud provider supports the provisioning of IPv6 enabled external load balancers, create the following Service with `PreferDualStack` in `.spec.ipFamilyPolicy`, IPv6 as the first element of the `.spec.ipFamilies` array and the type field set to `LoadBalancer`.

[service/networking/dual-stack-prefer-ipv6-lb-svc.yaml](#)

```
apiVersion: v1
kind: Service
metadata:
  name: my-service
  labels:
    app.kubernetes.io/name: MyApp
spec:
  ipFamilyPolicy: PreferDualStack
  ipFamilies:
    - IPv6
  type: LoadBalancer
  selector:
    app.kubernetes.io/name: MyApp
  ports:
    - protocol: TCP
      port: 80
```

Check the Service:

```
kubectl get svc -l app.kubernetes.io/name=MyApp
```

Validate that the Service receives a CLUSTER-IP address from the IPv6 address block along with an EXTERNAL-IP. You may then validate access to the service via the IP and port.

| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE |
|------------|--------------|---------------------|------------------|--------------|-----|
| my-service | LoadBalancer | 2001:db8:fd00::7ebc | 2603:1030:805::5 | 80:30790/TCP | 35s |

Extend kubectl with plugins

Extend kubectl by creating and installing kubectl plugins.

This guide demonstrates how to install and write extensions for [kubectl](#). By thinking of core kubectl commands as essential building blocks for interacting with a Kubernetes cluster, a cluster administrator can think of plugins as a means of utilizing these building blocks to create more complex behavior. Plugins extend kubectl with new sub-commands, allowing for new and custom features not included in the main distribution of kubectl.

Before you begin

You need to have a working `kubectl` binary installed.

Installing `kubectl` plugins

A plugin is a standalone executable file, whose name begins with `kubectl-`. To install a plugin, move its executable file to anywhere on your `PATH`.

You can also discover and install `kubectl` plugins available in the open source using [Krew](#). Krew is a plugin manager maintained by the Kubernetes SIG CLI community.

Caution:

`Kubectl` plugins available via the Krew [plugin index](#) are not audited for security. You should install and run third-party plugins at your own risk, since they are arbitrary programs running on your machine.

Discovering plugins

`kubectl` provides a command `kubectl plugin list` that searches your `PATH` for valid plugin executables. Executing this command causes a traversal of all files in your `PATH`. Any files that are executable, and begin with `kubectl-` will show up *in the order in which they are present in your PATH* in this command's output. A warning will be included for any files beginning with `kubectl-` that are *not* executable. A warning will also be included for any valid plugin files that overlap each other's name.

You can use [Krew](#) to discover and install `kubectl` plugins from a community-curated [plugin index](#).

Limitations

It is currently not possible to create plugins that overwrite existing `kubectl` commands. For example, creating a plugin `kubectl-version` will cause that plugin to never be executed, as the existing `kubectl version` command will always take precedence over it. Due to this limitation, it is also *not* possible to use plugins to add new subcommands to existing `kubectl` commands. For example, adding a subcommand `kubectl create foo` by naming your plugin `kubectl-create-foo` will cause that plugin to be ignored.

`kubectl plugin list` shows warnings for any valid plugins that attempt to do this.

Writing `kubectl` plugins

You can write a plugin in any programming language or script that allows you to write command-line commands.

There is no plugin installation or pre-loading required. Plugin executables receive the inherited environment from the `kubectl` binary. A plugin determines which command path it wishes to implement based on its name. For example, a plugin named `kubectl-foo` provides a command `kubectl foo`. You must install the plugin executable somewhere in your `PATH`.

Example plugin

```
#!/bin/bash

# optional argument handling
if [[ "$1" == "version" ]]
then
    echo "1.0.0"
    exit 0
fi

# optional argument handling
if [[ "$1" == "config" ]]
then
    echo "$KUBECONFIG"
    exit 0
fi

echo "I am a plugin named kubectl-foo"
```

Using a plugin

To use a plugin, make the plugin executable:

```
sudo chmod +x ./kubectl-foo
```

and place it anywhere in your PATH:

```
sudo mv ./kubectl-foo /usr/local/bin
```

You may now invoke your plugin as a kubectl command:

```
kubectl foo
```

```
I am a plugin named kubectl-foo
```

All args and flags are passed as-is to the executable:

```
kubectl foo version
```

```
1.0.0
```

All environment variables are also passed as-is to the executable:

```
export KUBECONFIG=~/.kube/config
kubectl foo config
```

```
/home/<user>/.kube/config
```

```
KUBECONFIG=/etc/kube/config kubectl foo config
```

```
/etc/kube/config
```

Additionally, the first argument that is passed to a plugin will always be the full path to the location where it was invoked (\$0 would equal /usr/local/bin/kubectl-foo in the example above).

Naming a plugin

As seen in the example above, a plugin determines the command path that it will implement based on its filename. Every sub-command in the command path that a plugin targets, is separated by a dash (-). For example, a plugin that wishes to be invoked whenever the command `kubectl foo bar baz` is invoked by the user, would have the filename of `kubectl-foo-bar-baz`.

Flags and argument handling

Note:

The plugin mechanism does *not* create any custom, plugin-specific values or environment variables for a plugin process.

An older kubectl plugin mechanism provided environment variables such as `KUBECTL_PLUGINS_CURRENT_NAMESPACE`; that no longer happens.

kubectl plugins must parse and validate all of the arguments passed to them. See [using the command line runtime package](#) for details of a Go library aimed at plugin authors.

Here are some additional cases where users invoke your plugin while providing additional flags and arguments. This builds upon the `kubectl-foo-bar-baz` plugin from the scenario above.

If you run `kubectl foo bar baz arg1 --flag=value arg2`, kubectl's plugin mechanism will first try to find the plugin with the longest possible name, which in this case would be `kubectl-foo-bar-baz-arg1`. Upon not finding that plugin, kubectl then treats the last dash-separated value as an argument (`arg1` in this case), and attempts to find the next longest possible name, `kubectl-foo-bar-baz`. Upon having found a plugin with this name, kubectl then invokes that plugin, passing all args and flags after the plugin's name as arguments to the plugin process.

Example:

```
# create a plugin
echo -e '#!/bin/bash\n\nnecho "My first command-line argument was $1"' > kubectl-foo-bar-baz
sudo chmod +x ./kubectl-foo-bar-baz

# "install" your plugin by moving it to a directory in your $PATH
sudo mv ./kubectl-foo-bar-baz /usr/local/bin

# check that kubectl recognizes your plugin
kubectl plugin list
```

The following kubectl-compatible plugins are available:

```
/usr/local/bin/kubectl-foo-bar-baz
```

```
# test that calling your plugin via a "kubectl" command works
# even when additional arguments and flags are passed to your
```

```
# plugin executable by the user.
kubectl foo bar baz arg1 --meaningless-flag=true
```

My first command-line argument was arg1

As you can see, your plugin was found based on the kubectl command specified by a user, and all extra arguments and flags were passed as-is to the plugin executable once it was found.

Names with dashes and underscores

Although the kubectl plugin mechanism uses the dash (-) in plugin filenames to separate the sequence of sub-commands processed by the plugin, it is still possible to create a plugin command containing dashes in its commandline invocation by using underscores (_) in its filename.

Example:

```
# create a plugin containing an underscore in its filename
echo -e '#!/bin/bash\n\necho "I am a plugin with a dash in my name"' > ./kubectl-foo_bar
sudo chmod +x ./kubectl-foo_bar

# move the plugin into your $PATH
sudo mv ./kubectl-foo_bar /usr/local/bin

# You can now invoke your plugin via kubectl:
kubectl foo-bar
```

I am a plugin with a dash in my name

Note that the introduction of underscores to a plugin filename does not prevent you from having commands such as kubectl foo_bar. The command from the above example, can be invoked using either a dash (-) or an underscore (_):

```
# You can invoke your custom command with a dash
kubectl foo-bar
```

I am a plugin with a dash in my name

```
# You can also invoke your custom command with an underscore
kubectl foo_bar
```

I am a plugin with a dash in my name

Name conflicts and overshadowing

It is possible to have multiple plugins with the same filename in different locations throughout your PATH. For example, given a PATH with the following value: PATH=/usr/local/bin/plugins:/usr/local/bin/moreplugins, a copy of plugin kubectl-foo could exist in /usr/local/bin/plugins and /usr/local/bin/moreplugins, such that the output of the kubectl plugin list command is:

```
PATH=/usr/local/bin/plugins:/usr/local/bin/moreplugins kubectl plugin list
```

The following kubectl-compatible plugins are available:

```
/usr/local/bin/plugins/kubectl-foo
/usr/local/bin/moreplugins/kubectl-foo
- warning: /usr/local/bin/moreplugins/kubectl-foo is overshadowed by a similarly named
plugin: /usr/local/bin/plugins/kubectl-foo

error: one plugin warning was found
```

In the above scenario, the warning under `/usr/local/bin/moreplugins/kubectl-foo` tells you that this plugin will never be executed. Instead, the executable that appears first in your PATH, `/usr/local/bin/plugins/kubectl-foo`, will always be found and executed first by the kubectl plugin mechanism.

A way to resolve this issue is to ensure that the location of the plugin that you wish to use with kubectl always comes first in your PATH. For example, if you want to always use `/usr/local/bin/moreplugins/kubectl-foo` anytime that the kubectl command `kubectl foo` was invoked, change the value of your PATH to be `/usr/local/bin/moreplugins:/usr/local/bin/plugins`.

Invocation of the longest executable filename

There is another kind of overshadowing that can occur with plugin filenames. Given two plugins present in a user's PATH: `kubectl-foo-bar` and `kubectl-foo-bar-baz`, the kubectl plugin mechanism will always choose the longest possible plugin name for a given user command. Some examples below, clarify this further:

```
# for a given kubectl command, the plugin with the longest possible filename will always be
preferred
kubectl foo bar baz
```

Plugin `kubectl-foo-bar-baz` is executed

```
kubectl foo bar
```

Plugin `kubectl-foo-bar` is executed

```
kubectl foo bar baz buz
```

Plugin `kubectl-foo-bar-baz` is executed, with "buz" as its first argument

```
kubectl foo bar buz
```

Plugin `kubectl-foo-bar` is executed, with "buz" as its first argument

This design choice ensures that plugin sub-commands can be implemented across multiple files, if needed, and that these sub-commands can be nested under a "parent" plugin command:

```
ls ./plugin_command_tree
```

```
kubectl-parent
kubectl-parent-subcommand
kubectl-parent-subcommand-subsubcommand
```

Checking for plugin warnings

You can use the aforementioned `kubectl plugin list` command to ensure that your plugin is visible by `kubectl`, and verify that there are no warnings preventing it from being called as a `kubectl` command.

```
kubectl plugin list
```

The following `kubectl`-compatible plugins are available:

```
test/fixtures/pkg/kubectl/plugins/kubectl-foo
/usr/local/bin/kubectl-foo
- warning: /usr/local/bin/kubectl-foo is overshadowed by a similarly named plugin: test/
fixtures/pkg/kubectl/plugins/kubectl-foo
plugins/kubectl-invalid
- warning: plugins/kubectl-invalid identified as a kubectl plugin, but it is not executable

error: 2 plugin warnings were found
```

Using the command line runtime package

If you're writing a plugin for `kubectl` and you're using Go, you can make use of the [cli-runtime](#) utility libraries.

These libraries provide helpers for parsing or updating a user's [kubeconfig](#) file, for making REST-style requests to the API server, or to bind flags associated with configuration and printing.

See the [Sample CLI Plugin](#) for an example usage of the tools provided in the CLI Runtime repo.

Distributing kubectl plugins

If you have developed a plugin for others to use, you should consider how you package it, distribute it and deliver updates to your users.

Krew

[Krew](#) offers a cross-platform way to package and distribute your plugins. This way, you use a single packaging format for all target platforms (Linux, Windows, macOS etc) and deliver updates to your users. Krew also maintains a [plugin index](#) so that other people can discover your plugin and install it.

Native / platform specific package management

Alternatively, you can use traditional package managers such as, `apt` or `yum` on Linux, Chocolatey on Windows, and Homebrew on macOS. Any package manager will be suitable if it can place new executables placed somewhere in the user's `PATH`. As a plugin author, if you pick this option then you also have the burden of updating your `kubectl` plugin's distribution package across multiple platforms for each release.

Source code

You can publish the source code; for example, as a Git repository. If you choose this option, someone who wants to use that plugin must fetch the code, set up a build environment (if it needs compiling), and deploy the plugin. If you also make compiled packages available, or use Krew, that will make installs easier.

What's next

- Check the Sample CLI Plugin repository for a [detailed example](#) of a plugin written in Go. In case of any questions, feel free to reach out to the [SIG CLI team](#).
- Read about [Krew](#), a package manager for kubectl plugins.

Manage HugePages

Configure and manage huge pages as a schedulable resource in a cluster.

FEATURE STATE: Kubernetes v1.30 [stable]

Kubernetes supports the allocation and consumption of pre-allocated huge pages by applications in a Pod. This page describes how users can consume huge pages.

Before you begin

Kubernetes nodes must [pre-allocate huge pages](#) in order for the node to report its huge page capacity.

A node can pre-allocate huge pages for multiple sizes, for instance, the following line in `/etc/default/grub` allocates 2*1GiB of 1 GiB and 512*2 MiB of 2 MiB pages:

```
GRUB_CMDLINE_LINUX="hugepagesz=1G hugepages=2 hugepagesz=2M hugepages=512"
```

The nodes will automatically discover and report all huge page resources as schedulable resources.

When you describe the Node, you should see something similar to the following in the following in the Capacity and Allocatable sections:

Capacity:

```
cpu:      ...
ephemeral-storage: ...
hugepages-1Gi:    2Gi
hugepages-2Mi:    1Gi
memory:      ...
pods:        ...
```

Allocatable:

```
cpu:      ...
ephemeral-storage: ...
hugepages-1Gi:    2Gi
hugepages-2Mi:    1Gi
memory:      ...
pods:        ...
```

Note:

For dynamically allocated pages (after boot), the Kubelet needs to be restarted for the new allocations to be refrelected.

API

Huge pages can be consumed via container level resource requirements using the resource name `hugepages-<size>`, where `<size>` is the most compact binary notation using integer values supported on a particular node. For example, if a node supports 2048KiB and 1048576KiB page sizes, it will expose a schedulable resources `hugepages-2Mi` and `hugepages-1Gi`. Unlike CPU or memory, huge pages do not support overcommit. Note that when requesting hugepage resources, either memory or CPU resources must be requested as well.

A pod may consume multiple huge page sizes in a single pod spec. In this case it must use `medium: HugePages-<hugepagesize>` notation for all volume mounts.

```
apiVersion: v1
kind: Pod
metadata:
  name: huge-pages-example
spec:
  containers:
    - name: example
      image: fedora:latest
      command:
        - sleep
        - inf
      volumeMounts:
        - mountPath: /hugepages-2Mi
          name: hugepage-2mi
        - mountPath: /hugepages-1Gi
          name: hugepage-1gi
      resources:
        limits:
          hugepages-2Mi: 100Mi
          hugepages-1Gi: 2Gi
          memory: 100Mi
        requests:
          memory: 100Mi
  volumes:
    - name: hugepage-2mi
      emptyDir:
        medium: HugePages-2Mi
    - name: hugepage-1gi
      emptyDir:
        medium: HugePages-1Gi
```

A pod may use `medium: HugePages` only if it requests huge pages of one size.

```
apiVersion: v1
kind: Pod
```

```
metadata:
  name: huge-pages-example
spec:
  containers:
  - name: example
    image: fedora:latest
    command:
    - sleep
    - inf
    volumeMounts:
    - mountPath: /hugepages
      name: hugepage
  resources:
    limits:
      hugepages-2Mi: 100Mi
      memory: 100Mi
    requests:
      memory: 100Mi
  volumes:
  - name: hugepage
    emptyDir:
      medium: HugePages
```

- Huge page requests must equal the limits. This is the default if limits are specified, but requests are not.
- Huge pages are isolated at a container scope, so each container has own limit on their cgroup sandbox as requested in a container spec.
- EmptyDir volumes backed by huge pages may not consume more huge page memory than the pod request.
- Applications that consume huge pages via `shmget()` with `SHM_HUGETLB` must run with a supplemental group that matches `proc/sys/vm/hugetlb_shm_group`.
- Huge page usage in a namespace is controllable via `ResourceQuota` similar to other compute resources like `cpu` or `memory` using the `hugepages-<size>` token.

Schedule GPUs

Configure and schedule GPUs for use as a resource by nodes in a cluster.

FEATURE STATE: Kubernetes v1.26 [stable]

Kubernetes includes **stable** support for managing AMD and NVIDIA GPUs (graphical processing units) across different nodes in your cluster, using [device plugins](#).

This page describes how users can consume GPUs, and outlines some of the limitations in the implementation.

Using device plugins

Kubernetes implements device plugins to let Pods access specialized hardware features such as GPUs.

Note: This section links to third party projects that provide functionality required by Kubernetes. The Kubernetes project authors aren't responsible for these projects, which are listed alphabetically. To add a project to this list, read the [content guide](#) before submitting a change. [More information](#).

As an administrator, you have to install GPU drivers from the corresponding hardware vendor on the nodes and run the corresponding device plugin from the GPU vendor. Here are some links to vendors' instructions:

- [AMD](#)
- [Intel](#)
- [NVIDIA](#)

Once you have installed the plugin, your cluster exposes a custom schedulable resource such as `amd.com/gpu` or `nvidia.com/gpu`.

You can consume these GPUs from your containers by requesting the custom GPU resource, the same way you request `cpu` or `memory`. However, there are some limitations in how you specify the resource requirements for custom devices.

GPUs are only supposed to be specified in the `limits` section, which means:

- You can specify GPU limits without specifying requests, because Kubernetes will use the limit as the request value by default.
- You can specify GPU in both `limits` and `requests` but these two values must be equal.
- You cannot specify GPU requests without specifying limits.

Here's an example manifest for a Pod that requests a GPU:

```
apiVersion: v1
kind: Pod
metadata:
  name: example-vector-add
spec:
  restartPolicy: OnFailure
  containers:
  - name: example-vector-add
    image: "registry.example/example-vector-add:v42"
    resources:
      limits:
        gpu-vendor.example/example-gpu: 1 # requesting 1 GPU
```

Manage clusters with different types of GPUs

If different nodes in your cluster have different types of GPUs, then you can use [Node Labels and Node Selectors](#) to schedule pods to appropriate nodes.

For example:

```
# Label your nodes with the accelerator type they have.
kubectl label nodes node1 accelerator=example-gpu-x100
kubectl label nodes node2 accelerator=other-gpu-k915
```

That label key `accelerator` is just an example; you can use a different label key if you prefer.

Automatic node labelling

As an administrator, you can automatically discover and label all your GPU enabled nodes by deploying Kubernetes [Node Feature Discovery](#) (NFD). NFD detects the hardware features that are available on each node in a Kubernetes cluster. Typically, NFD is configured to advertise those features as node labels, but NFD can also add extended resources, annotations, and node taints. NFD is compatible with all [supported versions](#) of Kubernetes. By default NFD create the [feature labels](#) for the detected features. Administrators can leverage NFD to also taint nodes with specific features, so that only pods that request those features can be scheduled on those nodes.

You also need a plugin for NFD that adds appropriate labels to your nodes; these might be generic labels or they could be vendor specific. Your GPU vendor may provide a third party plugin for NFD; check their documentation for more details.

```
apiVersion: v1
kind: Pod
metadata:
  name: example-vector-add
spec:
  restartPolicy: OnFailure
  # You can use Kubernetes node affinity to schedule this Pod onto a node
  # that provides the kind of GPU that its container needs in order to work
  affinity:
    nodeAffinity:
      requiredDuringSchedulingIgnoredDuringExecution:
        nodeSelectorTerms:
          - matchExpressions:
              - key: "gpu.gpu-vendor.example/installed-memory"
                operator: Gt # (greater than)
                values: ["40535"]
              - key: "feature.node.kubernetes.io/pci-10.present" # NFD Feature label
                values: ["true"] # (optional) only schedule on nodes with PCI device 10
  containers:
    - name: example-vector-add
      image: "registry.example/example-vector-add:v42"
      resources:
        limits:
          gpu-vendor.example/example-gpu: 1 # requesting 1 GPU
```

GPU vendor implementations

- [Intel](#)
- [NVIDIA](#)

This section of the Kubernetes documentation contains tutorials. A tutorial shows how to accomplish a goal that is larger than a single [task](#). Typically a tutorial has several sections, each of which has a sequence of steps. Before walking through each tutorial, you may want to bookmark the [Standardized Glossary](#) page for later references.

Basics

- [Kubernetes Basics](#) is an in-depth interactive tutorial that helps you understand the Kubernetes system and try out some basic Kubernetes features.
- [Introduction to Kubernetes \(edX\)](#)
- [Hello Minikube](#)

Configuration

- [Example: Configuring a Java Microservice](#)

What's next

If you would like to write a tutorial, see [Content Page Types](#) for information about the tutorial page type.

Hello Minikube

This tutorial shows you how to run a sample app on Kubernetes using minikube. The tutorial provides a container image that uses NGINX to echo back all the requests.

Objectives

- Deploy a sample application to minikube.
- Run the app.
- View application logs.

Before you begin

This tutorial assumes that you have already set up minikube. See **Step 1** in [minikube start](#) for installation instructions.

Note:

Only execute the instructions in **Step 1, Installation**. The rest is covered on this page.

You also need to install kubectl. See [Install tools](#) for installation instructions.

Create a minikube cluster

```
minikube start
```

Open the Dashboard

Open the Kubernetes dashboard. You can do this two different ways:

- [Launch a browser](#)
- [URL copy and paste](#)

Open a **new** terminal, and run:

```
# Start a new terminal, and leave this running.  
minikube dashboard
```

Now, switch back to the terminal where you ran minikube start.

Note:

The dashboard command enables the dashboard add-on and opens the proxy in the default web browser. You can create Kubernetes resources on the dashboard such as Deployment and Service.

To find out how to avoid directly invoking the browser from the terminal and get a URL for the web dashboard, see the "URL copy and paste" tab.

By default, the dashboard is only accessible from within the internal Kubernetes virtual network. The dashboard command creates a temporary proxy to make the dashboard accessible from outside the Kubernetes virtual network.

To stop the proxy, run Ctrl+C to exit the process. After the command exits, the dashboard remains running in the Kubernetes cluster. You can run the dashboard command again to create another proxy to access the dashboard.

If you don't want minikube to open a web browser for you, run the dashboard subcommand with the --url flag. minikube outputs a URL that you can open in the browser you prefer.

Open a **new** terminal, and run:

```
# Start a new terminal, and leave this running.
minikube dashboard --url
```

Now, you can use this URL and switch back to the terminal where you ran minikube start.

Create a Deployment

A Kubernetes [Pod](#) is a group of one or more Containers, tied together for the purposes of administration and networking. The Pod in this tutorial has only one Container. A Kubernetes [Deployment](#) checks on the health of your Pod and restarts the Pod's Container if it terminates. Deployments are the recommended way to manage the creation and scaling of Pods.

1. Use the kubectl create command to create a Deployment that manages a Pod. The Pod runs a Container based on the provided Docker image.

```
# Run a test container image that includes a webserver
kubectl create deployment hello-node --image=registry.k8s.io/e2e-test-images/agnhost:
2.39 -- /agnhost netexec --http-port=8080
```

2. View the Deployment:

```
kubectl get deployments
```

The output is similar to:

| NAME | READY | UP-TO-DATE | AVAILABLE | AGE |
|------------|-------|------------|-----------|-----|
| hello-node | 1/1 | 1 | 1 | 1m |

(It may take some time for the pod to become available. If you see "0/1", try again in a few seconds.)

3. View the Pod:

```
kubectl get pods
```

The output is similar to:

| NAME | READY | STATUS | RESTARTS | AGE |
|-----------------------------|-------|---------|----------|-----|
| hello-node-5f76cf6ccf-br9b5 | 1/1 | Running | 0 | 1m |

4. View cluster events:

```
kubectctl get events
```

5. View the kubectctl configuration:

```
kubectctl config view
```

6. View application logs for a container in a pod.

```
kubectctl logs hello-node-5f76cf6ccf-br9b5
```

The output is similar to:

```
I0911 09:19:26.677397    1 log.go:195] Started HTTP server on port 8080
I0911 09:19:26.677586    1 log.go:195] Started UDP server on port 8081
```

Note:

For more information about kubectctl commands, see the [kubectctl overview](#).

Create a Service

By default, the Pod is only accessible by its internal IP address within the Kubernetes cluster. To make the hello-node Container accessible from outside the Kubernetes virtual network, you have to expose the Pod as a Kubernetes [Service](#).

1. Expose the Pod to the public internet using the kubectctl expose command:

```
kubectctl expose deployment hello-node --type=LoadBalancer --port=8080
```

The `--type=LoadBalancer` flag indicates that you want to expose your Service outside of the cluster.

The application code inside the test image only listens on TCP port 8080. If you used `kubectctl expose` to expose a different port, clients could not connect to that other port.

2. View the Service you created:

```
kubectctl get services
```

The output is similar to:

| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE |
|------------|--------------|---------------|-------------|----------------|-----|
| hello-node | LoadBalancer | 10.108.144.78 | <pending> | 8080:30369/TCP | 21s |
| kubernetes | ClusterIP | 10.96.0.1 | <none> | 443/TCP | 23m |

On cloud providers that support load balancers, an external IP address would be provisioned to access the Service. On minikube, the LoadBalancer type makes the Service accessible through the `minikube service` command.

3. Run the following command:

```
minikube service hello-node
```

This opens up a browser window that serves your app and shows the app's response.

Enable addons

The minikube tool includes a set of built-in [addons](#) that can be enabled, disabled and opened in the local Kubernetes environment.

1. List the currently supported addons:

```
minikube addons list
```

The output is similar to:

```
addon-manager: enabled
dashboard: enabled
default-storageclass: enabled
efk: disabled
freshpod: disabled
gvisor: disabled
helm-tiller: disabled
ingress: disabled
ingress-dns: disabled
logviewer: disabled
metrics-server: disabled
nvidia-driver-installer: disabled
nvidia-gpu-device-plugin: disabled
registry: disabled
registry-creds: disabled
storage-provisioner: enabled
storage-provisioner-gluster: disabled
```

2. Enable an addon, for example, metrics-server:

```
minikube addons enable metrics-server
```

The output is similar to:

```
The 'metrics-server' addon is enabled
```

3. View the Pod and Service you created by installing that addon:

```
kubectl get pod,svc -n kube-system
```

The output is similar to:

| NAME | READY | STATUS | RESTARTS | AGE |
|--------------------------------------|-------|---------|----------|-----|
| pod/coredns-5644d7b6d9-mh9ll | 1/1 | Running | 0 | 34m |
| pod/coredns-5644d7b6d9-pqd2t | 1/1 | Running | 0 | 34m |
| pod/metrics-server-67fb648c5 | 1/1 | Running | 0 | 26s |
| pod/etcd-minikube | 1/1 | Running | 0 | 34m |
| pod/influxdb-grafana-b29w8 | 2/2 | Running | 0 | 26s |
| pod/kube-addon-manager-minikube | 1/1 | Running | 0 | 34m |
| pod/kube-apiserver-minikube | 1/1 | Running | 0 | 34m |
| pod/kube-controller-manager-minikube | 1/1 | Running | 0 | 34m |
| pod/kube-proxy-rnlps | 1/1 | Running | 0 | 34m |
| pod/kube-scheduler-minikube | 1/1 | Running | 0 | 34m |

| pod/storage-provisioner | | 1/1 | Running | 0 | 34m | |
|-----------------------------|-----------|---------------|-------------|-------------------|-----|--|
| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE | |
| service/metrics-server | ClusterIP | 10.96.241.45 | <none> | 80/TCP | 26s | |
| service/kube-dns | ClusterIP | 10.96.0.10 | <none> | 53/UDP,53/TCP | 34m | |
| service/monitoring-grafana | NodePort | 10.99.24.54 | <none> | 80:30002/TCP | 26s | |
| service/monitoring-influxdb | ClusterIP | 10.111.169.94 | <none> | 8083/TCP,8086/TCP | 26s | |

4. Check the output from metrics-server:

```
kubectl top pods
```

The output is similar to:

| NAME | CPU(cores) | MEMORY(bytes) |
|----------------------------|------------|---------------|
| hello-node-ccf4b9788-4jn97 | 1m | 6Mi |

If you see the following message, wait, and try again:

```
error: Metrics API not available
```

5. Disable metrics-server:

```
minikube addons disable metrics-server
```

The output is similar to:

```
metrics-server was successfully disabled
```

Clean up

Now you can clean up the resources you created in your cluster:

```
kubectl delete service hello-node
kubectl delete deployment hello-node
```

Stop the Minikube cluster

```
minikube stop
```

Optionally, delete the Minikube VM:

```
# Optional
minikube delete
```

If you want to use minikube again to learn more about Kubernetes, you don't need to delete it.

Conclusion

This page covered the basic aspects to get a minikube cluster up and running. You are now ready to deploy applications.

Learn Kubernetes Basics

html

Kubernetes Basics

This tutorial provides a walkthrough of the basics of the Kubernetes cluster orchestration system. Each module contains some background information on major Kubernetes features and concepts, and a tutorial for you to follow along.

Using the tutorials, you can learn to:

- Deploy a containerized application on a cluster.
- Scale the deployment.
- Update the containerized application with a new software version.
- Debug the containerized application.

What can Kubernetes do for you?

With modern web services, users expect applications to be available 24/7, and developers expect to deploy new versions of those applications several times a day. Containerization helps package software to serve these goals, enabling applications to be released and updated without downtime. Kubernetes helps you make sure those containerized applications run where and when you want, and helps them find the resources and tools they need to work. Kubernetes is a production-ready, open source platform designed with Google's accumulated experience in container orchestration, combined with best-of-breed ideas from the community.

Kubernetes Clusters

Kubernetes coordinates a highly available cluster of computers that are connected to work as a single unit. The abstractions in Kubernetes allow you to deploy containerized applications to a cluster without tying them specifically to individual machines. To make use of this new model of deployment, applications need to be packaged in a way that decouples them from individual hosts: they need to be containerized. Containerized applications are more flexible and available than in past deployment models, where applications were installed directly onto specific machines as packages deeply integrated into the host. **Kubernetes automates the distribution and scheduling of application containers across a cluster in a more efficient way.** Kubernetes is an open-source platform and is production-ready.

A Kubernetes cluster consists of two types of resources:

- The **Control Plane** coordinates the cluster
- **Nodes** are the workers that run applications

Summary:

- Kubernetes cluster

- Minikube

Kubernetes is a production-grade, open-source platform that orchestrates the placement (scheduling) and execution of application containers within and across computer clusters.

Cluster Diagram

The Control Plane is responsible for managing the cluster. The Control Plane coordinates all activities in your cluster, such as scheduling applications, maintaining applications' desired state, scaling applications, and rolling out new updates.

A node is a VM or a physical computer that serves as a worker machine in a Kubernetes cluster. Each node has a Kubelet, which is an agent for managing the node and communicating with the Kubernetes control plane. The node should also have tools for handling container operations, such as [containerd](#) or [CRI-O](#). A Kubernetes cluster that handles production traffic should have a minimum of three nodes because if one node goes down, both an [etcd](#) member and a control plane instance are lost, and redundancy is compromised. You can mitigate this risk by adding more control plane nodes.

Control Planes manage the cluster and the nodes that are used to host the running applications.

When you deploy applications on Kubernetes, you tell the control plane to start the application containers. The control plane schedules the containers to run on the cluster's nodes. **Node-level components, such as the kubelet, communicate with the control plane using the [Kubernetes API](#)**, which the control plane exposes. End users can also use the Kubernetes API directly to interact with the cluster.

A Kubernetes cluster can be deployed on either physical or virtual machines. To get started with Kubernetes development, you can use Minikube. Minikube is a lightweight Kubernetes implementation that creates a VM on your local machine and deploys a simple cluster containing only one node. Minikube is available for Linux, macOS, and Windows systems. The Minikube CLI provides basic bootstrapping operations for working with your cluster, including start, stop, status, and delete.

Now that you know more about what Kubernetes is, visit [Hello Minikube](#) to try this out on your computer.

Kubernetes Deployments

Note:

This tutorial uses a container that requires the AMD64 architecture. If you are using minikube on a computer with a different CPU architecture, you could try using minikube with a driver that can emulate AMD64. For example, the Docker Desktop driver can do this.

Once you have a [running Kubernetes cluster](#), you can deploy your containerized applications on top of it. To do so, you create a Kubernetes **Deployment**. The Deployment instructs Kubernetes how to create and update instances of your application. Once you've created a Deployment, the Kubernetes control plane schedules the application instances included in that Deployment to run on individual Nodes in the cluster.

Once the application instances are created, a Kubernetes Deployment controller continuously monitors those instances. If the Node hosting an instance goes down or is deleted, the Deployment controller replaces the instance with an instance on another Node in the cluster. **This provides a self-healing mechanism to address machine failure or maintenance.**

In a pre-orchestration world, installation scripts would often be used to start applications, but they did not allow recovery from machine failure. By both creating your application instances and keeping them running across Nodes, Kubernetes Deployments provide a fundamentally different approach to application management.

Summary:

- Deployments
- Kubectl

A Deployment is responsible for creating and updating instances of your application

Deploying your first app on Kubernetes

You can create and manage a Deployment by using the Kubernetes command line interface, **kubectl**. Kubectl uses the Kubernetes API to interact with the cluster. In this module, you'll

learn the most common kubectl commands needed to create Deployments that run your applications on a Kubernetes cluster.

When you create a Deployment, you'll need to specify the container image for your application and the number of replicas that you want to run. You can change that information later by updating your Deployment; Modules [5](#) and [6](#) of the bootcamp discuss how you can scale and update your Deployments.

Applications need to be packaged into one of the supported container formats in order to be deployed on Kubernetes

For your first Deployment, you'll use a hello-node application packaged in a Docker container that uses NGINX to echo back all the requests. (If you didn't already try creating a hello-node application and deploying it using a container, you can do that first by following the instructions from the [Hello Minikube tutorial](#)).

You will need to have installed kubectl as well. If you need to install it, visit [install tools](#).

Now that you know what Deployments are, let's deploy our first app!

kubectl basics

The common format of a kubectl command is: `kubectl action resource`

This performs the specified *action* (like create, describe or delete) on the specified *resource* (like node or deployment). You can use `--help` after the subcommand to get additional info about possible parameters (for example: `kubectl get nodes --help`).

Check that kubectl is configured to talk to your cluster, by running the **kubectl version** command.

Check that kubectl is installed and you can see both the client and the server versions.

To view the nodes in the cluster, run the **kubectl get nodes** command.

You see the available nodes. Later, Kubernetes will choose where to deploy our application based on Node available resources.

Deploy an app

Let's deploy our first app on Kubernetes with the `kubectl create deployment` command. We need to provide the deployment name and app image location (include the full repository url for images hosted outside Docker Hub).

```
kubectl create deployment kubernetes-bootcamp --image=gcr.io/google-samples/  
kubernetes-bootcamp:v1
```

Great! You just deployed your first application by creating a deployment. This performed a few things for you:

- searched for a suitable node where an instance of the application could be run (we have only 1 available node)
- scheduled the application to run on that Node
- configured the cluster to reschedule the instance on a new Node when needed

To list your deployments use the `kubectl get deployments` command:

kubectl get deployments

We see that there is 1 deployment running a single instance of your app. The instance is running inside a container on your node.

View the app

[Pods](#) that are running inside Kubernetes are running on a private, isolated network. By default they are visible from other pods and services within the same Kubernetes cluster, but not outside that network. When we use `kubectl`, we're interacting through an API endpoint to communicate with our application.

We will cover other options on how to expose your application outside the Kubernetes cluster later, in [Module 4](#). Also as a basic tutorial, we're not explaining what Pods are in any detail here, it will be covered in later topics.

The `kubectl proxy` command can create a proxy that will forward communications into the cluster-wide, private network. The proxy can be terminated by pressing control-C and won't show any output while it's running.

You need to open a second terminal window to run the proxy.

kubectl proxy

We now have a connection between our host (the terminal) and the Kubernetes cluster. The proxy enables direct access to the API from these terminals.

You can see all those APIs hosted through the proxy endpoint. For example, we can query the version directly through the API using the `curl` command:

`curl http://localhost:8001/version`

Note: If port 8001 is not accessible, ensure that the `kubectl proxy` that you started above is running in the second terminal.

The API server will automatically create an endpoint for each pod, based on the pod name, that is also accessible through the proxy.

First we need to get the Pod name, and we'll store it in the environment variable `POD_NAME`:

```
export POD_NAME=$(kubectl get pods -o go-template --template '{{range .items}}  
{{.metadata.name}}{{"\n"}}{{end}}')  
echo Name of the Pod: $POD_NAME
```

You can access the Pod through the proxied API, by running:

```
curl http://localhost:8001/api/v1/namespaces/default/pods/$POD_NAME:8080/proxy/
```

In order for the new Deployment to be accessible without using the proxy, a Service is required which will be explained in [Module 4](#).

Once you're ready, move on to [Viewing Pods and Nodes](#).

html

Objectives

- Learn about Kubernetes Pods.
- Learn about Kubernetes Nodes.
- Troubleshoot deployed applications.

Kubernetes Pods

When you created a Deployment in [Module 2](#), Kubernetes created a **Pod** to host your application instance. A Pod is a Kubernetes abstraction that represents a group of one or more application containers (such as Docker), and some shared resources for those containers. Those resources include:

- Shared storage, as Volumes
- Networking, as a unique cluster IP address
- Information about how to run each container, such as the container image version or specific ports to use

A Pod models an application-specific "logical host" and can contain different application containers which are relatively tightly coupled. For example, a Pod might include both the container with your Node.js app as well as a different container that feeds the data to be published by the Node.js webserver. The containers in a Pod share an IP Address and port space, are always co-located and co-scheduled, and run in a shared context on the same Node.

Pods are the atomic unit on the Kubernetes platform. When we create a Deployment on Kubernetes, that Deployment creates Pods with containers inside them (as opposed to creating containers directly). Each Pod is tied to the Node where it is scheduled, and remains there until

termination (according to restart policy) or deletion. In case of a Node failure, identical Pods are scheduled on other available Nodes in the cluster.

Summary:

- Pods
- Nodes
- Kubectl main commands

A Pod is a group of one or more application containers (such as Docker) and includes shared storage (volumes), IP address and information about how to run them.

Pods overview

Nodes

A Pod always runs on a **Node**. A Node is a worker machine in Kubernetes and may be either a virtual or a physical machine, depending on the cluster. Each Node is managed by the control plane. A Node can have multiple pods, and the Kubernetes control plane automatically handles scheduling the pods across the Nodes in the cluster. The control plane's automatic scheduling takes into account the available resources on each Node.

Every Kubernetes Node runs at least:

- Kubelet, a process responsible for communication between the Kubernetes control plane and the Node; it manages the Pods and the containers running on a machine.
- A container runtime (like Docker) responsible for pulling the container image from a registry, unpacking the container, and running the application.

Containers should only be scheduled together in a single Pod if they are tightly coupled and need to share resources such as disk.

Node overview

Troubleshooting with kubectl

In Module [2](#), you used the kubectl command-line interface. You'll continue to use it in Module 3 to get information about deployed applications and their environments. The most common operations can be done with the following kubectl subcommands:

- **kubectl get** - list resources

- **kubectl describe** - show detailed information about a resource
- **kubectl logs** - print the logs from a container in a pod
- **kubectl exec** - execute a command on a container in a pod

You can use these commands to see when applications were deployed, what their current statuses are, where they are running and what their configurations are.

Now that we know more about our cluster components and the command line, let's explore our application.

A node is a worker machine in Kubernetes and may be a VM or physical machine, depending on the cluster. Multiple Pods can run on one Node.

Check application configuration

Let's verify that the application we deployed in the previous scenario is running. We'll use the kubectl get command and look for existing Pods:

kubectl get pods

If no pods are running, please wait a couple of seconds and list the Pods again. You can continue once you see one Pod running.

Next, to view what containers are inside that Pod and what images are used to build those containers we run the kubectl describe pods command:

kubectl describe pods

We see here details about the Pod's container: IP address, the ports used and a list of events related to the lifecycle of the Pod.

The output of the describe subcommand is extensive and covers some concepts that we didn't explain yet, but don't worry, they will become familiar by the end of this bootcamp.

***Note:** the describe subcommand can be used to get detailed information about most of the Kubernetes primitives, including Nodes, Pods, and Deployments. The describe output is designed to be human readable, not to be scripted against.*

Show the app in the terminal

Recall that Pods are running in an isolated, private network - so we need to proxy access to them so we can debug and interact with them. To do this, we'll use the kubectl proxy command to run a proxy in a **second terminal**. Open a new terminal window, and in that new terminal, run:

kubectl proxy

Now again, we'll get the Pod name and query that pod directly through the proxy. To get the Pod name and store it in the POD_NAME environment variable:

```
export POD_NAME="$(kubectl get pods -o go-template --template '{{range .items}}
{{.metadata.name}}{{"\n"}}{{end}}')"
```

echo Name of the Pod: \$POD_NAME

To see the output of our application, run a `curl` request:

```
curl http://localhost:8001/api/v1/namespaces/default/pods/$POD_NAME:8080/proxy/
```

The URL is the route to the API of the Pod.

View the container logs

Anything that the application would normally send to standard output becomes logs for the container within the Pod. We can retrieve these logs using the `kubectl logs` command:

```
kubectl logs "$POD_NAME"
```

***Note:** We don't need to specify the container name, because we only have one container inside the pod.*

Executing command on the container

We can execute commands directly on the container once the Pod is up and running. For this, we use the `exec` subcommand and use the name of the Pod as a parameter. Let's list the environment variables:

```
kubectl exec "$POD_NAME" -- env
```

Again, it's worth mentioning that the name of the container itself can be omitted since we only have a single container in the Pod.

Next let's start a bash session in the Pod's container:

```
kubectl exec -ti $POD_NAME -- bash
```

We have now an open console on the container where we run our NodeJS application. The source code of the app is in the `server.js` file:

```
cat server.js
```

You can check that the application is up by running a `curl` command:

```
curl http://localhost:8080
```

***Note:** here we used localhost because we executed the command inside the NodeJS Pod. If you cannot connect to localhost:8080, check to make sure you have run the `kubectl exec` command and are launching the command from within the Pod*

To close your container connection, type `exit`.

Once you're ready, move on to [Using A Service To Expose Your App](#).

Expose Your App Publicly

[Using a Service to Expose Your App](#)

Learn about a Service in Kubernetes. Understand how labels and selectors relate to a Service. Expose an application outside a Kubernetes cluster.

Using a Service to Expose Your App

Learn about a Service in Kubernetes. Understand how labels and selectors relate to a Service. Expose an application outside a Kubernetes cluster.
html

Objectives

- Learn about a Service in Kubernetes
- Understand how labels and selectors relate to a Service
- Expose an application outside a Kubernetes cluster using a Service

Overview of Kubernetes Services

Kubernetes [Pods](#) are mortal. Pods have a [lifecycle](#). When a worker node dies, the Pods running on the Node are also lost. A [ReplicaSet](#) might then dynamically drive the cluster back to the desired state via the creation of new Pods to keep your application running. As another example, consider an image-processing backend with 3 replicas. Those replicas are exchangeable; the front-end system should not care about backend replicas or even if a Pod is lost and recreated. That said, each Pod in a Kubernetes cluster has a unique IP address, even Pods on the same Node, so there needs to be a way of automatically reconciling changes among Pods so that your applications continue to function.

A Service in Kubernetes is an abstraction which defines a logical set of Pods and a policy by which to access them. Services enable a loose coupling between dependent Pods. A Service is defined using YAML or JSON, like all Kubernetes object manifests. The set of Pods targeted by a Service is usually determined by a *label selector* (see below for why you might want a Service without including a selector in the spec).

Although each Pod has a unique IP address, those IPs are not exposed outside the cluster without a Service. Services allow your applications to receive traffic. Services can be exposed in different ways by specifying a type in the spec of the Service:

- *ClusterIP* (default) - Exposes the Service on an internal IP in the cluster. This type makes the Service only reachable from within the cluster.
- *NodePort* - Exposes the Service on the same port of each selected Node in the cluster using NAT. Makes a Service accessible from outside the cluster using `<NodeIP>:<NodePort>`. Superset of ClusterIP.
- *LoadBalancer* - Creates an external load balancer in the current cloud (if supported) and assigns a fixed, external IP to the Service. Superset of NodePort.
- *ExternalName* - Maps the Service to the contents of the externalName field (e.g. `foo.bar.example.com`), by returning a CNAME record with its value. No proxying of any kind is set up. This type requires v1.7 or higher of kube-dns, or CoreDNS version 0.0.8 or higher.

More information about the different types of Services can be found in the [Using Source IP](#) tutorial. Also see [Connecting Applications with Services](#).

Additionally, note that there are some use cases with Services that involve not defining a selector in the spec. A Service created without selector will also not create the corresponding Endpoints object. This allows users to manually map a Service to specific endpoints. Another possibility why there may be no selector is you are strictly using type: ExternalName.

Summary

- Exposing Pods to external traffic
- Load balancing traffic across multiple Pods
- Using labels

A Kubernetes Service is an abstraction layer which defines a logical set of Pods and enables external traffic exposure, load balancing and service discovery for those Pods.

Services and Labels

A Service routes traffic across a set of Pods. Services are the abstraction that allows pods to die and replicate in Kubernetes without impacting your application. Discovery and routing among dependent Pods (such as the frontend and backend components in an application) are handled by Kubernetes Services.

Services match a set of Pods using [labels and selectors](#), a grouping primitive that allows logical operation on objects in Kubernetes. Labels are key/value pairs attached to objects and can be used in any number of ways:

- Designate objects for development, test, and production
- Embed version tags
- Classify an object using tags

Labels can be attached to objects at creation time or later on. They can be modified at any time. Let's expose our application now using a Service and apply some labels.

Step 1: Creating a new Service

Let's verify that our application is running. We'll use the `kubectl get` command and look for existing Pods:

kubectl get pods

If no Pods are running then it means the objects from the previous tutorials were cleaned up. In this case, go back and recreate the deployment from the [Using kubectl to create a Deployment](#) tutorial. Please wait a couple of seconds and list the Pods again. You can continue once you see the one Pod running.

Next, let's list the current Services from our cluster:

kubectl get services

We have a Service called kubernetes that is created by default when minikube starts the cluster. To create a new service and expose it to external traffic we'll use the expose command with NodePort as parameter.

kubectl expose deployment/kubernetes-bootcamp --type="NodePort" --port 8080

Let's run again the get services subcommand:

kubectl get services

We have now a running Service called kubernetes-bootcamp. Here we see that the Service received a unique cluster-IP, an internal port and an external-IP (the IP of the Node).

To find out what port was opened externally (for the type: NodePort Service) we'll run the describe service subcommand:

kubectl describe services/kubernetes-bootcamp

Create an environment variable called NODE_PORT that has the value of the Node port assigned:

```
export NODE_PORT="$(kubectl get services/kubernetes-bootcamp -o go-template='{{(index .spec.ports 0).nodePort}}')"  
echo "NODE_PORT=$NODE_PORT"
```

Now we can test that the app is exposed outside of the cluster using curl, the IP address of the Node and the externally exposed port:

```
curl http://$(minikube ip):$NODE_PORT"
```

Note:

If you're running minikube with Docker Desktop as the container driver, a minikube tunnel is needed. This is because containers inside Docker Desktop are isolated from your host computer.

In a separate terminal window, execute:

```
minikube service kubernetes-bootcamp --url
```

The output looks like this:

```
http://127.0.0.1:51082
```

```
! Because you are using a Docker driver on darwin, the terminal needs to be open to run it.
```

Then use the given URL to access the app:

```
curl 127.0.0.1:51082
```

And we get a response from the server. The Service is exposed.

Step 2: Using labels

The Deployment created automatically a label for our Pod. With the `describe deployment` subcommand you can see the name (the *key*) of that label:

`kubectl describe deployment`

Let's use this label to query our list of Pods. We'll use the `kubectl get pods` command with `-l` as a parameter, followed by the label values:

`kubectl get pods -l app=kubernetes-bootcamp`

You can do the same to list the existing Services:

`kubectl get services -l app=kubernetes-bootcamp`

Get the name of the Pod and store it in the `POD_NAME` environment variable:

```
export POD_NAME="$(kubectl get pods -o go-template --template '{{range .items}}
{{.metadata.name}}{{"\n"}}{{end}}')"
```

`echo "Name of the Pod: $POD_NAME"`

To apply a new label we use the `label` subcommand followed by the object type, object name and the new label:

`kubectl label pods "$POD_NAME" version=v1`

This will apply a new label to our Pod (we pinned the application version to the Pod), and we can check it with the `describe pod` command:

`kubectl describe pods "$POD_NAME"`

We see here that the label is attached now to our Pod. And we can query now the list of pods using the new label:

`kubectl get pods -l version=v1`

And we see the Pod.

Step 3: Deleting a service

To delete Services you can use the `delete service` subcommand. Labels can be used also here:

`kubectl delete service -l app=kubernetes-bootcamp`

Confirm that the Service is gone:

`kubectl get services`

This confirms that our Service was removed. To confirm that route is not exposed anymore you can `curl` the previously exposed IP and port:

```
curl http://"$(minikube ip):$NODE_PORT"
```

This proves that the application is not reachable anymore from outside of the cluster. You can confirm that the app is still running with a curl from inside the pod:

```
kubectl exec -ti $POD_NAME -- curl http://localhost:8080
```

We see here that the application is up. This is because the Deployment is managing the application. To shut down the application, you would need to delete the Deployment as well.

Once you're ready, move on to [Running Multiple Instances of Your App](#).

Scale Your App

[Running Multiple Instances of Your App](#)

Scale an existing app manually using kubectl.

Running Multiple Instances of Your App

Scale an existing app manually using kubectl.
html

Objectives

- Scale an app using kubectl.

Scaling an application

Previously we created a [Deployment](#), and then exposed it publicly via a [Service](#). The Deployment created only one Pod for running our application. When traffic increases, we will need to scale the application to keep up with user demand.

If you haven't worked through the earlier sections, start from [Using minikube to create a cluster](#).

Scaling is accomplished by changing the number of replicas in a Deployment

Summary:

- Scaling a Deployment

You can create from the start a Deployment with multiple instances using the --replicas parameter for the kubectl create deployment command

Note:

If you are trying this after [the previous section](#), then you may have deleted the service you created, or have created a Service of type: NodePort. In this section, it is assumed that a service with type: LoadBalancer is created for the kubernetes-bootcamp Deployment.

If you have *not* deleted the Service created in [the previous section](#), first delete that Service and then run the following command to create a new Service with its type set to LoadBalancer:

```
kubectl expose deployment/kubernetes-bootcamp --type="LoadBalancer" --port 8080
```

Scaling overview

- 1.
- 2.

[Previous](#) [Next](#)

Scaling out a Deployment will ensure new Pods are created and scheduled to Nodes with available resources. Scaling will increase the number of Pods to the new desired state. Kubernetes also supports [autoscaling](#) of Pods, but it is outside of the scope of this tutorial. Scaling to zero is also possible, and it will terminate all Pods of the specified Deployment.

Running multiple instances of an application will require a way to distribute the traffic to all of them. Services have an integrated load-balancer that will distribute network traffic to all Pods of an exposed Deployment. Services will monitor continuously the running Pods using endpoints, to ensure the traffic is sent only to available Pods.

Scaling is accomplished by changing the number of replicas in a Deployment.

Once you have multiple instances of an application running, you would be able to do Rolling updates without downtime. We'll cover that in the next section of the tutorial. Now, let's go to the terminal and scale our application.

Scaling a Deployment

To list your Deployments, use the `get deployments` subcommand:

```
kubectl get deployments
```

The output should be similar to:

| NAME | READY | UP-TO-DATE | AVAILABLE | AGE |
|---------------------|-------|------------|-----------|-----|
| kubernetes-bootcamp | 1/1 | 1 | 1 | 11m |

We should have 1 Pod. If not, run the command again. This shows:

- *NAME* lists the names of the Deployments in the cluster.
- *READY* shows the ratio of CURRENT/DESIRED replicas
- *UP-TO-DATE* displays the number of replicas that have been updated to achieve the desired state.
- *AVAILABLE* displays how many replicas of the application are available to your users.
- *AGE* displays the amount of time that the application has been running.

To see the ReplicaSet created by the Deployment, run:

kubectl get rs

Notice that the name of the ReplicaSet is always formatted as [DEPLOYMENT-NAME]-[RANDOM-STRING]. The random string is randomly generated and uses the *pod-template-hash* as a seed.

Two important columns of this output are:

- *DESIRED* displays the desired number of replicas of the application, which you define when you create the Deployment. This is the desired state.
- *CURRENT* displays how many replicas are currently running.

Next, let's scale the Deployment to 4 replicas. We'll use the `kubectl scale` command, followed by the Deployment type, name and desired number of instances:

```
kubectl scale deployments/kubernetes-bootcamp --replicas=4
```

To list your Deployments once again, use `get deployments`:

kubectl get deployments

The change was applied, and we have 4 instances of the application available. Next, let's check if the number of Pods changed:

kubectl get pods -o wide

There are 4 Pods now, with different IP addresses. The change was registered in the Deployment events log. To check that, use the `describe` subcommand:

kubectl describe deployments/kubernetes-bootcamp

You can also view in the output of this command that there are 4 replicas now.

Load Balancing

Let's check that the Service is load-balancing the traffic. To find out the exposed IP and Port we can use the `describe service` as we learned in the previous part of the tutorial:

kubectl describe services/kubernetes-bootcamp

Create an environment variable called `NODE_PORT` that has a value as the Node port:

```
export NODE_PORT="$(kubectl get services/kubernetes-bootcamp -o go-template='{{(index .spec.ports 0).nodePort}}')"
```

```
echo NODE_PORT=$NODE_PORT
```

Next, we'll do a `curl` to the exposed IP address and port. Execute the command multiple times:

```
curl http://"$(minikube ip):$NODE_PORT"
```

We hit a different Pod with every request. This demonstrates that the load-balancing is working.

Note:

If you're running minikube with Docker Desktop as the container driver, a minikube tunnel is needed. This is because containers inside Docker Desktop are isolated from your host computer.

In a separate terminal window, execute:

```
minikube service kubernetes-bootcamp --url
```

The output looks like this:

```
http://127.0.0.1:51082
```

```
! Because you are using a Docker driver on darwin, the terminal needs to be open to run it.
```

Then use the given URL to access the app:

```
curl 127.0.0.1:51082
```

Scale Down

To scale down the Deployment to 2 replicas, run again the `scale` subcommand:

```
kubectl scale deployments/kubernetes-bootcamp --replicas=2
```

List the Deployments to check if the change was applied with the `get deployments` subcommand:

```
kubectl get deployments
```

The number of replicas decreased to 2. List the number of Pods, with `get pods`:

```
kubectl get pods -o wide
```

This confirms that 2 Pods were terminated.

Once you're ready, move on to [Performing a Rolling Update](#).

Update Your App

[Performing a Rolling Update](#)

Perform a rolling update using `kubectl`.

Performing a Rolling Update

Perform a rolling update using `kubectl`.

```
html
```

Objectives

- Perform a rolling update using kubectl.

Updating an application

Users expect applications to be available all the time, and developers are expected to deploy new versions of them several times a day. In Kubernetes this is done with rolling updates. A **rolling update** allows a Deployment update to take place with zero downtime. It does this by incrementally replacing the current Pods with new ones. The new Pods are scheduled on Nodes with available resources, and Kubernetes waits for those new Pods to start before removing the old Pods.

In the previous module we scaled our application to run multiple instances. This is a requirement for performing updates without affecting application availability. By default, the maximum number of Pods that can be unavailable during the update and the maximum number of new Pods that can be created, is one. Both options can be configured to either numbers or percentages (of Pods). In Kubernetes, updates are versioned and any Deployment update can be reverted to a previous (stable) version.

Summary:

- Updating an app

Rolling updates allow Deployments' update to take place with zero downtime by incrementally updating Pods instances with new ones.

Rolling updates overview

- 1.
- 2.
- 3.
- 4.

[Previous](#) [Next](#)

Similar to application Scaling, if a Deployment is exposed publicly, the Service will load-balance the traffic only to available Pods during the update. An available Pod is an instance that is available to the users of the application.

Rolling updates allow the following actions:

- Promote an application from one environment to another (via container image updates)
- Rollback to previous versions
- Continuous Integration and Continuous Delivery of applications with zero downtime

If a Deployment is exposed publicly, the Service will load-balance the traffic only to available Pods during the update.

In the following interactive tutorial, we'll update our application to a new version, and also perform a rollback.

Update the version of the app

To list your Deployments, run the get deployments subcommand: **kubectl get deployments**

To list the running Pods, run the get pods subcommand:

kubectl get pods

To view the current image version of the app, run the describe pods subcommand and look for the Image field:

kubectl describe pods

To update the image of the application to version 2, use the set image subcommand, followed by the deployment name and the new image version:

```
kubectl set image deployments/kubernetes-bootcamp kubernetes-  
bootcamp=docker.io/jocatalin/kubernetes-bootcamp:v2
```

The command notified the Deployment to use a different image for your app and initiated a rolling update. Check the status of the new Pods, and view the old one terminating with the get pods subcommand:

kubectl get pods

Verify an update

First, check that the service is running, as you might have deleted it in previous tutorial step, run describe services/kubernetes-bootcamp. If it's missing, you can create it again with:

```
kubectl expose deployment/kubernetes-bootcamp --type="NodePort" --port 8080
```

Create an environment variable called NODE_PORT that has the value of the Node port assigned:

```
export NODE_PORT="$(kubectl get services/kubernetes-bootcamp -o go-  
template='{{(index .spec.ports 0).nodePort}}')"  
echo "NODE_PORT=$NODE_PORT"
```

Next, do a curl to the exposed IP and port:

```
curl http://$(minikube ip):$NODE_PORT
```

Every time you run the curl command, you will hit a different Pod. Notice that all Pods are now running the latest version (v2).

You can also confirm the update by running the rollout status subcommand:

kubectl rollout status deployments/kubernetes-bootcamp

To view the current image version of the app, run the `describe pods` subcommand:

kubectl describe pods

In the `Image` field of the output, verify that you are running the latest image version (v2).

Roll back an update

Let's perform another update, and try to deploy an image tagged with v10:

```
kubectl set image deployments/kubernetes-bootcamp kubernetes-bootcamp=gcr.io/google-samples/kubernetes-bootcamp:v10
```

Use `get deployments` to see the status of the deployment:

kubectl get deployments

Notice that the output doesn't list the desired number of available Pods. Run the `get pods` subcommand to list all Pods:

kubectl get pods

Notice that some of the Pods have a status of `ImagePullBackOff`.

To get more insight into the problem, run the `describe pods` subcommand:

kubectl describe pods

In the `Events` section of the output for the affected Pods, notice that the v10 image version did not exist in the repository.

To roll back the deployment to your last working version, use the `rollout undo` subcommand:

kubectl rollout undo deployments/kubernetes-bootcamp

The `rollout undo` command reverts the deployment to the previous known state (v2 of the image). Updates are versioned and you can revert to any previously known state of a Deployment.

Use the `get pods` subcommand to list the Pods again:

kubectl get pods

Four Pods are running. To check the image deployed on these Pods, use the `describe pods` subcommand:

kubectl describe pods

The Deployment is once again using a stable version of the app (v2). The rollback was successful.

Remember to clean up your local cluster

kubectl delete deployments/kubernetes-bootcamp services/kubernetes-bootcamp

Configuration

[Example: Configuring a Java Microservice](#)

[Updating Configuration via a ConfigMap](#)

[Configuring Redis using a ConfigMap](#)

Example: Configuring a Java Microservice

[Externalizing config using MicroProfile, ConfigMaps and Secrets](#)

Externalizing config using MicroProfile, ConfigMaps and Secrets

In this tutorial you will learn how and why to externalize your microservice's configuration. Specifically, you will learn how to use Kubernetes ConfigMaps and Secrets to set environment variables and then consume them using MicroProfile Config.

Before you begin

Creating Kubernetes ConfigMaps & Secrets

There are several ways to set environment variables for a Docker container in Kubernetes, including: Dockerfile, kubernetes.yml, Kubernetes ConfigMaps, and Kubernetes Secrets. In the tutorial, you will learn how to use the latter two for setting your environment variables whose values will be injected into your microservices. One of the benefits for using ConfigMaps and Secrets is that they can be re-used across multiple containers, including being assigned to different environment variables for the different containers.

ConfigMaps are API Objects that store non-confidential key-value pairs. In the Interactive Tutorial you will learn how to use a ConfigMap to store the application's name. For more information regarding ConfigMaps, you can find the documentation [here](#).

Although Secrets are also used to store key-value pairs, they differ from ConfigMaps in that they're intended for confidential/sensitive information and are stored using Base64 encoding. This makes secrets the appropriate choice for storing such things as credentials, keys, and tokens, the former of which you'll do in the Interactive Tutorial. For more information on Secrets, you can find the documentation [here](#).

Externalizing Config from Code

Externalized application configuration is useful because configuration usually changes depending on your environment. In order to accomplish this, we'll use Java's Contexts and Dependency Injection (CDI) and MicroProfile Config. MicroProfile Config is a feature of MicroProfile, a set of open Java technologies for developing and deploying cloud-native microservices.

CDI provides a standard dependency injection capability enabling an application to be assembled from collaborating, loosely-coupled beans. MicroProfile Config provides apps and microservices a standard way to obtain config properties from various sources, including the application, runtime, and environment. Based on the source's defined priority, the properties are automatically combined into a single set of properties that the application can access via an API. Together, CDI & MicroProfile will be used in the Interactive Tutorial to retrieve the externally provided properties from the Kubernetes ConfigMaps and Secrets and get injected into your application code.

Many open source frameworks and runtimes implement and support MicroProfile Config. Throughout the interactive tutorial, you'll be using Open Liberty, a flexible open-source Java runtime for building and running cloud-native apps and microservices. However, any MicroProfile compatible runtime could be used instead.

Objectives

- Create a Kubernetes ConfigMap and Secret
- Inject microservice configuration using MicroProfile Config

Example: Externalizing config using MicroProfile, ConfigMaps and Secrets

[Start Interactive Tutorial](#)

Updating Configuration via a ConfigMap

This page provides a step-by-step example of updating configuration within a Pod via a ConfigMap and builds upon the [Configure a Pod to Use a ConfigMap](#) task.

At the end of this tutorial, you will understand how to change the configuration for a running application.

This tutorial uses the alpine and nginx images as examples.

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

You need to have the [curl](#) command-line tool for making HTTP requests from the terminal or command prompt. If you do not have curl available, you can install it. Check the documentation for your local operating system.

Objectives

- Update configuration via a ConfigMap mounted as a Volume
- Update environment variables of a Pod via a ConfigMap
- Update configuration via a ConfigMap in a multi-container Pod
- Update configuration via a ConfigMap in a Pod possessing a Sidecar Container

Update configuration via a ConfigMap mounted as a Volume

Use the `kubectl create configmap sport --from-literal=sport=football` command to create a ConfigMap from [literal values](#):

```
kubectl create configmap sport --from-literal=sport=football
```

Below is an example of a Deployment manifest with the ConfigMap `sport` mounted as a [volume](#) into the Pod's only container.

[deployments/deployment-with-configmap-as-volume.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
  name: configmap-volume
  labels:
    app.kubernetes.io/name: configmap-volume
spec:
  replicas: 3
  selector:
    matchLabels:
      app.kubernetes.io/name: configmap-volume
  template:
    metadata:
      labels:
        app.kubernetes.io/name: configmap-volume
    spec:
      containers:
        - name: alpine
          image: alpine:3
          command:
            - /bin/sh
            - -c
            - while true; do echo "$(date) My preferred sport is $(cat /etc/config/sport)";
              sleep 10; done;
          ports:
            - containerPort: 80
          volumeMounts:
            - name: config-volume
```

```
    mountPath: /etc/config
volumes:
- name: config-volume
  configMap:
    name: sport
```

Create the Deployment:

```
kubectl apply -f https://k8s.io/examples/deployments/deployment-with-configmap-as-volume.yaml
```

Check the pods for this Deployment to ensure they are ready (matching by [selector](#)):

```
kubectl get pods --selector=app.kubernetes.io/name=configmap-volume
```

You should see an output similar to:

| NAME | READY | STATUS | RESTARTS | AGE |
|-----------------------------------|-------|---------|----------|-----|
| configmap-volume-6b976dfdcf-qxvbm | 1/1 | Running | 0 | 72s |
| configmap-volume-6b976dfdcf-skpvm | 1/1 | Running | 0 | 72s |
| configmap-volume-6b976dfdcf-tbc6r | 1/1 | Running | 0 | 72s |

On each node where one of these Pods is running, the kubelet fetches the data for that ConfigMap and translates it to files in a local volume. The kubelet then mounts that volume into the container, as specified in the Pod template. The code running in that container loads the information from the file and uses it to print a report to stdout. You can check this report by viewing the logs for one of the Pods in that Deployment:

```
# Pick one Pod that belongs to the Deployment, and view its logs
kubectl logs deployments/configmap-volume
```

You should see an output similar to:

```
Found 3 pods, using pod/configmap-volume-76d9c5678f-x5rgj
Thu Jan 4 14:06:46 UTC 2024 My preferred sport is football
Thu Jan 4 14:06:56 UTC 2024 My preferred sport is football
Thu Jan 4 14:07:06 UTC 2024 My preferred sport is football
Thu Jan 4 14:07:16 UTC 2024 My preferred sport is football
Thu Jan 4 14:07:26 UTC 2024 My preferred sport is football
```

Edit the ConfigMap:

```
kubectl edit configmap sport
```

In the editor that appears, change the value of key sport from football to cricket. Save your changes. The kubectl tool updates the ConfigMap accordingly (if you see an error, try again).

Here's an example of how that manifest could look after you edit it:

```
apiVersion: v1
data:
  sport: cricket
kind: ConfigMap
# You can leave the existing metadata as they are.
# The values you'll see won't exactly match these.
```

```
metadata:
  creationTimestamp: "2024-01-04T14:05:06Z"
  name: sport
  namespace: default
  resourceVersion: "1743935"
  uid: 024ee001-fe72-487e-872e-34d6464a8a23
```

You should see the following output:

```
configmap/sport edited
```

Tail (follow the latest entries in) the logs of one of the pods that belongs to this Deployment:

```
kubectl logs deployments/configmap-volume --follow
```

After few seconds, you should see the log output change as follows:

```
Thu Jan 4 14:11:36 UTC 2024 My preferred sport is football
Thu Jan 4 14:11:46 UTC 2024 My preferred sport is football
Thu Jan 4 14:11:56 UTC 2024 My preferred sport is football
Thu Jan 4 14:12:06 UTC 2024 My preferred sport is cricket
Thu Jan 4 14:12:16 UTC 2024 My preferred sport is cricket
```

When you have a ConfigMap that is mapped into a running Pod using either a configMap volume or a projected volume, and you update that ConfigMap, the running Pod sees the update almost immediately.

However, your application only sees the change if it is written to either poll for changes, or watch for file updates.

An application that loads its configuration once at startup will not notice a change.

Note:

The total delay from the moment when the ConfigMap is updated to the moment when new keys are projected to the Pod can be as long as kubelet sync period.

Also check [Mounted ConfigMaps are updated automatically](#).

Update environment variables of a Pod via a ConfigMap

Use the `kubectl create configmap` command to create a ConfigMap from [literal values](#):

```
kubectl create configmap fruits --from-literal=fruits=apples
```

Below is an example of a Deployment manifest with an environment variable configured via the ConfigMap `fruits`.

[deployments/deployment-with-configmap-as-envvar.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
  name: configmap-env-var
  labels:
    app.kubernetes.io/name: configmap-env-var
```

```
spec:
  replicas: 3
  selector:
    matchLabels:
      app.kubernetes.io/name: configmap-env-var
  template:
    metadata:
      labels:
        app.kubernetes.io/name: configmap-env-var
    spec:
      containers:
        - name: alpine
          image: alpine:3
          env:
            - name: FRUITS
              valueFrom:
                configMapKeyRef:
                  key: fruits
                  name: fruits
          command:
            - /bin/sh
            - -c
            - while true; do echo "$(date) The basket is full of $FRUITS";
              sleep 10; done;
          ports:
            - containerPort: 80
```

Create the Deployment:

```
kubectl apply -f https://k8s.io/examples/deployments/deployment-with-configmap-as-envvar.yaml
```

Check the pods for this Deployment to ensure they are ready (matching by [selector](#)):

```
kubectl get pods --selector=app.kubernetes.io/name=configmap-env-var
```

You should see an output similar to:

| NAME | READY | STATUS | RESTARTS | AGE |
|------------------------------------|-------|---------|----------|-----|
| configmap-env-var-59cfc64f7d-74d7z | 1/1 | Running | 0 | 46s |
| configmap-env-var-59cfc64f7d-c4wmj | 1/1 | Running | 0 | 46s |
| configmap-env-var-59cfc64f7d-dpr98 | 1/1 | Running | 0 | 46s |

The key-value pair in the ConfigMap is configured as an environment variable in the container of the Pod. Check this by viewing the logs of one Pod that belongs to the Deployment.

```
kubectl logs deployment/configmap-env-var
```

You should see an output similar to:

```
Found 3 pods, using pod/configmap-env-var-7c994f7769-l74nq
Thu Jan 4 16:07:06 UTC 2024 The basket is full of apples
Thu Jan 4 16:07:16 UTC 2024 The basket is full of apples
Thu Jan 4 16:07:26 UTC 2024 The basket is full of apples
```

Edit the ConfigMap:

```
kubectl edit configmap fruits
```

In the editor that appears, change the value of key fruits from apples to mangoes. Save your changes. The kubectl tool updates the ConfigMap accordingly (if you see an error, try again).

Here's an example of how that manifest could look after you edit it:

```
apiVersion: v1
data:
  fruits: mangoes
kind: ConfigMap
# You can leave the existing metadata as they are.
# The values you'll see won't exactly match these.
metadata:
  creationTimestamp: "2024-01-04T16:04:19Z"
  name: fruits
  namespace: default
  resourceVersion: "1749472"
```

You should see the following output:

```
configmap/fruits edited
```

Tail the logs of the Deployment and observe the output for few seconds:

```
# As the text explains, the output does NOT change
kubectl logs deployments/configmap-env-var --follow
```

Notice that the output remains **unchanged**, even though you edited the ConfigMap:

```
Thu Jan 4 16:12:56 UTC 2024 The basket is full of apples
Thu Jan 4 16:13:06 UTC 2024 The basket is full of apples
Thu Jan 4 16:13:16 UTC 2024 The basket is full of apples
Thu Jan 4 16:13:26 UTC 2024 The basket is full of apples
```

Note:

Although the value of the key inside the ConfigMap has changed, the environment variable in the Pod still shows the earlier value. This is because environment variables for a process running inside a Pod are **not** updated when the source data changes; if you wanted to force an update, you would need to have Kubernetes replace your existing Pods. The new Pods would then run with the updated information.

You can trigger that replacement. Perform a rollout for the Deployment, using [kubectl rollout](#):

```
# Trigger the rollout
kubectl rollout restart deployment configmap-env-var

# Wait for the rollout to complete
kubectl rollout status deployment configmap-env-var --watch=true
```

Next, check the Deployment:

```
kubectl get deployment configmap-env-var
```

You should see an output similar to:

| NAME | READY | UP-TO-DATE | AVAILABLE | AGE |
|-------------------|-------|------------|-----------|-----|
| configmap-env-var | 3/3 | 3 | 3 | 12m |

Check the Pods:

```
kubectl get pods --selector=app.kubernetes.io/name=configmap-env-var
```

The rollout causes Kubernetes to make a new [ReplicaSet](#) for the Deployment; that means the existing Pods eventually terminate, and new ones are created. After few seconds, you should see an output similar to:

| NAME | READY | STATUS | RESTARTS | AGE |
|------------------------------------|-------|---------|----------|-----|
| configmap-env-var-6d94d89bf5-2ph2l | 1/1 | Running | 0 | 13s |
| configmap-env-var-6d94d89bf5-74twx | 1/1 | Running | 0 | 8s |
| configmap-env-var-6d94d89bf5-d5vx8 | 1/1 | Running | 0 | 11s |

Note:

Please wait for the older Pods to fully terminate before proceeding with the next steps.

View the logs for a Pod in this Deployment:

```
# Pick one Pod that belongs to the Deployment, and view its logs
kubectl logs deployment/configmap-env-var
```

You should see an output similar to the below:

```
Found 3 pods, using pod/configmap-env-var-6d9ff89fb6-bzcf6
Thu Jan 4 16:30:35 UTC 2024 The basket is full of mangoes
Thu Jan 4 16:30:45 UTC 2024 The basket is full of mangoes
Thu Jan 4 16:30:55 UTC 2024 The basket is full of mangoes
```

This demonstrates the scenario of updating environment variables in a Pod that are derived from a ConfigMap. Changes to the ConfigMap values are applied to the Pod during the subsequent rollout. If Pods get created for another reason, such as scaling up the Deployment, then the new Pods also use the latest configuration values; if you don't trigger a rollout, then you might find that your app is running with a mix of old and new environment variable values.

Update configuration via a ConfigMap in a multi-container Pod

Use the `kubectl create configmap` command to create a ConfigMap from [literal values](#):

```
kubectl create configmap color --from-literal=color=red
```

Below is an example manifest for a Deployment that manages a set of Pods, each with two containers. The two containers share an emptyDir volume that they use to communicate. The first container runs a web server (nginx). The mount path for the shared volume in the web

server container is `/usr/share/nginx/html`. The second helper container is based on `alpine`, and for this container the `emptyDir` volume is mounted at `/pod-data`. The helper container writes a file in HTML that has its content based on a `ConfigMap`. The web server container serves the HTML via HTTP.

[deployments/deployment-with-configmap-two-containers.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
  name: configmap-two-containers
  labels:
    app.kubernetes.io/name: configmap-two-containers
spec:
  replicas: 3
  selector:
    matchLabels:
      app.kubernetes.io/name: configmap-two-containers
  template:
    metadata:
      labels:
        app.kubernetes.io/name: configmap-two-containers
    spec:
      volumes:
        - name: shared-data
          emptyDir: {}
        - name: config-volume
          configMap:
            name: color
      containers:
        - name: nginx
          image: nginx
          volumeMounts:
            - name: shared-data
              mountPath: /usr/share/nginx/html
        - name: alpine
          image: alpine:3
          volumeMounts:
            - name: shared-data
              mountPath: /pod-data
            - name: config-volume
              mountPath: /etc/config
          command:
            - /bin/sh
            - -c
            - while true; do echo "$(date) My preferred color is $(cat /etc/config/color)" > /pod-data/
              index.html;
              sleep 10; done;
```

Create the Deployment:

```
kubectl apply -f https://k8s.io/examples/deployments/deployment-with-configmap-two-containers.yaml
```

Check the pods for this Deployment to ensure they are ready (matching by [selector](#)):

```
kubectl get pods --selector=app.kubernetes.io/name=configmap-two-containers
```

You should see an output similar to:

| NAME | READY | STATUS | RESTARTS | AGE |
|---|-------|---------|----------|-----|
| configmap-two-containers-565fb6d4f4-2xhxf | 2/2 | Running | 0 | 20s |
| configmap-two-containers-565fb6d4f4-g5v4j | 2/2 | Running | 0 | 20s |
| configmap-two-containers-565fb6d4f4-mzsmf | 2/2 | Running | 0 | 20s |

Expose the Deployment (the kubectl tool creates a [Service](#) for you):

```
kubectl expose deployment configmap-two-containers --name=configmap-service --port=8080 --target-port=80
```

Use kubectl to forward the port:

```
kubectl port-forward service/configmap-service 8080:8080 & # this stays running in the background
```

Access the service.

```
curl http://localhost:8080
```

You should see an output similar to:

```
Fri Jan 5 08:08:22 UTC 2024 My preferred color is red
```

Edit the ConfigMap:

```
kubectl edit configmap color
```

In the editor that appears, change the value of key color from red to blue. Save your changes. The kubectl tool updates the ConfigMap accordingly (if you see an error, try again).

Here's an example of how that manifest could look after you edit it:

```
apiVersion: v1
data:
  color: blue
kind: ConfigMap
# You can leave the existing metadata as they are.
# The values you'll see won't exactly match these.
metadata:
  creationTimestamp: "2024-01-05T08:12:05Z"
  name: color
  namespace: configmap
  resourceVersion: "1801272"
  uid: 80d33e4a-cbb4-4bc9-ba8c-544c68e425d6
```

Loop over the service URL for few seconds.

```
# Cancel this when you're happy with it (Ctrl-C)
while true; do curl --connect-timeout 7.5 http://localhost:8080; sleep 10; done
```

You should see the output change as follows:

```
Fri Jan 5 08:14:00 UTC 2024 My preferred color is red
Fri Jan 5 08:14:02 UTC 2024 My preferred color is red
Fri Jan 5 08:14:20 UTC 2024 My preferred color is red
Fri Jan 5 08:14:22 UTC 2024 My preferred color is red
Fri Jan 5 08:14:32 UTC 2024 My preferred color is blue
Fri Jan 5 08:14:43 UTC 2024 My preferred color is blue
Fri Jan 5 08:15:00 UTC 2024 My preferred color is blue
```

Update configuration via a ConfigMap in a Pod possessing a sidecar container

The above scenario can be replicated by using a [Sidecar Container](#) as a helper container to write the HTML file.

As a Sidecar Container is conceptually an Init Container, it is guaranteed to start before the main web server container.

This ensures that the HTML file is always available when the web server is ready to serve it. Please see [Enabling sidecar containers](#) to utilize this feature.

If you are continuing from the previous scenario, you can reuse the ConfigMap named color for this scenario.

If you are executing this scenario independently, use the `kubectl create configmap` command to create a ConfigMap from [literal values](#):

```
kubectl create configmap color --from-literal=color=blue
```

Below is an example manifest for a Deployment that manages a set of Pods, each with a main container and a sidecar container. The two containers share an emptyDir volume that they use to communicate. The main container runs a web server (NGINX). The mount path for the shared volume in the web server container is `/usr/share/nginx/html`. The second container is a Sidecar Container based on Alpine Linux which acts as a helper container. For this container the emptyDir volume is mounted at `/pod-data`. The Sidecar Container writes a file in HTML that has its content based on a ConfigMap. The web server container serves the HTML via HTTP.

[deployments/deployment-with-configmap-and-sidecar-container.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
  name: configmap-sidecar-container
  labels:
    app.kubernetes.io/name: configmap-sidecar-container
spec:
  replicas: 3
  selector:
    matchLabels:
      app.kubernetes.io/name: configmap-sidecar-container
  template:
    metadata:
      labels:
```

```

    app.kubernetes.io/name: configmap-sidecar-container
spec:
  volumes:
    - name: shared-data
      emptyDir: {}
    - name: config-volume
      configMap:
        name: color
  containers:
    - name: nginx
      image: nginx
      volumeMounts:
        - name: shared-data
          mountPath: /usr/share/nginx/html
  initContainers:
    - name: alpine
      image: alpine:3
      restartPolicy: Always
      volumeMounts:
        - name: shared-data
          mountPath: /pod-data
        - name: config-volume
          mountPath: /etc/config
      command:
        - /bin/sh
        - -c
        - while true; do echo "$(date) My preferred color is $(cat /etc/config/color)" > /pod-data/
index.html;
        sleep 10; done;

```

Create the Deployment:

```
kubectl apply -f https://k8s.io/examples/deployments/deployment-with-configmap-and-sidecar-container.yaml
```

Check the pods for this Deployment to ensure they are ready (matching by [selector](#)):

```
kubectl get pods --selector=app.kubernetes.io/name=configmap-sidecar-container
```

You should see an output similar to:

| NAME | READY | STATUS | RESTARTS | AGE |
|--|-------|---------|----------|-----|
| configmap-sidecar-container-5fb59f558b-87rp7 | 2/2 | Running | 0 | 94s |
| configmap-sidecar-container-5fb59f558b-ccs7s | 2/2 | Running | 0 | 94s |
| configmap-sidecar-container-5fb59f558b-wnmgk | 2/2 | Running | 0 | 94s |

Expose the Deployment (the kubectl tool creates a [Service](#) for you):

```
kubectl expose deployment configmap-sidecar-container --name=configmap-sidecar-service --port=8081 --target-port=80
```

Use kubectl to forward the port:

```
kubectrl port-forward service/configmap-sidecar-service 8081:8081 & # this stays running in the background
```

Access the service.

```
curl http://localhost:8081
```

You should see an output similar to:

```
Sat Feb 17 13:09:05 UTC 2024 My preferred color is blue
```

Edit the ConfigMap:

```
kubectrl edit configmap color
```

In the editor that appears, change the value of key `color` from `blue` to `green`. Save your changes. The `kubectrl` tool updates the ConfigMap accordingly (if you see an error, try again).

Here's an example of how that manifest could look after you edit it:

```
apiVersion: v1
data:
  color: green
kind: ConfigMap
# You can leave the existing metadata as they are.
# The values you'll see won't exactly match these.
metadata:
  creationTimestamp: "2024-02-17T12:20:30Z"
  name: color
  namespace: default
  resourceVersion: "1054"
  uid: e40bb34c-58df-4280-8bea-6ed16edccfaa
```

Loop over the service URL for few seconds.

```
# Cancel this when you're happy with it (Ctrl-C)
while true; do curl --connect-timeout 7.5 http://localhost:8081; sleep 10; done
```

You should see the output change as follows:

```
Sat Feb 17 13:12:35 UTC 2024 My preferred color is blue
Sat Feb 17 13:12:45 UTC 2024 My preferred color is blue
Sat Feb 17 13:12:55 UTC 2024 My preferred color is blue
Sat Feb 17 13:13:05 UTC 2024 My preferred color is blue
Sat Feb 17 13:13:15 UTC 2024 My preferred color is green
Sat Feb 17 13:13:25 UTC 2024 My preferred color is green
Sat Feb 17 13:13:35 UTC 2024 My preferred color is green
```

Update configuration via an immutable ConfigMap that is mounted as a volume

Note:

Immutable ConfigMaps are especially used for configuration that is constant and is **not** expected to change over time. Marking a ConfigMap as immutable allows a performance improvement where the kubelet does not watch for changes.

If you do need to make a change, you should plan to either:

- change the name of the ConfigMap, and switch to running Pods that reference the new name
- replace all the nodes in your cluster that have previously run a Pod that used the old value
- restart the kubelet on any node where the kubelet previously loaded the old ConfigMap

An example manifest for an [Immutable ConfigMap](#) is shown below.

[configmap/immutable-configmap.yaml](#)

```
apiVersion: v1
data:
  company_name: "ACME, Inc." # existing fictional company name
kind: ConfigMap
immutable: true
metadata:
  name: company-name-20150801
```

Create the Immutable ConfigMap:

```
kubectl apply -f https://k8s.io/examples/configmap/immutable-configmap.yaml
```

Below is an example of a Deployment manifest with the Immutable ConfigMap company-name-20150801 mounted as a [volume](#) into the Pod's only container.

[deployments/deployment-with-immutable-configmap-as-volume.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
  name: immutable-configmap-volume
  labels:
    app.kubernetes.io/name: immutable-configmap-volume
spec:
  replicas: 3
  selector:
    matchLabels:
      app.kubernetes.io/name: immutable-configmap-volume
  template:
    metadata:
      labels:
        app.kubernetes.io/name: immutable-configmap-volume
```

```
spec:
  containers:
  - name: alpine
    image: alpine:3
    command:
    - /bin/sh
    - -c
    - while true; do echo "$(date) The name of the company is $(cat /etc/config/
company_name)";
      sleep 10; done;
    ports:
    - containerPort: 80
    volumeMounts:
    - name: config-volume
      mountPath: /etc/config
  volumes:
  - name: config-volume
    configMap:
      name: company-name-20150801
```

Create the Deployment:

```
kubectl apply -f https://k8s.io/examples/deployments/deployment-with-immutable-configmap-
as-volume.yaml
```

Check the pods for this Deployment to ensure they are ready (matching by [selector](#)):

```
kubectl get pods --selector=app.kubernetes.io/name=immutable-configmap-volume
```

You should see an output similar to:

| NAME | READY | STATUS | RESTARTS | AGE |
|---|-------|---------|----------|-----|
| immutable-configmap-volume-78b6fbff95-5gsfh | 1/1 | Running | 0 | 62s |
| immutable-configmap-volume-78b6fbff95-7vcj4 | 1/1 | Running | 0 | 62s |
| immutable-configmap-volume-78b6fbff95-vdslm | 1/1 | Running | 0 | 62s |

The Pod's container refers to the data defined in the ConfigMap and uses it to print a report to stdout. You can check this report by viewing the logs for one of the Pods in that Deployment:

```
# Pick one Pod that belongs to the Deployment, and view its logs
kubectl logs deployments/immutable-configmap-volume
```

You should see an output similar to:

```
Found 3 pods, using pod/immutable-configmap-volume-78b6fbff95-5gsfh
Wed Mar 20 03:52:34 UTC 2024 The name of the company is ACME, Inc.
Wed Mar 20 03:52:44 UTC 2024 The name of the company is ACME, Inc.
Wed Mar 20 03:52:54 UTC 2024 The name of the company is ACME, Inc.
```

Note:

Once a ConfigMap is marked as immutable, it is not possible to revert this change nor to mutate the contents of the data or the binaryData field.

In order to modify the behavior of the Pods that use this configuration, you will create a new

immutable ConfigMap and edit the Deployment to define a slightly different pod template, referencing the new ConfigMap.

Create a new immutable ConfigMap by using the manifest shown below:

[configmap/new-immutable-configmap.yaml](https://k8s.io/examples/configmap/new-immutable-configmap.yaml)

```
apiVersion: v1
data:
  company_name: "Fiktivesunternehmen GmbH" # new fictional company name
kind: ConfigMap
immutable: true
metadata:
  name: company-name-20240312
```

```
kubectl apply -f https://k8s.io/examples/configmap/new-immutable-configmap.yaml
```

You should see an output similar to:

```
configmap/company-name-20240312 created
```

Check the newly created ConfigMap:

```
kubectl get configmap
```

You should see an output displaying both the old and new ConfigMaps:

| NAME | DATA | AGE |
|-----------------------|------|-----|
| company-name-20150801 | 1 | 22m |
| company-name-20240312 | 1 | 24s |

Modify the Deployment to reference the new ConfigMap.

Edit the Deployment:

```
kubectl edit deployment immutable-configmap-volume
```

In the editor that appears, update the existing volume definition to use the new ConfigMap.

```
volumes:
- configMap:
  defaultMode: 420
  name: company-name-20240312 # Update this field
  name: config-volume
```

You should see the following output:

```
deployment.apps/immutable-configmap-volume edited
```

This will trigger a rollout. Wait for all the previous Pods to terminate and the new Pods to be in a ready state.

Monitor the status of the Pods:

```
kubectl get pods --selector=app.kubernetes.io/name=immutable-configmap-volume
```

| NAME | READY | STATUS | RESTARTS | AGE |
|---|-------|-------------|----------|-----|
| immutable-configmap-volume-5fdb88fcc8-29v8n | 1/1 | Running | 0 | 13s |
| immutable-configmap-volume-5fdb88fcc8-52ddd | 1/1 | Running | 0 | 14s |
| immutable-configmap-volume-5fdb88fcc8-n5jx4 | 1/1 | Running | 0 | 15s |
| immutable-configmap-volume-78b6fbff95-5gsfh | 1/1 | Terminating | 0 | 32m |
| immutable-configmap-volume-78b6fbff95-7vcj4 | 1/1 | Terminating | 0 | 32m |
| immutable-configmap-volume-78b6fbff95-vdslm | 1/1 | Terminating | 0 | 32m |

You should eventually see an output similar to:

| NAME | READY | STATUS | RESTARTS | AGE |
|---|-------|---------|----------|-----|
| immutable-configmap-volume-5fdb88fcc8-29v8n | 1/1 | Running | 0 | 43s |
| immutable-configmap-volume-5fdb88fcc8-52ddd | 1/1 | Running | 0 | 44s |
| immutable-configmap-volume-5fdb88fcc8-n5jx4 | 1/1 | Running | 0 | 45s |

View the logs for a Pod in this Deployment:

```
# Pick one Pod that belongs to the Deployment, and view its logs
kubectl logs deployment/immutable-configmap-volume
```

You should see an output similar to the below:

```
Found 3 pods, using pod/immutable-configmap-volume-5fdb88fcc8-n5jx4
Wed Mar 20 04:24:17 UTC 2024 The name of the company is Fiktivesunternehmen GmbH
Wed Mar 20 04:24:27 UTC 2024 The name of the company is Fiktivesunternehmen GmbH
Wed Mar 20 04:24:37 UTC 2024 The name of the company is Fiktivesunternehmen GmbH
```

Once all the deployments have migrated to use the new immutable ConfigMap, it is advised to delete the old one.

```
kubectl delete configmap company-name-20150801
```

Summary

Changes to a ConfigMap mounted as a Volume on a Pod are available seamlessly after the subsequent kubelet sync.

Changes to a ConfigMap that configures environment variables for a Pod are available after the subsequent rollout for the Pod.

Once a ConfigMap is marked as immutable, it is not possible to revert this change (you cannot make an immutable ConfigMap mutable), and you also cannot make any change to the contents of the data or the binaryData field. You can delete and recreate the ConfigMap, or you can make a new different ConfigMap. When you delete a ConfigMap, running containers and their Pods maintain a mount point to any volume that referenced that existing ConfigMap.

Cleaning up

Terminate the kubectl port-forward commands in case they are running.

Delete the resources created during the tutorial:

```
kubectl delete deployment configmap-volume configmap-env-var configmap-two-containers  
configmap-sidecar-container immutable-configmap-volume  
kubectl delete service configmap-service configmap-sidecar-service  
kubectl delete configmap sport fruits color company-name-20240312
```

```
kubectl delete configmap company-name-20150801 # In case it was not handled during the task  
execution
```

Configuring Redis using a ConfigMap

This page provides a real world example of how to configure Redis using a ConfigMap and builds upon the [Configure a Pod to Use a ConfigMap](#) task.

Objectives

- Create a ConfigMap with Redis configuration values
- Create a Redis Pod that mounts and uses the created ConfigMap
- Verify that the configuration was correctly applied.

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter kubectl version.

- The example shown on this page works with kubectl 1.14 and above.
- Understand [Configure a Pod to Use a ConfigMap](#).

Real World Example: Configuring Redis using a ConfigMap

Follow the steps below to configure a Redis cache using data stored in a ConfigMap.

First create a ConfigMap with an empty configuration block:

```
cat <<EOF >./example-redis-config.yaml  
apiVersion: v1  
kind: ConfigMap  
metadata:  
  name: example-redis-config  
data:  
  redis-config: ""  
EOF
```

Apply the ConfigMap created above, along with a Redis pod manifest:

```
kubectl apply -f example-redis-config.yaml
kubectl apply -f https://raw.githubusercontent.com/kubernetes/website/main/content/en/
examples/pods/config/redis-pod.yaml
```

Examine the contents of the Redis pod manifest and note the following:

- A volume named config is created by spec.volumes[1]
- The key and path under spec.volumes[1].configMap.items[0] exposes the redis-config key from the example-redis-config ConfigMap as a file named redis.conf on the config volume.
- The config volume is then mounted at /redis-master by spec.containers[0].volumeMounts[1].

This has the net effect of exposing the data in data.redis-config from the example-redis-config ConfigMap above as /redis-master/redis.conf inside the Pod.

[pods/config/redis-pod.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
  name: redis
spec:
  containers:
  - name: redis
    image: redis:5.0.4
    command:
      - redis-server
      - "/redis-master/redis.conf"
    env:
      - name: MASTER
        value: "true"
    ports:
      - containerPort: 6379
    resources:
      limits:
        cpu: "0.1"
    volumeMounts:
      - mountPath: /redis-master-data
        name: data
      - mountPath: /redis-master
        name: config
  volumes:
  - name: data
    emptyDir: {}
  - name: config
    configMap:
      name: example-redis-config
      items:
      - key: redis-config
        path: redis.conf
```

Examine the created objects:

```
kubectl get pod/redis configmap/example-redis-config
```

You should see the following output:

| NAME | READY | STATUS | RESTARTS | AGE |
|-----------|-------|---------|----------|-----|
| pod/redis | 1/1 | Running | 0 | 8s |

| NAME | DATA | AGE |
|--------------------------------|------|-----|
| configmap/example-redis-config | 1 | 14s |

Recall that we left redis-config key in the example-redis-config ConfigMap blank:

```
kubectl describe configmap/example-redis-config
```

You should see an empty redis-config key:

```
Name:      example-redis-config
Namespace:  default
Labels:     <none>
Annotations: <none>
```

```
Data
====
redis-config:
```

Use kubectl exec to enter the pod and run the redis-cli tool to check the current configuration:

```
kubectl exec -it redis -- redis-cli
```

Check maxmemory:

```
127.0.0.1:6379> CONFIG GET maxmemory
```

It should show the default value of 0:

- 1) "maxmemory"
- 2) "0"

Similarly, check maxmemory-policy:

```
127.0.0.1:6379> CONFIG GET maxmemory-policy
```

Which should also yield its default value of noeviction:

- 1) "maxmemory-policy"
- 2) "noeviction"

Now let's add some configuration values to the example-redis-config ConfigMap:

[pods/config/example-redis-config.yaml](#)

```
apiVersion: v1
kind: ConfigMap
```

```
metadata:
  name: example-redis-config
data:
  redis-config: |
    maxmemory 2mb
    maxmemory-policy allkeys-lru
```

Apply the updated ConfigMap:

```
kubectl apply -f example-redis-config.yaml
```

Confirm that the ConfigMap was updated:

```
kubectl describe configmap/example-redis-config
```

You should see the configuration values we just added:

```
Name:      example-redis-config
Namespace:  default
Labels:     <none>
Annotations: <none>
```

Data

====

```
redis-config:
```

```
maxmemory 2mb
maxmemory-policy allkeys-lru
```

Check the Redis Pod again using `redis-cli` via `kubectl exec` to see if the configuration was applied:

```
kubectl exec -it redis -- redis-cli
```

Check `maxmemory`:

```
127.0.0.1:6379> CONFIG GET maxmemory
```

It remains at the default value of 0:

- 1) "maxmemory"
- 2) "0"

Similarly, `maxmemory-policy` remains at the `noeviction` default setting:

```
127.0.0.1:6379> CONFIG GET maxmemory-policy
```

Returns:

- 1) "maxmemory-policy"
- 2) "noeviction"

The configuration values have not changed because the Pod needs to be restarted to grab updated values from associated ConfigMaps. Let's delete and recreate the Pod:

```
kubectrl delete pod redis
kubectrl apply -f https://raw.githubusercontent.com/kubernetes/website/main/content/en/examples/pods/config/redis-pod.yaml
```

Now re-check the configuration values one last time:

```
kubectrl exec -it redis -- redis-cli
```

Check maxmemory:

```
127.0.0.1:6379> CONFIG GET maxmemory
```

It should now return the updated value of 2097152:

```
1) "maxmemory"
2) "2097152"
```

Similarly, maxmemory-policy has also been updated:

```
127.0.0.1:6379> CONFIG GET maxmemory-policy
```

It now reflects the desired value of allkeys-lru:

```
1) "maxmemory-policy"
2) "allkeys-lru"
```

Clean up your work by deleting the created resources:

```
kubectrl delete pod/redis configmap/example-redis-config
```

What's next

- Learn more about [ConfigMaps](#).
- Follow an example of [Updating configuration via a ConfigMap](#).

Security

Security is an important concern for most organizations and people who run Kubernetes clusters. You can find a basic [security checklist](#) elsewhere in the Kubernetes documentation.

To learn how to deploy and manage security aspects of Kubernetes, you can follow the tutorials in this section.

[Apply Pod Security Standards at the Cluster Level](#)

[Apply Pod Security Standards at the Namespace Level](#)

[Restrict a Container's Access to Resources with AppArmor](#)

[Restrict a Container's Syscalls with seccomp](#)

Apply Pod Security Standards at the Cluster Level

Note

This tutorial applies only for new clusters.

Pod Security is an admission controller that carries out checks against the Kubernetes [Pod Security Standards](#) when new pods are created. It is a feature GA'ed in v1.25. This tutorial shows you how to enforce the baseline Pod Security Standard at the cluster level which applies a standard configuration to all namespaces in a cluster.

To apply Pod Security Standards to specific namespaces, refer to [Apply Pod Security Standards at the namespace level](#).

If you are running a version of Kubernetes other than v1.30, check the documentation for that version.

Before you begin

Install the following on your workstation:

- [kind](#)
- [kubectrl](#)

This tutorial demonstrates what you can configure for a Kubernetes cluster that you fully control. If you are learning how to configure Pod Security Admission for a managed cluster where you are not able to configure the control plane, read [Apply Pod Security Standards at the namespace level](#).

Choose the right Pod Security Standard to apply

[Pod Security Admission](#) lets you apply built-in [Pod Security Standards](#) with the following modes: enforce, audit, and warn.

To gather information that helps you to choose the Pod Security Standards that are most appropriate for your configuration, do the following:

1. Create a cluster with no Pod Security Standards applied:

```
kind create cluster --name psa-wo-cluster-pss
```

The output is similar to:

```
Creating cluster "psa-wo-cluster-pss" ...
Ensuring node image (kindest/node:v1.30.0)
Preparing nodes
Writing configuration
Starting control-plane
Installing CNI
```

```
Installing StorageClass
Set kubectl context to "kind-psa-wo-cluster-pss"
You can now use your cluster with:
```

```
kubectl cluster-info --context kind-psa-wo-cluster-pss
```

```
Thanks for using kind!
```

2. Set the kubectl context to the new cluster:

```
kubectl cluster-info --context kind-psa-wo-cluster-pss
```

The output is similar to this:

```
Kubernetes control plane is running at https://127.0.0.1:61350
```

```
CoreDNS is running at https://127.0.0.1:61350/api/v1/namespaces/kube-system/services/
kube-dns:dns/proxy
```

```
To further debug and diagnose cluster problems, use 'kubectl cluster-info dump'.
```

3. Get a list of namespaces in the cluster:

```
kubectl get ns
```

The output is similar to this:

| NAME | STATUS | AGE |
|--------------------|--------|-------|
| default | Active | 9m30s |
| kube-node-lease | Active | 9m32s |
| kube-public | Active | 9m32s |
| kube-system | Active | 9m32s |
| local-path-storage | Active | 9m26s |

4. Use --dry-run=server to understand what happens when different Pod Security Standards are applied:

1. Privileged

```
kubectl label --dry-run=server --overwrite ns --all \
pod-security.kubernetes.io/enforce=privileged
```

The output is similar to:

```
namespace/default labeled
namespace/kube-node-lease labeled
namespace/kube-public labeled
namespace/kube-system labeled
namespace/local-path-storage labeled
```

2. Baseline

```
kubectl label --dry-run=server --overwrite ns --all \
pod-security.kubernetes.io/enforce=baseline
```

The output is similar to:

```
namespace/default labeled
namespace/kube-node-lease labeled
namespace/kube-public labeled
Warning: existing pods in namespace "kube-system" violate the new PodSecurity
enforce level "baseline:latest"
Warning: etcd-psa-wo-cluster-pss-control-plane (and 3 other pods): host
namespaces, hostPath volumes
Warning: kindnet-vzj42: non-default capabilities, host namespaces, hostPath
volumes
Warning: kube-proxy-m6hwf: host namespaces, hostPath volumes, privileged
namespace/kube-system labeled
namespace/local-path-storage labeled
```

3. Restricted

```
kubectl label --dry-run=server --overwrite ns --all \
pod-security.kubernetes.io/enforce=restricted
```

The output is similar to:

```
namespace/default labeled
namespace/kube-node-lease labeled
namespace/kube-public labeled
Warning: existing pods in namespace "kube-system" violate the new PodSecurity
enforce level "restricted:latest"
Warning: coredns-7bb9c7b568-hsptc (and 1 other pod): unrestricted capabilities,
runAsNonRoot != true, seccompProfile
Warning: etcd-psa-wo-cluster-pss-control-plane (and 3 other pods): host
namespaces, hostPath volumes, allowPrivilegeEscalation != false, unrestricted
capabilities, restricted volume types, runAsNonRoot != true
Warning: kindnet-vzj42: non-default capabilities, host namespaces, hostPath
volumes, allowPrivilegeEscalation != false, unrestricted capabilities, restricted
volume types, runAsNonRoot != true, seccompProfile
Warning: kube-proxy-m6hwf: host namespaces, hostPath volumes, privileged,
allowPrivilegeEscalation != false, unrestricted capabilities, restricted volume types,
runAsNonRoot != true, seccompProfile
namespace/kube-system labeled
Warning: existing pods in namespace "local-path-storage" violate the new
PodSecurity enforce level "restricted:latest"
Warning: local-path-provisioner-d6d9f7ffc-lw9lh: allowPrivilegeEscalation != false,
unrestricted capabilities, runAsNonRoot != true, seccompProfile
namespace/local-path-storage labeled
```

From the previous output, you'll notice that applying the privileged Pod Security Standard shows no warnings for any namespaces. However, baseline and restricted standards both have warnings, specifically in the kube-system namespace.

Set modes, versions and standards

In this section, you apply the following Pod Security Standards to the latest version:

- baseline standard in enforce mode.
- restricted standard in warn and audit mode.

The baseline Pod Security Standard provides a convenient middle ground that allows keeping the exemption list short and prevents known privilege escalations.

Additionally, to prevent pods from failing in kube-system, you'll exempt the namespace from having Pod Security Standards applied.

When you implement Pod Security Admission in your own environment, consider the following:

1. Based on the risk posture applied to a cluster, a stricter Pod Security Standard like restricted might be a better choice.
2. Exempting the kube-system namespace allows pods to run as privileged in this namespace. For real world use, the Kubernetes project strongly recommends that you apply strict RBAC policies that limit access to kube-system, following the principle of least privilege. To implement the preceding standards, do the following:
3. Create a configuration file that can be consumed by the Pod Security Admission Controller to implement these Pod Security Standards:

```
mkdir -p /tmp/pss
cat <<EOF > /tmp/pss/cluster-level-pss.yaml
apiVersion: apiserver.config.k8s.io/v1
kind: AdmissionConfiguration
plugins:
- name: PodSecurity
  configuration:
    apiVersion: pod-security.admission.config.k8s.io/v1
    kind: PodSecurityConfiguration
    defaults:
      enforce: "baseline"
      enforce-version: "latest"
      audit: "restricted"
      audit-version: "latest"
      warn: "restricted"
      warn-version: "latest"
    exemptions:
      usernames: []
      runtimeClasses: []
      namespaces: [kube-system]
EOF
```

Note:

pod-security.admission.config.k8s.io/v1 configuration requires v1.25+. For v1.23 and v1.24, use [v1beta1](#). For v1.22, use [v1alpha1](#).

Configure the API server to consume this file during cluster creation:

4.

```
cat <<EOF > /tmp/pss/cluster-config.yaml
kind: Cluster
apiVersion: kind.x-k8s.io/v1alpha4
nodes:
- role: control-plane
  kubeadmConfigPatches:
  - |
    kind: ClusterConfiguration
    apiServer:
      extraArgs:
        admission-control-config-file: /etc/config/cluster-level-pss.yaml
      extraVolumes:
        - name: accf
          hostPath: /etc/config
          mountPath: /etc/config
          readOnly: false
          pathType: "DirectoryOrCreate"
    extraMounts:
      - hostPath: /tmp/pss
        containerPath: /etc/config
        # optional: if set, the mount is read-only.
        # default false
        readOnly: false
        # optional: if set, the mount needs SELinux relabeling.
        # default false
        selinuxRelabel: false
        # optional: set propagation mode (None, HostToContainer or Bidirectional)
        # see https://kubernetes.io/docs/concepts/storage/volumes/#mount-propagation
        # default None
        propagation: None
EOF
```

Note:

If you use Docker Desktop with *kind* on macOS, you can add /tmp as a Shared Directory under the menu item **Preferences > Resources > File Sharing**.

5. Create a cluster that uses Pod Security Admission to apply these Pod Security Standards:

```
kind create cluster --name psa-with-cluster-pss --config /tmp/pss/cluster-config.yaml
```

The output is similar to this:

```
Creating cluster "psa-with-cluster-pss" ...
  Ensuring node image (kindest/node:v1.30.0)
  Preparing nodes
  Writing configuration
  Starting control-plane
  Installing CNI
  Installing StorageClass
Set kubectl context to "kind-psa-with-cluster-pss"
```

You can now use your cluster with:

```
kubectl cluster-info --context kind-psa-with-cluster-pss
```

Have a question, bug, or feature request? Let us know! <https://kind.sigs.k8s.io/#community>

6. Point kubectl to the cluster:

```
kubectl cluster-info --context kind-psa-with-cluster-pss
```

The output is similar to this:

```
Kubernetes control plane is running at https://127.0.0.1:63855
CoreDNS is running at https://127.0.0.1:63855/api/v1/namespaces/kube-system/services/
kube-dns:dns/proxy
```

To further debug and diagnose cluster problems, use 'kubectl cluster-info dump'.

7. Create a Pod in the default namespace:

[security/example-baseline-pod.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
  name: nginx
spec:
  containers:
  - image: nginx
    name: nginx
    ports:
    - containerPort: 80
```

```
kubectl apply -f https://k8s.io/examples/security/example-baseline-pod.yaml
```

The pod is started normally, but the output includes a warning:

```
Warning: would violate PodSecurity "restricted:latest": allowPrivilegeEscalation != false
(container "nginx" must set securityContext.allowPrivilegeEscalation=false), unrestricted
capabilities (container "nginx" must set securityContext.capabilities.drop=["ALL"]),
runAsNonRoot != true (pod or container "nginx" must set
securityContext.runAsNonRoot=true), seccompProfile (pod or container "nginx" must set
securityContext.seccompProfile.type to "RuntimeDefault" or "Localhost")
pod/nginx created
```

Clean up

Now delete the clusters which you created above by running the following command:

```
kind delete cluster --name psa-with-cluster-pss
```

```
kind delete cluster --name psa-wo-cluster-pss
```

What's next

- Run a [shell script](#) to perform all the preceding steps at once:
 1. Create a Pod Security Standards based cluster level Configuration
 2. Create a file to let API server consume this configuration
 3. Create a cluster that creates an API server with this configuration
 4. Set kubectl context to this new cluster
 5. Create a minimal pod yaml file
 6. Apply this file to create a Pod in the new cluster
- [Pod Security Admission](#)
- [Pod Security Standards](#)
- [Apply Pod Security Standards at the namespace level](#)

Apply Pod Security Standards at the Namespace Level

Note

This tutorial applies only for new clusters.

Pod Security Admission is an admission controller that applies [Pod Security Standards](#) when pods are created. It is a feature GA'ed in v1.25. In this tutorial, you will enforce the baseline Pod Security Standard, one namespace at a time.

You can also apply Pod Security Standards to multiple namespaces at once at the cluster level. For instructions, refer to [Apply Pod Security Standards at the cluster level](#).

Before you begin

Install the following on your workstation:

- [kind](#)
- [kubectl](#)

Create cluster

1. Create a kind cluster as follows:

```
kind create cluster --name psa-ns-level
```

The output is similar to this:

```
Creating cluster "psa-ns-level" ...
  Ensuring node image (kindest/node:v1.30.0)
  Preparing nodes
  Writing configuration
  Starting control-plane
  Installing CNI
  Installing StorageClass
```

Set kubectl context to "kind-psa-ns-level"

You can now use your cluster with:

```
kubectl cluster-info --context kind-psa-ns-level
```

Not sure what to do next? Check out <https://kind.sigs.k8s.io/docs/user/quick-start/>

2. Set the kubectl context to the new cluster:

```
kubectl cluster-info --context kind-psa-ns-level
```

The output is similar to this:

Kubernetes control plane is running at <https://127.0.0.1:50996>

CoreDNS is running at <https://127.0.0.1:50996/api/v1/namespaces/kube-system/services/kube-dns:dns/proxy>

To further debug and diagnose cluster problems, use 'kubectl cluster-info dump'.

Create a namespace

Create a new namespace called example:

```
kubectl create ns example
```

The output is similar to this:

```
namespace/example created
```

Enable Pod Security Standards checking for that namespace

1. Enable Pod Security Standards on this namespace using labels supported by built-in Pod Security Admission. In this step you will configure a check to warn on Pods that don't meet the latest version of the *baseline* pod security standard.

```
kubectl label --overwrite ns example \
  pod-security.kubernetes.io/warn=baseline \
  pod-security.kubernetes.io/warn-version=latest
```

2. You can configure multiple pod security standard checks on any namespace, using labels. The following command will enforce the baseline Pod Security Standard, but warn and audit for restricted Pod Security Standards as per the latest version (default value)

```
kubectl label --overwrite ns example \
  pod-security.kubernetes.io/enforce=baseline \
  pod-security.kubernetes.io/enforce-version=latest \
  pod-security.kubernetes.io/warn=restricted \
  pod-security.kubernetes.io/warn-version=latest \
  pod-security.kubernetes.io/audit=restricted \
  pod-security.kubernetes.io/audit-version=latest
```

Verify the Pod Security Standard enforcement

1. Create a baseline Pod in the example namespace:

```
kubectl apply -n example -f https://k8s.io/examples/security/example-baseline-pod.yaml
```

The Pod does start OK; the output includes a warning. For example:

```
Warning: would violate PodSecurity "restricted:latest": allowPrivilegeEscalation != false (container "nginx" must set securityContext.allowPrivilegeEscalation=false), unrestricted capabilities (container "nginx" must set securityContext.capabilities.drop=["ALL"]), runAsNonRoot != true (pod or container "nginx" must set securityContext.runAsNonRoot=true), seccompProfile (pod or container "nginx" must set securityContext.seccompProfile.type to "RuntimeDefault" or "Localhost")
pod/nginx created
```

2. Create a baseline Pod in the default namespace:

```
kubectl apply -n default -f https://k8s.io/examples/security/example-baseline-pod.yaml
```

Output is similar to this:

```
pod/nginx created
```

The Pod Security Standards enforcement and warning settings were applied only to the example namespace. You could create the same Pod in the default namespace with no warnings.

Clean up

Now delete the cluster which you created above by running the following command:

```
kind delete cluster --name psa-ns-level
```

What's next

- Run a [shell script](#) to perform all the preceding steps all at once.
 1. Create kind cluster
 2. Create new namespace
 3. Apply baseline Pod Security Standard in enforce mode while applying restricted Pod Security Standard also in warn and audit mode.
 4. Create a new pod with the following pod security standards applied
- [Pod Security Admission](#)
- [Pod Security Standards](#)
- [Apply Pod Security Standards at the cluster level](#)

Restrict a Container's Access to Resources with AppArmor

FEATURE STATE: Kubernetes v1.4 [beta]

This page shows you how to load AppArmor profiles on your nodes and enforce those profiles in Pods. To learn more about how Kubernetes can confine Pods using AppArmor, see [Linux kernel security constraints for Pods and containers](#).

Objectives

- See an example of how to load a profile on a Node
- Learn how to enforce the profile on a Pod
- Learn how to check that the profile is loaded
- See what happens when a profile is violated
- See what happens when a profile cannot be loaded

Before you begin

AppArmor is an optional kernel module and Kubernetes feature, so verify it is supported on your Nodes before proceeding:

1. AppArmor kernel module is enabled -- For the Linux kernel to enforce an AppArmor profile, the AppArmor kernel module must be installed and enabled. Several distributions enable the module by default, such as Ubuntu and SUSE, and many others provide optional support. To check whether the module is enabled, check the `/sys/module/apparmor/parameters/enabled` file:

```
cat /sys/module/apparmor/parameters/enabled
Y
```

The kubelet verifies that AppArmor is enabled on the host before admitting a pod with AppArmor explicitly configured.

2. Container runtime supports AppArmor -- All common Kubernetes-supported container runtimes should support AppArmor, including [containerd](#) and [CRI-O](#). Please refer to the corresponding runtime documentation and verify that the cluster fulfills the requirements to use AppArmor.
3. Profile is loaded -- AppArmor is applied to a Pod by specifying an AppArmor profile that each container should be run with. If any of the specified profiles are not loaded in the kernel, the kubelet will reject the Pod. You can view which profiles are loaded on a node by checking the `/sys/kernel/security/apparmor/profiles` file. For example:

```
ssh gke-test-default-pool-239f5d02-gyn2 "sudo cat /sys/kernel/security/apparmor/profiles | sort"
```

```
apparmor-test-deny-write (enforce)
apparmor-test-audit-write (enforce)
```

```
docker-default (enforce)
k8s-nginx (enforce)
```

For more details on loading profiles on nodes, see [Setting up nodes with profiles](#).

Securing a Pod

Note:

Prior to Kubernetes v1.30, AppArmor was specified through annotations. Use the documentation version selector to view the documentation with this deprecated API.

AppArmor profiles can be specified at the pod level or container level. The container AppArmor profile takes precedence over the pod profile.

```
securityContext:
  appArmorProfile:
    type: <profile_type>
```

Where <profile_type> is one of:

- RuntimeDefault to use the runtime's default profile
- Localhost to use a profile loaded on the host (see below)
- Unconfined to run without AppArmor

See the [API Reference](#) for the full details on the AppArmor profile API.

To verify that the profile was applied, you can check that the container's root process is running with the correct profile by examining its proc attr:

```
kubectl exec <pod_name> -- cat /proc/1/attr/current
```

The output should look something like this:

```
cri-containerd.apparmor.d (enforce)
```

Example

This example assumes you have already set up a cluster with AppArmor support.

First, load the profile you want to use onto your Nodes. This profile blocks all file write operations:

```
#include <tunables/global>

profile k8s-apparmor-example-deny-write flags=(attach_disconnected) {
  #include <abstractions/base>

  file,

  # Deny all file writes.
  deny /** w,
}
```

The profile needs to be loaded onto all nodes, since you don't know where the pod will be scheduled. For this example you can use SSH to install the profiles, but other approaches are discussed in [Setting up nodes with profiles](#).

```
# This example assumes that node names match host names, and are reachable via SSH.
NODES=$(kubectl get nodes -o name)

for NODE in ${NODES[*]}; do ssh $NODE 'sudo apparmor_parser -q <EOF
#include <tunables/global>

profile k8s-apparmor-example-deny-write flags=(attach_disconnected) {
#include <abstractions/base>

file,

# Deny all file writes.
deny /** w,
}
EOF'
done
```

Next, run a simple "Hello AppArmor" Pod with the deny-write profile:

[pods/security/hello-apparmor.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
  name: hello-apparmor
spec:
  securityContext:
    appArmorProfile:
      type: Localhost
      localhostProfile: k8s-apparmor-example-deny-write
  containers:
  - name: hello
    image: busybox:1.28
    command: [ "sh", "-c", "echo 'Hello AppArmor!' && sleep 1h" ]
```

```
kubectl create -f hello-apparmor.yaml
```

You can verify that the container is actually running with that profile by checking `/proc/1/attr/current`:

```
kubectl exec hello-apparmor -- cat /proc/1/attr/current
```

The output should be:

```
k8s-apparmor-example-deny-write (enforce)
```

Finally, you can see what happens if you violate the profile by writing to a file:

```
kubectl exec hello-apparmor -- touch /tmp/test
```

```
touch: /tmp/test: Permission denied
error: error executing remote command: command terminated with non-zero exit code: Error
executing in Docker Container: 1
```

To wrap up, see what happens if you try to specify a profile that hasn't been loaded:

```
kubectl create -f /dev/stdin <<EOF
apiVersion: v1
kind: Pod
metadata:
  name: hello-apparmor-2
spec:
  securityContext:
    appArmorProfile:
      type: Localhost
      localhostProfile: k8s-apparmor-example-allow-write
  containers:
  - name: hello
    image: busybox:1.28
    command: [ "sh", "-c", "echo 'Hello AppArmor!' && sleep 1h" ]
EOF
```

```
pod/hello-apparmor-2 created
```

Although the Pod was created successfully, further examination will show that it is stuck in pending:

```
kubectl describe pod hello-apparmor-2
```

```
Name:      hello-apparmor-2
Namespace: default
Node:      gke-test-default-pool-239f5d02-x1kf/10.128.0.27
Start Time: Tue, 30 Aug 2016 17:58:56 -0700
Labels:    <none>
Annotations: container.apparmor.security.beta.kubernetes.io/hello=localhost/k8s-apparmor-
example-allow-write
Status:    Pending
...
Events:
  Type     Reason      Age           From          Message
  ----     -
  Normal   Scheduled   10s           default-scheduler Successfully assigned default/hello-
apparmor to gke-test-default-pool-239f5d02-x1kf
  Normal   Pulled      8s            kubelet       Successfully pulled image "busybox:1.28" in
370.157088ms (370.172701ms including waiting)
  Normal   Pulling     7s (x2 over 9s) kubelet       Pulling image "busybox:1.28"
  Warning   Failed      7s (x2 over 8s) kubelet       Error: failed to get container spec opts: failed
to generate apparmor spec opts: apparmor profile not found k8s-apparmor-example-allow-write
  Normal   Pulled      7s            kubelet       Successfully pulled image "busybox:1.28" in
90.980331ms (91.005869ms including waiting)
```

An Event provides the error message with the reason, the specific wording is runtime-dependent:

```
Warning Failed 7s (x2 over 8s) kubelet Error: failed to get container spec opts: failed to generate apparmor spec opts: apparmor profile not found
```

Administration

Setting up Nodes with profiles

Kubernetes 1.30 does not provide any built-in mechanisms for loading AppArmor profiles onto Nodes. Profiles can be loaded through custom infrastructure or tools like the [Kubernetes Security Profiles Operator](#).

The scheduler is not aware of which profiles are loaded onto which Node, so the full set of profiles must be loaded onto every Node. An alternative approach is to add a Node label for each profile (or class of profiles) on the Node, and use a [node selector](#) to ensure the Pod is run on a Node with the required profile.

Authoring Profiles

Getting AppArmor profiles specified correctly can be a tricky business. Fortunately there are some tools to help with that:

- aa-genprof and aa-logprof generate profile rules by monitoring an application's activity and logs, and admitting the actions it takes. Further instructions are provided by the [AppArmor documentation](#).
- [bane](#) is an AppArmor profile generator for Docker that uses a simplified profile language.

To debug problems with AppArmor, you can check the system logs to see what, specifically, was denied. AppArmor logs verbose messages to dmesg, and errors can usually be found in the system logs or through journalctl. More information is provided in [AppArmor failures](#).

Specifying AppArmor confinement

Caution:

Prior to Kubernetes v1.30, AppArmor was specified through annotations. Use the documentation version selector to view the documentation with this deprecated API.

AppArmor profile within security context

You can specify the appArmorProfile on either a container's securityContext or on a Pod's securityContext. If the profile is set at the pod level, it will be used as the default profile for all containers in the pod (including init, sidecar, and ephemeral containers). If both a pod & container AppArmor profile are set, the container's profile will be used.

An AppArmor profile has 2 fields:

type (*required*) - indicates which kind of AppArmor profile will be applied. Valid options are:

Localhost

a profile pre-loaded on the node (specified by localhostProfile).

RuntimeDefault

the container runtime's default profile.
Unconfined
no AppArmor enforcement.

localhostProfile - The name of a profile loaded on the node that should be used. The profile must be preconfigured on the node to work. This option must be provided if and only if the type is Localhost.

What's next

Additional resources:

- [Quick guide to the AppArmor profile language](#)
- [AppArmor core policy reference](#)

Restrict a Container's Syscalls with seccomp

FEATURE STATE: Kubernetes v1.19 [stable]

Seccomp stands for secure computing mode and has been a feature of the Linux kernel since version 2.6.12. It can be used to sandbox the privileges of a process, restricting the calls it is able to make from userspace into the kernel. Kubernetes lets you automatically apply seccomp profiles loaded onto a [node](#) to your Pods and containers.

Identifying the privileges required for your workloads can be difficult. In this tutorial, you will go through how to load seccomp profiles into a local Kubernetes cluster, how to apply them to a Pod, and how you can begin to craft profiles that give only the necessary privileges to your container processes.

Objectives

- Learn how to load seccomp profiles on a node
- Learn how to apply a seccomp profile to a container
- Observe auditing of syscalls made by a container process
- Observe behavior when a missing profile is specified
- Observe a violation of a seccomp profile
- Learn how to create fine-grained seccomp profiles
- Learn how to apply a container runtime default seccomp profile

Before you begin

In order to complete all steps in this tutorial, you must install [kind](#) and [kubectl](#).

The commands used in the tutorial assume that you are using [Docker](#) as your container runtime. (The cluster that kind creates may use a different container runtime internally). You could also use [Podman](#) but in that case, you would have to follow specific [instructions](#) in order to complete the tasks successfully.

This tutorial shows some examples that are still beta (since v1.25) and others that use only generally available seccomp functionality. You should make sure that your cluster is [configured correctly](#) for the version you are using.

The tutorial also uses the `curl` tool for downloading examples to your computer. You can adapt the steps to use a different tool if you prefer.

Note:

It is not possible to apply a seccomp profile to a container running with `privileged: true` set in the container's `securityContext`. Privileged containers always run as Unconfined.

Download example seccomp profiles

The contents of these profiles will be explored later on, but for now go ahead and download them into a directory named `profiles/` so that they can be loaded into the cluster.

- [audit.json](#)
- [violation.json](#)
- [fine-grained.json](#)

[pods/security/seccomp/profiles/audit.json](#)

```
{
  "defaultAction": "SCMP_ACT_LOG"
}
```

[pods/security/seccomp/profiles/violation.json](#)

```
{
  "defaultAction": "SCMP_ACT_ERRNO"
}
```

[pods/security/seccomp/profiles/fine-grained.json](#)

```
{
  "defaultAction": "SCMP_ACT_ERRNO",
  "architectures": [
    "SCMP_ARCH_X86_64",
    "SCMP_ARCH_X86",
    "SCMP_ARCH_X32"
  ],

        "readlinkat",
        "exit_group",
        "epoll_create1",
        "listen",
        "rt_sigreturn",
        "sched_yield",
        "clock_gettime",
        "connect",
        "dup2",
        "epoll_pwait",
        "execve",
        "exit",
        "fcntl",
        "getpid",
        "getuid",
        "ioctl",
        "mprotect",
        "nanosleep",
        "open",
        "poll",
        "recvfrom",
        "sendto",
        "set_tid_address",
        "setitimer",
        "writev",
        "fstatfs",
        "getdents64",
        "pipe2",
        "getrlimit"
    ],
    "action": "SCMP_ACT_ALLOW"
}
]
}

```

Run these commands:

```
mkdir ./profiles
curl -L -o profiles/audit.json https://k8s.io/examples/pods/security/seccomp/profiles/audit.json
curl -L -o profiles/violation.json https://k8s.io/examples/pods/security/seccomp/profiles/
violation.json
curl -L -o profiles/fine-grained.json https://k8s.io/examples/pods/security/seccomp/profiles/
fine-grained.json
ls profiles
```

You should see three profiles listed at the end of the final step:

```
audit.json fine-grained.json violation.json
```

Create a local Kubernetes cluster with kind

For simplicity, [kind](#) can be used to create a single node cluster with the seccomp profiles loaded. Kind runs Kubernetes in Docker, so each node of the cluster is a container. This allows for files to be mounted in the filesystem of each container similar to loading files onto a node.

[pods/security/seccomp/kind.yaml](#)

```
apiVersion: kind.x-k8s.io/v1alpha4
kind: Cluster
nodes:
- role: control-plane
  extraMounts:
  - hostPath: "./profiles"
    containerPath: "/var/lib/kubelet/seccomp/profiles"
```

Download that example kind configuration, and save it to a file named kind.yaml:

```
curl -L -O https://k8s.io/examples/pods/security/seccomp/kind.yaml
```

You can set a specific Kubernetes version by setting the node's container image. See [Nodes](#) within the kind documentation about configuration for more details on this. This tutorial assumes you are using Kubernetes v1.30.

As a beta feature, you can configure Kubernetes to use the profile that the [container runtime](#) prefers by default, rather than falling back to Unconfined. If you want to try that, see [enable the use of RuntimeDefault as the default seccomp profile for all workloads](#) before you continue.

Once you have a kind configuration in place, create the kind cluster with that configuration:

```
kind create cluster --config=kind.yaml
```

After the new Kubernetes cluster is ready, identify the Docker container running as the single node cluster:

```
docker ps
```

You should see output indicating that a container is running with name kind-control-plane. The output is similar to:

| CONTAINER ID | IMAGE | COMMAND | CREATED |
|--------------|-------|---------|---------|
| STATUS | PORTS | NAMES | |

```
6a96207fed4b    kindest/node:v1.18.2  "/usr/local/bin/entr..." 27 seconds ago    Up 24
seconds        127.0.0.1:42223->6443/tcp  kind-control-plane
```

If observing the filesystem of that container, you should see that the profiles/ directory has been successfully loaded into the default seccomp path of the kubelet. Use `docker exec` to run a command in the Pod:

```
# Change 6a96207fed4b to the container ID you saw from "docker ps"
docker exec -it 6a96207fed4b ls /var/lib/kubelet/seccomp/profiles
```

```
audit.json  fine-grained.json  violation.json
```

You have verified that these seccomp profiles are available to the kubelet running within kind.

Create a Pod that uses the container runtime default seccomp profile

Most container runtimes provide a sane set of default syscalls that are allowed or not. You can adopt these defaults for your workload by setting the seccomp type in the security context of a pod or container to `RuntimeDefault`.

Note:

If you have the seccompDefault [configuration](#) enabled, then Pods use the `RuntimeDefault` seccomp profile whenever no other seccomp profile is specified. Otherwise, the default is `Unconfined`.

Here's a manifest for a Pod that requests the `RuntimeDefault` seccomp profile for all its containers:

[pods/security/seccomp/ga/default-pod.yaml](#)

```
apiVersion: v1
kind: Pod
metadata:
  name: default-pod
  labels:
    app: default-pod
spec:
  securityContext:
    seccompProfile:
      type: RuntimeDefault
  containers:
    - name: test-container
      image: hashicorp/http-echo:1.0
      args:
        - "-text=just made some more syscalls!"
      securityContext:
        allowPrivilegeEscalation: false
```

Create that Pod:

```
kubectl apply -f https://k8s.io/examples/pods/security/seccomp/ga/default-pod.yaml
```

```
kubectl get pod default-pod
```

The Pod should be showing as having started successfully:

| NAME | READY | STATUS | RESTARTS | AGE |
|-------------|-------|---------|----------|-----|
| default-pod | 1/1 | Running | 0 | 20s |

Delete the Pod before moving to the next section:

```
kubectl delete pod default-pod --wait --now
```

Create a Pod with a seccomp profile for syscall auditing

To start off, apply the `audit.json` profile, which will log all syscalls of the process, to a new Pod.

Here's a manifest for that Pod:

[pods/security/seccomp/ga/audit-pod.yaml](https://k8s.io/examples/pods/security/seccomp/ga/audit-pod.yaml)

```
apiVersion: v1
kind: Pod
metadata:
  name: audit-pod
  labels:
    app: audit-pod
spec:
  securityContext:
    seccompProfile:
      type: Localhost
      localhostProfile: profiles/audit.json
  containers:
  - name: test-container
    image: hashicorp/http-echo:1.0
    args:
    - "-text=just made some syscalls!"
    securityContext:
      allowPrivilegeEscalation: false
```

Note:

Older versions of Kubernetes allowed you to configure seccomp behavior using [annotations](#). Kubernetes 1.30 only supports using fields within `.spec.securityContext` to configure seccomp, and this tutorial explains that approach.

Create the Pod in the cluster:

```
kubectl apply -f https://k8s.io/examples/pods/security/seccomp/ga/audit-pod.yaml
```

This profile does not restrict any syscalls, so the Pod should start successfully.

```
kubectl get pod audit-pod
```

| NAME | READY | STATUS | RESTARTS | AGE |
|-----------|-------|---------|----------|-----|
| audit-pod | 1/1 | Running | 0 | 30s |

In order to be able to interact with this endpoint exposed by this container, create a [NodePort Service](#) that allows access to the endpoint from inside the kind control plane container.

```
kubectrl expose pod audit-pod --type NodePort --port 5678
```

Check what port the Service has been assigned on the node.

```
kubectrl get service audit-pod
```

The output is similar to:

| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE |
|-----------|----------|---------------|-------------|----------------|-----|
| audit-pod | NodePort | 10.111.36.142 | <none> | 5678:32373/TCP | 72s |

Now you can use curl to access that endpoint from inside the kind control plane container, at the port exposed by this Service. Use docker exec to run the curl command within the container belonging to that control plane container:

```
# Change 6a96207fed4b to the control plane container ID and 32373 to the port number you saw from "docker ps"
docker exec -it 6a96207fed4b curl localhost:32373
```

just made some syscalls!

You can see that the process is running, but what syscalls did it actually make? Because this Pod is running in a local cluster, you should be able to see those in /var/log/syslog on your local system. Open up a new terminal window and tail the output for calls from http-echo:

```
# The log path on your computer might be different from "/var/log/syslog"
tail -f /var/log/syslog | grep 'http-echo'
```

You should already see some logs of syscalls made by http-echo, and if you run curl again inside the control plane container you will see more output written to the log.

For example:

```
Jul 6 15:37:40 my-machine kernel: [369128.669452] audit: type=1326
audit(1594067860.484:14536): auid=4294967295 uid=0 gid=0 ses=4294967295 pid=29064

code=0x7ffc0000
Jul 6 15:37:40 my-machine kernel: [369128.669519] audit: type=1326
audit(1594067860.484:14541): auid=4294967295 uid=0 gid=0 ses=4294967295 pid=29064
comm="http-echo" exe="/http-echo" sig=0 arch=c000003e syscall=270 compat=0 ip=0x4559b1
code=0x7ffc0000
Jul 6 15:38:40 my-machine kernel: [369188.671648] audit: type=1326
audit(1594067920.488:14559): auid=4294967295 uid=0 gid=0 ses=4294967295 pid=29064
comm="http-echo" exe="/http-echo" sig=0 arch=c000003e syscall=270 compat=0 ip=0x4559b1
code=0x7ffc0000
Jul 6 15:38:40 my-machine kernel: [369188.671726] audit: type=1326
audit(1594067920.488:14560): auid=4294967295 uid=0 gid=0 ses=4294967295 pid=29064
comm="http-echo" exe="/http-echo" sig=0 arch=c000003e syscall=202 compat=0 ip=0x455e53
code=0x7ffc0000

```

You can begin to understand the syscalls required by the http-echo process by looking at the syscall= entry on each line. While these are unlikely to encompass all syscalls it uses, it can serve as a basis for a seccomp profile for this container.

Delete the Service and the Pod before moving to the next section:

```

kubectl delete service audit-pod --wait
kubectl delete pod audit-pod --wait --now

```

Create a Pod with a seccomp profile that causes violation

For demonstration, apply a profile to the Pod that does not allow for any syscalls.

The manifest for this demonstration is:

<pods/security/seccomp/ga/violation-pod.yaml>

```

apiVersion: v1
kind: Pod
metadata:
  name: violation-pod
  labels:
    app: violation-pod
spec:
  securityContext:
    seccompProfile:
      type: Localhost
      localhostProfile: profiles/violation.json
  containers:
    - name: test-container
      image: hashicorp/http-echo:1.0
      args:
        - "-text=just made some syscalls!"
      securityContext:
        allowPrivilegeEscalation: false

```

Attempt to create the Pod in the cluster:

```
kubectl apply -f https://k8s.io/examples/pods/security/seccomp/ga/violation-pod.yaml
```

The Pod creates, but there is an issue. If you check the status of the Pod, you should see that it failed to start.

```
kubectl get pod violation-pod
```

| NAME | READY | STATUS | RESTARTS | AGE |
|---------------|-------|------------------|----------|-----|
| violation-pod | 0/1 | CrashLoopBackOff | 1 | 6s |

As seen in the previous example, the http-echo process requires quite a few syscalls. Here seccomp has been instructed to error on any syscall by setting "defaultAction": "SCMP_ACT_ERRNO". This is extremely secure, but removes the ability to do anything meaningful. What you really want is to give workloads only the privileges they need.

Delete the Pod before moving to the next section:

```
kubectl delete pod violation-pod --wait --now
```

Create a Pod with a seccomp profile that only allows necessary syscalls

If you take a look at the fine-grained.json profile, you will notice some of the syscalls seen in syslog of the first example where the profile set "defaultAction": "SCMP_ACT_LOG". Now the profile is setting "defaultAction": "SCMP_ACT_ERRNO", but explicitly allowing a set of syscalls in the "action": "SCMP_ACT_ALLOW" block. Ideally, the container will run successfully and you will see no messages sent to syslog.

The manifest for this example is:

[pods/security/seccomp/ga/fine-pod.yaml](https://k8s.io/examples/pods/security/seccomp/ga/fine-pod.yaml)

```
apiVersion: v1
kind: Pod
metadata:
  name: fine-pod
  labels:
    app: fine-pod
spec:
  securityContext:
    seccompProfile:
      type: Localhost
      localhostProfile: profiles/fine-grained.json
  containers:
  - name: test-container
    image: hashicorp/http-echo:1.0
    args:
    - "-text=just made some syscalls!"
    securityContext:
      allowPrivilegeEscalation: false
```

Create the Pod in your cluster:

```
kubectl apply -f https://k8s.io/examples/pods/security/seccomp/ga/fine-pod.yaml
```

```
kubectl get pod fine-pod
```

The Pod should be showing as having started successfully:

| NAME | READY | STATUS | RESTARTS | AGE |
|----------|-------|---------|----------|-----|
| fine-pod | 1/1 | Running | 0 | 30s |

Open up a new terminal window and use tail to monitor for log entries that mention calls from http-echo:

```
# The log path on your computer might be different from "/var/log/syslog"  
tail -f /var/log/syslog | grep 'http-echo'
```

Next, expose the Pod with a NodePort Service:

```
kubectl expose pod fine-pod --type NodePort --port 5678
```

Check what port the Service has been assigned on the node:

```
kubectl get service fine-pod
```

The output is similar to:

| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE |
|----------|----------|---------------|-------------|----------------|-----|
| fine-pod | NodePort | 10.111.36.142 | <none> | 5678:32373/TCP | 72s |

Use curl to access that endpoint from inside the kind control plane container:

```
# Change 6a96207fed4b to the control plane container ID and 32373 to the port number you saw  
from "docker ps"  
docker exec -it 6a96207fed4b curl localhost:32373
```

```
just made some syscalls!
```

You should see no output in the syslog. This is because the profile allowed all necessary syscalls and specified that an error should occur if one outside of the list is invoked. This is an ideal situation from a security perspective, but required some effort in analyzing the program. It would be nice if there was a simple way to get closer to this security without requiring as much effort.

Delete the Service and the Pod before moving to the next section:

```
kubectl delete service fine-pod --wait  
kubectl delete pod fine-pod --wait --now
```

Enable the use of RuntimeDefault as the default seccomp profile for all workloads

FEATURE STATE: Kubernetes v1.27 [stable]

To use seccomp profile defaulting, you must run the kubelet with the `--seccomp-default` [command line flag](#) enabled for each node where you want to use it.

If enabled, the kubelet will use the RuntimeDefault seccomp profile by default, which is defined by the container runtime, instead of using the Unconfined (seccomp disabled) mode. The default profiles aim to provide a strong set of security defaults while preserving the functionality of the workload. It is possible that the default profiles differ between container runtimes and their release versions, for example when comparing those from CRI-O and containerd.

Note:

Enabling the feature will neither change the Kubernetes `securityContext.seccompProfile` API field nor add the deprecated annotations of the workload. This provides users the possibility to rollback anytime without actually changing the workload configuration. Tools like [crictrl inspect](#) can be used to verify which seccomp profile is being used by a container.

Some workloads may require a lower amount of syscall restrictions than others. This means that they can fail during runtime even with the RuntimeDefault profile. To mitigate such a failure, you can:

- Run the workload explicitly as Unconfined.
- Disable the SeccompDefault feature for the nodes. Also making sure that workloads get scheduled on nodes where the feature is disabled.
- Create a custom seccomp profile for the workload.

If you were introducing this feature into production-like cluster, the Kubernetes project recommends that you enable this feature gate on a subset of your nodes and then test workload execution before rolling the change out cluster-wide.

You can find more detailed information about a possible upgrade and downgrade strategy in the related Kubernetes Enhancement Proposal (KEP): [Enable seccomp by default](#).

Kubernetes 1.30 lets you configure the seccomp profile that applies when the spec for a Pod doesn't define a specific seccomp profile. However, you still need to enable this defaulting for each node where you would like to use it.

If you are running a Kubernetes 1.30 cluster and want to enable the feature, either run the kubelet with the `--seccomp-default` command line flag, or enable it through the [kubelet configuration file](#). To enable the feature gate in [kind](#), ensure that kind provides the minimum required Kubernetes version and enables the SeccompDefault feature [in the kind configuration](#):

```
kind: Cluster
apiVersion: kind.x-k8s.io/v1alpha4
nodes:
- role: control-plane
  image: kindest/
node:v1.28.0@sha256:9f3ff58f19dcf1a0611d11e8ac989fdb30a28f40f236f59f0bea31fb956ccf5c
  kubeadmConfigPatches:
  - |
    kind: JoinConfiguration
    nodeRegistration:
      kubeletExtraArgs:
        seccomp-default: "true"
```

```
- role: worker
  image: kindest/
node:v1.28.0@sha256:9f3ff58f19dcf1a0611d11e8ac989fdb30a28f40f236f59f0bea31fb956ccf5c
  kubeadmConfigPatches:
    - |
      kind: JoinConfiguration
      nodeRegistration:
        kubeletExtraArgs:
          seccomp-default: "true"
```

If the cluster is ready, then running a pod:

```
kubectrl run --rm -it --restart=Never --image=alpine alpine -- sh
```

Should now have the default seccomp profile attached. This can be verified by using docker exec to run crictl inspect for the container on the kind worker:

```
docker exec -it kind-worker bash -c \
'crictl inspect $(crictl ps --name=alpine -q) | jq .info.runtimeSpec.linux.seccomp'
```

```
{
  "defaultAction": "SCMP_ACT_ERRNO",
  "architectures": ["SCMP_ARCH_X86_64", "SCMP_ARCH_X86", "SCMP_ARCH_X32"],
  "syscalls": [
    {
      "names": ["..."]
    }
  ]
}
```

What's next

You can learn more about Linux seccomp:

- [A seccomp Overview](#)
- [Seccomp Security Profiles for Docker](#)

Stateless Applications

[Exposing an External IP Address to Access an Application in a Cluster](#)

[Example: Deploying PHP Guestbook application with Redis](#)

Exposing an External IP Address to Access an Application in a Cluster

This page shows how to create a Kubernetes Service object that exposes an external IP address.

Before you begin

- Install [kubectl](#).
- Use a cloud provider like Google Kubernetes Engine or Amazon Web Services to create a Kubernetes cluster. This tutorial creates an [external load balancer](#), which requires a cloud provider.
- Configure kubectl to communicate with your Kubernetes API server. For instructions, see the documentation for your cloud provider.

Objectives

- Run five instances of a Hello World application.
- Create a Service object that exposes an external IP address.
- Use the Service object to access the running application.

Creating a service for an application running in five pods

1. Run a Hello World application in your cluster:

[service/load-balancer-example.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
  labels:
    app.kubernetes.io/name: load-balancer-example
  name: hello-world
spec:
  replicas: 5
  selector:
    matchLabels:
      app.kubernetes.io/name: load-balancer-example
  template:
    metadata:
      labels:
        app.kubernetes.io/name: load-balancer-example
    spec:
      containers:
        - image: gcr.io/google-samples/node-hello:1.0
          name: hello-world
          ports:
            - containerPort: 8080
```

```
kubectl apply -f https://k8s.io/examples/service/load-balancer-example.yaml
```

The preceding command creates a [Deployment](#) and an associated [ReplicaSet](#). The ReplicaSet has five [Pods](#) each of which runs the Hello World application.

2. Display information about the Deployment:

```
kubectl get deployments hello-world
kubectl describe deployments hello-world
```

Display information about your ReplicaSet objects:

3.

```
kubectl get replicaset  
kubectl describe replicaset
```

4. Create a Service object that exposes the deployment:

```
kubectl expose deployment hello-world --type=LoadBalancer --name=my-service
```

5. Display information about the Service:

```
kubectl get services my-service
```

The output is similar to:

| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE |
|------------|--------------|--------------|----------------|----------|-----|
| my-service | LoadBalancer | 10.3.245.137 | 104.198.205.71 | 8080/TCP | 54s |

Note:

The type=LoadBalancer service is backed by external cloud providers, which is not covered in this example, please refer to [this page](#) for the details.

Note:

If the external IP address is shown as <pending>, wait for a minute and enter the same command again.

6. Display detailed information about the Service:

```
kubectl describe services my-service
```

The output is similar to:

```
Name:      my-service  
Namespace: default  
Labels:    app.kubernetes.io/name=load-balancer-example  
Annotations: <none>  
Selector:  app.kubernetes.io/name=load-balancer-example  
Type:      LoadBalancer  
IP:        10.3.245.137  
LoadBalancer Ingress: 104.198.205.71  
Port:      <unset> 8080/TCP  
NodePort:  <unset> 32377/TCP  
Endpoints: 10.0.0.6:8080,10.0.1.6:8080,10.0.1.7:8080 + 2 more...  
Session Affinity: None  
Events:    <none>
```

Make a note of the external IP address (LoadBalancer Ingress) exposed by your service. In this example, the external IP address is 104.198.205.71. Also note the value of Port and NodePort. In this example, the Port is 8080 and the NodePort is 32377.

7. In the preceding output, you can see that the service has several endpoints:

10.0.0.6:8080,10.0.1.6:8080,10.0.1.7:8080 + 2 more. These are internal addresses of the pods

that are running the Hello World application. To verify these are pod addresses, enter this command:

```
kubectl get pods --output=wide
```

The output is similar to:

| NAME | ... | IP | NODE |
|------------------------------|-----|----------|--|
| hello-world-2895499144-1jaz9 | ... | 10.0.1.6 | gke-cluster-1-default-pool-e0b8d269-1afc |
| hello-world-2895499144-2e5uh | ... | 10.0.1.8 | gke-cluster-1-default-pool-e0b8d269-1afc |
| hello-world-2895499144-9m4h1 | ... | 10.0.0.6 | gke-cluster-1-default-pool-e0b8d269-5v7a |
| hello-world-2895499144-o4z13 | ... | 10.0.1.7 | gke-cluster-1-default-pool-e0b8d269-1afc |
| hello-world-2895499144-segjf | ... | 10.0.2.5 | gke-cluster-1-default-pool-e0b8d269-cpuc |

8. Use the external IP address (LoadBalancer Ingress) to access the Hello World application:

```
curl http://<external-ip>:<port>
```

where <external-ip> is the external IP address (LoadBalancer Ingress) of your Service, and <port> is the value of Port in your Service description. If you are using minikube, typing minikube service my-service will automatically open the Hello World application in a browser.

The response to a successful request is a hello message:

```
Hello Kubernetes!
```

Cleaning up

To delete the Service, enter this command:

```
kubectl delete services my-service
```

To delete the Deployment, the ReplicaSet, and the Pods that are running the Hello World application, enter this command:

```
kubectl delete deployment hello-world
```

What's next

Learn more about [connecting applications with services](#).

Example: Deploying PHP Guestbook application with Redis

This tutorial shows you how to build and deploy a simple (*not production ready*), multi-tier web application using Kubernetes and [Docker](#). This example consists of the following components:

- A single-instance [Redis](#) to store guestbook entries
- Multiple web frontend instances

Objectives

- Start up a Redis leader.
- Start up two Redis followers.
- Start up the guestbook frontend.
- Expose and view the Frontend Service.
- Clean up.

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

Your Kubernetes server must be at or later than version v1.14. To check the version, enter kubectl version.

Start up the Redis Database

The guestbook application uses Redis to store its data.

Creating the Redis Deployment

The manifest file, included below, specifies a Deployment controller that runs a single replica Redis Pod.

[application/guestbook/redis-leader-deployment.yaml](#)

```
# SOURCE: https://cloud.google.com/kubernetes-engine/docs/tutorials/guestbook
apiVersion: apps/v1
kind: Deployment
metadata:
  name: redis-leader
  labels:
    app: redis
    role: leader
    tier: backend
spec:
  replicas: 1
  selector:
    matchLabels:
      app: redis
  template:
    metadata:
      labels:
        app: redis
        role: leader
```

```
    tier: backend
spec:
  containers:
  - name: leader
    image: "docker.io/redis:6.0.5"
    resources:
      requests:
        cpu: 100m
        memory: 100Mi
    ports:
    - containerPort: 6379
```

1. Launch a terminal window in the directory you downloaded the manifest files.
2. Apply the Redis Deployment from the redis-leader-deployment.yaml file:

```
kubectl apply -f https://k8s.io/examples/application/guestbook/redis-leader-
deployment.yaml
```

3. Query the list of Pods to verify that the Redis Pod is running:

```
kubectl get pods
```

The response should be similar to this:

| NAME | READY | STATUS | RESTARTS | AGE |
|------------------------------|-------|---------|----------|-----|
| redis-leader-fb76b4755-xjr2n | 1/1 | Running | 0 | 13s |

4. Run the following command to view the logs from the Redis leader Pod:

```
kubectl logs -f deployment/redis-leader
```

Creating the Redis leader Service

The guestbook application needs to communicate to the Redis to write its data. You need to apply a [Service](#) to proxy the traffic to the Redis Pod. A Service defines a policy to access the Pods.

[application/guestbook/redis-leader-service.yaml](#)

```
# SOURCE: https://cloud.google.com/kubernetes-engine/docs/tutorials/guestbook
apiVersion: v1
kind: Service
metadata:
  name: redis-leader
  labels:
    app: redis
    role: leader
    tier: backend
spec:
  ports:
  - port: 6379
    targetPort: 6379
  selector:
```

```
app: redis
role: leader
tier: backend
```

1. Apply the Redis Service from the following `redis-leader-service.yaml` file:

```
kubectl apply -f https://k8s.io/examples/application/guestbook/redis-leader-service.yaml
```

2. Query the list of Services to verify that the Redis Service is running:

```
kubectl get service
```

The response should be similar to this:

| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE |
|--------------|-----------|--------------|-------------|----------|-----|
| kubernetes | ClusterIP | 10.0.0.1 | <none> | 443/TCP | 1m |
| redis-leader | ClusterIP | 10.103.78.24 | <none> | 6379/TCP | 16s |

Note:

This manifest file creates a Service named `redis-leader` with a set of labels that match the labels previously defined, so the Service routes network traffic to the Redis Pod.

Set up Redis followers

Although the Redis leader is a single Pod, you can make it highly available and meet traffic demands by adding a few Redis followers, or replicas.

[application/guestbook/redis-follower-deployment.yaml](https://k8s.io/examples/application/guestbook/redis-follower-deployment.yaml)

```
# SOURCE: https://cloud.google.com/kubernetes-engine/docs/tutorials/guestbook
apiVersion: apps/v1
kind: Deployment
metadata:
  name: redis-follower
  labels:
    app: redis
    role: follower
    tier: backend
spec:
  replicas: 2
  selector:
    matchLabels:
      app: redis
  template:
    metadata:
      labels:
        app: redis
        role: follower
        tier: backend
    spec:
      containers:
        - name: follower
```

```
image: us-docker.pkg.dev/google-samples/containers/gke/gb-redis-follower:v2
resources:
  requests:
    cpu: 100m
    memory: 100Mi
ports:
- containerPort: 6379
```

1. Apply the Redis Deployment from the following redis-follower-deployment.yaml file:

```
kubectl apply -f https://k8s.io/examples/application/guestbook/redis-follower-deployment.yaml
```

2. Verify that the two Redis follower replicas are running by querying the list of Pods:

```
kubectl get pods
```

The response should be similar to this:

| NAME | READY | STATUS | RESTARTS | AGE |
|--------------------------------|-------|---------|----------|-----|
| redis-follower-dddfbdcc9-82sfr | 1/1 | Running | 0 | 37s |
| redis-follower-dddfbdcc9-qrt5k | 1/1 | Running | 0 | 38s |
| redis-leader-fb76b4755-xjr2n | 1/1 | Running | 0 | 11m |

Creating the Redis follower service

The guestbook application needs to communicate with the Redis followers to read data. To make the Redis followers discoverable, you must set up another [Service](#).

[application/guestbook/redis-follower-service.yaml](https://k8s.io/examples/application/guestbook/redis-follower-service.yaml)

```
# SOURCE: https://cloud.google.com/kubernetes-engine/docs/tutorials/guestbook
apiVersion: v1
kind: Service
metadata:
  name: redis-follower
labels:
  app: redis
  role: follower
  tier: backend
spec:
  ports:
    # the port that this service should serve on
    - port: 6379
  selector:
    app: redis
    role: follower
    tier: backend
```

1. Apply the Redis Service from the following redis-follower-service.yaml file:

```
kubectl apply -f https://k8s.io/examples/application/guestbook/redis-follower-service.yaml
```

- Query the list of Services to verify that the Redis Service is running:
2. `kubectl get service`

The response should be similar to this:

| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE |
|----------------|-----------|---------------|-------------|----------|-------|
| kubernetes | ClusterIP | 10.96.0.1 | <none> | 443/TCP | 3d19h |
| redis-follower | ClusterIP | 10.110.162.42 | <none> | 6379/TCP | 9s |
| redis-leader | ClusterIP | 10.103.78.24 | <none> | 6379/TCP | 6m10s |

Note:

This manifest file creates a Service named `redis-follower` with a set of labels that match the labels previously defined, so the Service routes network traffic to the Redis Pod.

Set up and Expose the Guestbook Frontend

Now that you have the Redis storage of your guestbook up and running, start the guestbook web servers. Like the Redis followers, the frontend is deployed using a Kubernetes Deployment.

The guestbook app uses a PHP frontend. It is configured to communicate with either the Redis follower or leader Services, depending on whether the request is a read or a write. The frontend exposes a JSON interface, and serves a jQuery-Ajax-based UX.

Creating the Guestbook Frontend Deployment

[application/guestbook/frontend-deployment.yaml](#)

```
# SOURCE: https://cloud.google.com/kubernetes-engine/docs/tutorials/guestbook
apiVersion: apps/v1
kind: Deployment
metadata:
  name: frontend
spec:
  replicas: 3
  selector:
    matchLabels:
      app: guestbook
      tier: frontend
  template:
    metadata:
      labels:
        app: guestbook
        tier: frontend
    spec:
      containers:
        - name: php-redis
          image: us-docker.pkg.dev/google-samples/containers/gke/gb-frontend:v5
          env:
            - name: GET_HOSTS_FROM
              value: "dns"
```

```
resources:
  requests:
    cpu: 100m
    memory: 100Mi
ports:
- containerPort: 80
```

1. Apply the frontend Deployment from the frontend-deployment.yaml file:

```
kubectl apply -f https://k8s.io/examples/application/guestbook/frontend-deployment.yaml
```

2. Query the list of Pods to verify that the three frontend replicas are running:

```
kubectl get pods -l app=guestbook -l tier=frontend
```

The response should be similar to this:

| NAME | READY | STATUS | RESTARTS | AGE |
|---------------------------|-------|---------|----------|-----|
| frontend-85595f5bf9-5tqhb | 1/1 | Running | 0 | 47s |
| frontend-85595f5bf9-qbzwm | 1/1 | Running | 0 | 47s |
| frontend-85595f5bf9-zchwc | 1/1 | Running | 0 | 47s |

Creating the Frontend Service

The Redis Services you applied is only accessible within the Kubernetes cluster because the default type for a Service is [ClusterIP](#). ClusterIP provides a single IP address for the set of Pods the Service is pointing to. This IP address is accessible only within the cluster.

If you want guests to be able to access your guestbook, you must configure the frontend Service to be externally visible, so a client can request the Service from outside the Kubernetes cluster. However a Kubernetes user can use `kubectl port-forward` to access the service even though it uses a ClusterIP.

Note:

Some cloud providers, like Google Compute Engine or Google Kubernetes Engine, support external load balancers. If your cloud provider supports load balancers and you want to use it, uncomment type: LoadBalancer.

[application/guestbook/frontend-service.yaml](#)

```
# SOURCE: https://cloud.google.com/kubernetes-engine/docs/tutorials/guestbook
apiVersion: v1
kind: Service
metadata:
  name: frontend
  labels:
    app: guestbook
    tier: frontend
spec:
  # if your cluster supports it, uncomment the following to automatically create
  # an external load-balanced IP for the frontend service.
  # type: LoadBalancer
```

```
#type: LoadBalancer
ports:
  # the port that this service should serve on
  - port: 80
selector:
  app: guestbook
  tier: frontend
```

1. Apply the frontend Service from the frontend-service.yaml file:

```
kubectl apply -f https://k8s.io/examples/application/guestbook/frontend-service.yaml
```

2. Query the list of Services to verify that the frontend Service is running:

```
kubectl get services
```

The response should be similar to this:

| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE |
|----------------|-----------|---------------|-------------|----------|-------|
| frontend | ClusterIP | 10.97.28.230 | <none> | 80/TCP | 19s |
| kubernetes | ClusterIP | 10.96.0.1 | <none> | 443/TCP | 3d19h |
| redis-follower | ClusterIP | 10.110.162.42 | <none> | 6379/TCP | 5m48s |
| redis-leader | ClusterIP | 10.103.78.24 | <none> | 6379/TCP | 11m |

Viewing the Frontend Service via kubectl port-forward

1. Run the following command to forward port 8080 on your local machine to port 80 on the service.

```
kubectl port-forward svc/frontend 8080:80
```

The response should be similar to this:

```
Forwarding from 127.0.0.1:8080 -> 80
Forwarding from [::1]:8080 -> 80
```

2. load the page <http://localhost:8080> in your browser to view your guestbook.

Viewing the Frontend Service via LoadBalancer

If you deployed the frontend-service.yaml manifest with type: LoadBalancer you need to find the IP address to view your Guestbook.

1. Run the following command to get the IP address for the frontend Service.

```
kubectl get service frontend
```

The response should be similar to this:

| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE |
|----------|--------------|---------------|----------------|--------------|-----|
| frontend | LoadBalancer | 10.51.242.136 | 109.197.92.229 | 80:32372/TCP | 1m |

2. Copy the external IP address, and load the page in your browser to view your guestbook.

Note:

Try adding some guestbook entries by typing in a message, and clicking Submit. The message you typed appears in the frontend. This message indicates that data is successfully added to Redis through the Services you created earlier.

Scale the Web Frontend

You can scale up or down as needed because your servers are defined as a Service that uses a Deployment controller.

1. Run the following command to scale up the number of frontend Pods:

```
kubectl scale deployment frontend --replicas=5
```

2. Query the list of Pods to verify the number of frontend Pods running:

```
kubectl get pods
```

The response should look similar to this:

| NAME | READY | STATUS | RESTARTS | AGE |
|--------------------------------|-------|---------|----------|------|
| frontend-85595f5bf9-5df5m | 1/1 | Running | 0 | 83s |
| frontend-85595f5bf9-7zmg5 | 1/1 | Running | 0 | 83s |
| frontend-85595f5bf9-cpskg | 1/1 | Running | 0 | 15m |
| frontend-85595f5bf9-l2l54 | 1/1 | Running | 0 | 14m |
| frontend-85595f5bf9-l9c8z | 1/1 | Running | 0 | 14m |
| redis-follower-dddfbdcc9-82sfr | 1/1 | Running | 0 | 97m |
| redis-follower-dddfbdcc9-qrt5k | 1/1 | Running | 0 | 97m |
| redis-leader-fb76b4755-xjr2n | 1/1 | Running | 0 | 108m |

3. Run the following command to scale down the number of frontend Pods:

```
kubectl scale deployment frontend --replicas=2
```

4. Query the list of Pods to verify the number of frontend Pods running:

```
kubectl get pods
```

The response should look similar to this:

| NAME | READY | STATUS | RESTARTS | AGE |
|--------------------------------|-------|---------|----------|------|
| frontend-85595f5bf9-cpskg | 1/1 | Running | 0 | 16m |
| frontend-85595f5bf9-l9c8z | 1/1 | Running | 0 | 15m |
| redis-follower-dddfbdcc9-82sfr | 1/1 | Running | 0 | 98m |
| redis-follower-dddfbdcc9-qrt5k | 1/1 | Running | 0 | 98m |
| redis-leader-fb76b4755-xjr2n | 1/1 | Running | 0 | 109m |

Cleaning up

Deleting the Deployments and Services also deletes any running Pods. Use labels to delete multiple resources with one command.

1. Run the following commands to delete all Pods, Deployments, and Services.

```
kubectl delete deployment -l app=redis
kubectl delete service -l app=redis
kubectl delete deployment frontend
kubectl delete service frontend
```

The response should look similar to this:

```
deployment.apps "redis-follower" deleted
deployment.apps "redis-leader" deleted
deployment.apps "frontend" deleted
service "frontend" deleted
```

2. Query the list of Pods to verify that no Pods are running:

```
kubectl get pods
```

The response should look similar to this:

```
No resources found in default namespace.
```

What's next

- Complete the [Kubernetes Basics](#) Interactive Tutorials
- Use Kubernetes to create a blog using [Persistent Volumes for MySQL and Wordpress](#)
- Read more about [connecting applications with services](#)
- Read more about [using labels effectively](#)

Stateful Applications

[StatefulSet Basics](#)

[Example: Deploying WordPress and MySQL with Persistent Volumes](#)

[Example: Deploying Cassandra with a StatefulSet](#)

[Running ZooKeeper, A Distributed System Coordinator](#)

StatefulSet Basics

This tutorial provides an introduction to managing applications with [StatefulSets](#). It demonstrates how to create, delete, scale, and update the Pods of StatefulSets.

Before you begin

Before you begin this tutorial, you should familiarize yourself with the following Kubernetes concepts:

- [Pods](#)
- [Cluster DNS](#)
- [Headless Services](#)
- [PersistentVolumes](#)
- [PersistentVolume Provisioning](#)
- The [kubectl](#) command line tool

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

You should configure kubectl to use a context that uses the default namespace. If you are using an existing cluster, make sure that it's OK to use that cluster's default namespace to practice. Ideally, practice in a cluster that doesn't run any real workloads.

It's also useful to read the concept page about [StatefulSets](#).

Note:

This tutorial assumes that your cluster is configured to dynamically provision PersistentVolumes. You'll also need to have a [default StorageClass](#). If your cluster is not configured to provision storage dynamically, you will have to manually provision two 1 GiB volumes prior to starting this tutorial and set up your cluster so that those PersistentVolumes map to the PersistentVolumeClaim templates that the StatefulSet defines.

Objectives

StatefulSets are intended to be used with stateful applications and distributed systems. However, the administration of stateful applications and distributed systems on Kubernetes is a broad, complex topic. In order to demonstrate the basic features of a StatefulSet, and not to conflate the former topic with the latter, you will deploy a simple web application using a StatefulSet.

After this tutorial, you will be familiar with the following.

- How to create a StatefulSet
- How a StatefulSet manages its Pods
- How to delete a StatefulSet
- How to scale a StatefulSet
- How to update a StatefulSet's Pods

Creating a StatefulSet

Begin by creating a StatefulSet (and the Service that it relies upon) using the example below. It is similar to the example presented in the [StatefulSets](#) concept. It creates a [headless Service](#), nginx, to publish the IP addresses of Pods in the StatefulSet, web.

[application/web/web.yaml](#)

```
apiVersion: v1
kind: Service
metadata:
  name: nginx
  labels:
    app: nginx
spec:
  ports:
    - port: 80
      name: web
  clusterIP: None
  selector:
    app: nginx
---
apiVersion: apps/v1
kind: StatefulSet
metadata:
  name: web
spec:
  serviceName: "nginx"
  replicas: 2
  selector:
    matchLabels:
      app: nginx
  template:
    metadata:
      labels:
        app: nginx
    spec:
      containers:
        - name: nginx
          image: registry.k8s.io/nginx-slim:0.8
          ports:
            - containerPort: 80
              name: web
          volumeMounts:
            - name: www
              mountPath: /usr/share/nginx/html
      volumeClaimTemplates:
        - metadata:
            name: www
          spec:
            accessModes: [ "ReadWriteOnce" ]
            resources:
```

```
requests:
  storage: 1Gi
```

You will need to use at least two terminal windows. In the first terminal, use [kubectl get](#) to watch the creation of the StatefulSet's Pods.

```
# use this terminal to run commands that specify --watch
# end this watch when you are asked to start a new watch
kubectl get pods --watch -l app=nginx
```

In the second terminal, use [kubectl apply](#) to create the headless Service and StatefulSet:

```
kubectl apply -f https://k8s.io/examples/application/web/web.yaml
```

```
service/nginx created
statefulset.apps/web created
```

The command above creates two Pods, each running an [NGINX](#) webserver. Get the nginx Service...

```
kubectl get service nginx
```

| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE |
|-------|-----------|------------|-------------|---------|-----|
| nginx | ClusterIP | None | <none> | 80/TCP | 12s |

...then get the web StatefulSet, to verify that both were created successfully:

```
kubectl get statefulset web
```

| NAME | DESIRED | CURRENT | AGE |
|------|---------|---------|-----|
| web | 2 | 1 | 20s |

Ordered Pod creation

A StatefulSet defaults to creating its Pods in a strict order.

For a StatefulSet with n replicas, when Pods are being deployed, they are created sequentially, ordered from $\{0..n-1\}$. Examine the output of the `kubectl get` command in the first terminal. Eventually, the output will look like the example below.

```
# Do not start a new watch;
# this should already be running
kubectl get pods --watch -l app=nginx
```

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|-------------------|----------|-----|
| web-0 | 0/1 | Pending | 0 | 0s |
| web-0 | 0/1 | Pending | 0 | 0s |
| web-0 | 0/1 | ContainerCreating | 0 | 0s |
| web-0 | 1/1 | Running | 0 | 19s |
| web-1 | 0/1 | Pending | 0 | 0s |
| web-1 | 0/1 | Pending | 0 | 0s |
| web-1 | 0/1 | ContainerCreating | 0 | 0s |
| web-1 | 1/1 | Running | 0 | 18s |

Notice that the web-1 Pod is not launched until the web-0 Pod is *Running* (see [Pod Phase](#)) and *Ready* (see type in [Pod Conditions](#)).

Later in this tutorial you will practice [parallel startup](#).

Note:

To configure the integer ordinal assigned to each Pod in a StatefulSet, see [Start ordinal](#).

Pods in a StatefulSet

Pods in a StatefulSet have a unique ordinal index and a stable network identity.

Examining the Pod's ordinal index

Get the StatefulSet's Pods:

```
kubectl get pods -l app=nginx
```

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|---------|----------|-----|
| web-0 | 1/1 | Running | 0 | 1m |
| web-1 | 1/1 | Running | 0 | 1m |

As mentioned in the [StatefulSets](#) concept, the Pods in a StatefulSet have a sticky, unique identity. This identity is based on a unique ordinal index that is assigned to each Pod by the StatefulSet [controller](#).

The Pods' names take the form <statefulset name>--<ordinal index>. Since the web StatefulSet has two replicas, it creates two Pods, web-0 and web-1.

Using stable network identities

Each Pod has a stable hostname based on its ordinal index. Use [kubectl exec](#) to execute the `hostname` command in each Pod:

```
for i in 0 1; do kubectl exec "web-$i" -- sh -c 'hostname'; done
```

```
web-0
web-1
```

Use [kubectl run](#) to execute a container that provides the `nslookup` command from the `dnsutils` package. Using `nslookup` on the Pods' hostnames, you can examine their in-cluster DNS addresses:

```
kubectl run -i --tty --image busybox:1.28 dns-test --restart=Never --rm
```

which starts a new shell. In that new shell, run:

```
# Run this in the dns-test container shell
nslookup web-0.nginx
```

The output is similar to:

```
Server: 10.0.0.10
Address 1: 10.0.0.10 kube-dns.kube-system.svc.cluster.local

Name: web-0.nginx
Address 1: 10.244.1.6

nslookup web-1.nginx
Server: 10.0.0.10
Address 1: 10.0.0.10 kube-dns.kube-system.svc.cluster.local

Name: web-1.nginx
Address 1: 10.244.2.6
```

(and now exit the container shell: exit)

The CNAME of the headless service points to SRV records (one for each Pod that is Running and Ready). The SRV records point to A record entries that contain the Pods' IP addresses.

In one terminal, watch the StatefulSet's Pods:

```
# Start a new watch
# End this watch when you've seen that the delete is finished
kubectrl get pod --watch -l app=nginx
```

In a second terminal, use [kubectrl delete](#) to delete all the Pods in the StatefulSet:

```
kubectrl delete pod -l app=nginx
```

```
pod "web-0" deleted
pod "web-1" deleted
```

Wait for the StatefulSet to restart them, and for both Pods to transition to Running and Ready:

```
# This should already be running
kubectrl get pod --watch -l app=nginx
```

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|-------------------|----------|-----|
| web-0 | 0/1 | ContainerCreating | 0 | 0s |

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|-------------------|----------|-----|
| web-0 | 1/1 | Running | 0 | 2s |
| web-1 | 0/1 | Pending | 0 | 0s |
| web-1 | 0/1 | Pending | 0 | 0s |
| web-1 | 0/1 | ContainerCreating | 0 | 0s |
| web-1 | 1/1 | Running | 0 | 34s |

Use `kubectrl exec` and `kubectrl run` to view the Pods' hostnames and in-cluster DNS entries. First, view the Pods' hostnames:

```
for i in 0 1; do kubectrl exec web-$i -- sh -c 'hostname'; done
```

```
web-0
web-1
```

then, run:

```
kubectrl run -i --tty --image busybox:1.28 dns-test --restart=Never --rm
```

which starts a new shell.

In that new shell, run:

```
# Run this in the dns-test container shell
nslookup web-0.nginx
```

The output is similar to:

```
Server: 10.0.0.10
Address 1: 10.0.0.10 kube-dns.kube-system.svc.cluster.local

Name: web-0.nginx
Address 1: 10.244.1.7

nslookup web-1.nginx
Server: 10.0.0.10
Address 1: 10.0.0.10 kube-dns.kube-system.svc.cluster.local

Name: web-1.nginx
Address 1: 10.244.2.8
```

(and now exit the container shell: exit)

The Pods' ordinals, hostnames, SRV records, and A record names have not changed, but the IP addresses associated with the Pods may have changed. In the cluster used for this tutorial, they have. This is why it is important not to configure other applications to connect to Pods in a StatefulSet by the IP address of a particular Pod (it is OK to connect to Pods by resolving their hostname).

Discovery for specific Pods in a StatefulSet

If you need to find and connect to the active members of a StatefulSet, you should query the CNAME of the headless Service (nginx.default.svc.cluster.local). The SRV records associated with the CNAME will contain only the Pods in the StatefulSet that are Running and Ready.

If your application already implements connection logic that tests for liveness and readiness, you can use the SRV records of the Pods (web-0.nginx.default.svc.cluster.local, web-1.nginx.default.svc.cluster.local), as they are stable, and your application will be able to discover the Pods' addresses when they transition to Running and Ready.

If your application wants to find any healthy Pod in a StatefulSet, and therefore does not need to track each specific Pod, you could also connect to the IP address of a type: ClusterIP Service, backed by the Pods in that StatefulSet. You can use the same Service that tracks the StatefulSet (specified in the serviceName of the StatefulSet) or a separate Service that selects the right set of Pods.

Writing to stable storage

Get the PersistentVolumeClaims for web-0 and web-1:

```
kubectrl get pvc -l app=nginx
```

The output is similar to:

| NAME | STATUS | VOLUME | CAPACITY | ACCESSMODES | AGE |
|-----------|--------|--|----------|-------------|-----|
| www-web-0 | Bound | pvc-15c268c7-b507-11e6-932f-42010a800002 | 1Gi | RWO | 48s |
| www-web-1 | Bound | pvc-15c79307-b507-11e6-932f-42010a800002 | 1Gi | RWO | 48s |

The StatefulSet controller created two [PersistentVolumeClaims](#) that are bound to two [PersistentVolumes](#).

As the cluster used in this tutorial is configured to dynamically provision PersistentVolumes, the PersistentVolumes were created and bound automatically.

The NGINX webserver, by default, serves an index file from `/usr/share/nginx/html/index.html`. The `volumeMounts` field in the StatefulSet's spec ensures that the `/usr/share/nginx/html` directory is backed by a PersistentVolume.

Write the Pods' hostnames to their `index.html` files and verify that the NGINX webserver serves the hostnames:

```
for i in 0 1; do kubectl exec "web-$i" -- sh -c 'echo "${hostname}" > /usr/share/nginx/html/index.html'; done
```

```
for i in 0 1; do kubectl exec -i -t "web-$i" -- curl http://localhost/; done
```

```
web-0
web-1
```

Note:

If you instead see **403 Forbidden** responses for the above `curl` command, you will need to fix the permissions of the directory mounted by the `volumeMounts` (due to a [bug when using hostPath volumes](#)), by running:

```
for i in 0 1; do kubectl exec web-$i -- chmod 755 /usr/share/nginx/html; done
```

before retrying the `curl` command above.

In one terminal, watch the StatefulSet's Pods:

```
# End this watch when you've reached the end of the section.
# At the start of "Scaling a StatefulSet" you'll start a new watch.
kubectl get pod --watch -l app=nginx
```

In a second terminal, delete all of the StatefulSet's Pods:

```
kubectl delete pod -l app=nginx
```

```
pod "web-0" deleted
pod "web-1" deleted
```

Examine the output of the `kubectl get` command in the first terminal, and wait for all of the Pods to transition to Running and Ready.

```
# This should already be running
kubectl get pod --watch -l app=nginx
```

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|-------------------|----------|-----|
| web-0 | 0/1 | ContainerCreating | 0 | 0s |

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|-------------------|----------|-----|
| web-0 | 1/1 | Running | 0 | 2s |
| web-1 | 0/1 | Pending | 0 | 0s |
| web-1 | 0/1 | Pending | 0 | 0s |
| web-1 | 0/1 | ContainerCreating | 0 | 0s |
| web-1 | 1/1 | Running | 0 | 34s |

Verify the web servers continue to serve their hostnames:

```
for i in 0 1; do kubectl exec -i -t "web-$i" -- curl http://localhost/; done
```

```
web-0
web-1
```

Even though web-0 and web-1 were rescheduled, they continue to serve their hostnames because the PersistentVolumes associated with their PersistentVolumeClaims are remounted to their volumeMounts. No matter what node web-0 and web-1 are scheduled on, their PersistentVolumes will be mounted to the appropriate mount points.

Scaling a StatefulSet

Scaling a StatefulSet refers to increasing or decreasing the number of replicas (horizontal scaling). This is accomplished by updating the replicas field. You can use either [kubectl scale](#) or [kubectl patch](#) to scale a StatefulSet.

Scaling up

Scaling up means adding more replicas. Provided that your app is able to distribute work across the StatefulSet, the new larger set of Pods can perform more of that work.

In one terminal window, watch the Pods in the StatefulSet:

```
# If you already have a watch running, you can continue using that.
# Otherwise, start one.
# End this watch when there are 5 healthy Pods for the StatefulSet
kubectl get pods --watch -l app=nginx
```

In another terminal window, use `kubectl scale` to scale the number of replicas to 5:

```
kubectl scale sts web --replicas=5
```

```
statefulset.apps/web scaled
```

Examine the output of the `kubectl get` command in the first terminal, and wait for the three additional Pods to transition to Running and Ready.

```
# This should already be running
kubectl get pod --watch -l app=nginx
```

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|---------|----------|-----|
| web-0 | 1/1 | Running | 0 | 2h |
| web-1 | 1/1 | Running | 0 | 2h |

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|-------------------|----------|-----|
| web-2 | 0/1 | Pending | 0 | 0s |
| web-2 | 0/1 | Pending | 0 | 0s |
| web-2 | 0/1 | ContainerCreating | 0 | 0s |
| web-2 | 1/1 | Running | 0 | 19s |
| web-3 | 0/1 | Pending | 0 | 0s |
| web-3 | 0/1 | Pending | 0 | 0s |
| web-3 | 0/1 | ContainerCreating | 0 | 0s |
| web-3 | 1/1 | Running | 0 | 18s |
| web-4 | 0/1 | Pending | 0 | 0s |
| web-4 | 0/1 | Pending | 0 | 0s |
| web-4 | 0/1 | ContainerCreating | 0 | 0s |
| web-4 | 1/1 | Running | 0 | 19s |

The StatefulSet controller scaled the number of replicas. As with [StatefulSet creation](#), the StatefulSet controller created each Pod sequentially with respect to its ordinal index, and it waited for each Pod's predecessor to be Running and Ready before launching the subsequent Pod.

Scaling down

Scaling down means reducing the number of replicas. For example, you might do this because the level of traffic to a service has decreased, and at the current scale there are idle resources.

In one terminal, watch the StatefulSet's Pods:

```
# End this watch when there are only 3 Pods for the StatefulSet
kubectl get pod --watch -l app=nginx
```

In another terminal, use kubectl patch to scale the StatefulSet back down to three replicas:

```
kubectl patch sts web -p '{"spec":{"replicas":3}}'
```

```
statefulset.apps/web patched
```

Wait for web-4 and web-3 to transition to Terminating.

```
# This should already be running
kubectl get pods --watch -l app=nginx
```

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|-------------------|----------|-----|
| web-0 | 1/1 | Running | 0 | 3h |
| web-1 | 1/1 | Running | 0 | 3h |
| web-2 | 1/1 | Running | 0 | 55s |
| web-3 | 1/1 | Running | 0 | 36s |
| web-4 | 0/1 | ContainerCreating | 0 | 18s |

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|-------------|----------|-----|
| web-4 | 1/1 | Running | 0 | 19s |
| web-4 | 1/1 | Terminating | 0 | 24s |
| web-4 | 1/1 | Terminating | 0 | 24s |

```
web-3    1/1    Terminating    0    42s
web-3    1/1    Terminating    0    42s
```

Ordered Pod termination

The control plane deleted one Pod at a time, in reverse order with respect to its ordinal index, and it waited for each Pod to be completely shut down before deleting the next one.

Get the StatefulSet's PersistentVolumeClaims:

```
kubectl get pvc -l app=nginx
```

| NAME | STATUS | VOLUME | CAPACITY | ACCESSMODES | AGE |
|-----------|--------|--|----------|-------------|-----|
| www-web-0 | Bound | pvc-15c268c7-b507-11e6-932f-42010a800002 | 1Gi | RWO | 13h |
| www-web-1 | Bound | pvc-15c79307-b507-11e6-932f-42010a800002 | 1Gi | RWO | 13h |
| www-web-2 | Bound | pvc-e1125b27-b508-11e6-932f-42010a800002 | 1Gi | RWO | 13h |
| www-web-3 | Bound | pvc-e1176df6-b508-11e6-932f-42010a800002 | 1Gi | RWO | 13h |
| www-web-4 | Bound | pvc-e11bb5f8-b508-11e6-932f-42010a800002 | 1Gi | RWO | 13h |

There are still five PersistentVolumeClaims and five PersistentVolumes. When exploring a Pod's [stable storage](#), you saw that the PersistentVolumes mounted to the Pods of a StatefulSet are not deleted when the StatefulSet's Pods are deleted. This is still true when Pod deletion is caused by scaling the StatefulSet down.

Updating StatefulSets

The StatefulSet controller supports automated updates. The strategy used is determined by the `spec.updateStrategy` field of the StatefulSet API object. This feature can be used to upgrade the container images, resource requests and/or limits, labels, and annotations of the Pods in a StatefulSet.

There are two valid update strategies, `RollingUpdate` (the default) and `OnDelete`.

RollingUpdate

The `RollingUpdate` update strategy will update all Pods in a StatefulSet, in reverse ordinal order, while respecting the StatefulSet guarantees.

You can split updates to a StatefulSet that uses the `RollingUpdate` strategy into *partitions*, by specifying `.spec.updateStrategy.rollingUpdate.partition`. You'll practice that later in this tutorial.

First, try a simple rolling update.

In one terminal window, patch the web StatefulSet to change the container image again:

```
kubectl patch statefulset web --type='json' -p='[{"op": "replace", "path": "/spec/template/spec/containers/0/image", "value": "gcr.io/google_containers/nginx-slim:0.8"}]'
```

```
statefulset.apps/web patched
```

In another terminal, watch the Pods in the StatefulSet:

```
# End this watch when the rollout is complete
#
# If you're not sure, leave it running one more minute
kubectl get pod -l app=nginx --watch
```

The output is similar to:

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|-------------------|----------|-----|
| web-0 | 1/1 | Running | 0 | 7m |
| web-1 | 1/1 | Running | 0 | 7m |
| web-2 | 1/1 | Running | 0 | 8m |
| web-2 | 1/1 | Terminating | 0 | 8m |
| web-2 | 1/1 | Terminating | 0 | 8m |
| web-2 | 0/1 | Terminating | 0 | 8m |
| web-2 | 0/1 | Terminating | 0 | 8m |
| web-2 | 0/1 | Terminating | 0 | 8m |
| web-2 | 0/1 | Terminating | 0 | 8m |
| web-2 | 0/1 | Pending | 0 | 0s |
| web-2 | 0/1 | Pending | 0 | 0s |
| web-2 | 0/1 | ContainerCreating | 0 | 0s |
| web-2 | 1/1 | Running | 0 | 19s |
| web-1 | 1/1 | Terminating | 0 | 8m |
| web-1 | 0/1 | Terminating | 0 | 8m |
| web-1 | 0/1 | Terminating | 0 | 8m |
| web-1 | 0/1 | Terminating | 0 | 8m |
| web-1 | 0/1 | Pending | 0 | 0s |
| web-1 | 0/1 | Pending | 0 | 0s |
| web-1 | 0/1 | ContainerCreating | 0 | 0s |
| web-1 | 1/1 | Running | 0 | 6s |
| web-0 | 1/1 | Terminating | 0 | 7m |
| web-0 | 1/1 | Terminating | 0 | 7m |
| web-0 | 0/1 | Terminating | 0 | 7m |
| web-0 | 0/1 | Terminating | 0 | 7m |
| web-0 | 0/1 | Terminating | 0 | 7m |
| web-0 | 0/1 | Terminating | 0 | 7m |
| web-0 | 0/1 | Pending | 0 | 0s |
| web-0 | 0/1 | Pending | 0 | 0s |
| web-0 | 0/1 | ContainerCreating | 0 | 0s |
| web-0 | 1/1 | Running | 0 | 10s |

The Pods in the StatefulSet are updated in reverse ordinal order. The StatefulSet controller terminates each Pod, and waits for it to transition to Running and Ready prior to updating the next Pod. Note that, even though the StatefulSet controller will not proceed to update the next Pod until its ordinal successor is Running and Ready, it will restore any Pod that fails during the update to that Pod's existing version.

Pods that have already received the update will be restored to the updated version, and Pods that have not yet received the update will be restored to the previous version. In this way, the controller attempts to continue to keep the application healthy and the update consistent in the presence of intermittent failures.

Get the Pods to view their container images:

```
for p in 0 1 2; do kubectl get pod "web-$p" --template '{{range $i, $c := .spec.containers}}{{$c.image}}{{end}}'; echo; done
```

```
registry.k8s.io/nginx-slim:0.8
registry.k8s.io/nginx-slim:0.8
registry.k8s.io/nginx-slim:0.8
```

All the Pods in the StatefulSet are now running the previous container image.

Note:

You can also use `kubectl rollout status sts/<name>` to view the status of a rolling update to a StatefulSet

Staging an update

You can split updates to a StatefulSet that uses the RollingUpdate strategy into *partitions*, by specifying `.spec.updateStrategy.rollingUpdate.partition`.

For more context, you can read [Partitioned rolling updates](#) in the StatefulSet concept page.

You can stage an update to a StatefulSet by using the `partition` field within `.spec.updateStrategy.rollingUpdate`. For this update, you will keep the existing Pods in the StatefulSet unchanged whilst you change the pod template for the StatefulSet. Then you - or, outside of a tutorial, some external automation - can trigger that prepared update.

First, patch the web StatefulSet to add a partition to the `updateStrategy` field:

```
# The value of "partition" determines which ordinals a change applies to
# Make sure to use a number bigger than the last ordinal for the
# StatefulSet
kubectl patch statefulset web -p '{"spec":{"updateStrategy":
{"type":"RollingUpdate","rollingUpdate":{"partition":3}}}}'
```

```
statefulset.apps/web patched
```

Patch the StatefulSet again to change the container image that this StatefulSet uses:

```
kubectl patch statefulset web --type='json' -p='[{"op": "replace", "path": "/spec/template/spec/containers/0/image", "value": "registry.k8s.io/nginx-slim:0.7"}]'
```

```
statefulset.apps/web patched
```

Delete a Pod in the StatefulSet:

```
kubectl delete pod web-2
```

```
pod "web-2" deleted
```

Wait for the replacement web-2 Pod to be Running and Ready:

```
# End the watch when you see that web-2 is healthy
kubectl get pod -l app=nginx --watch
```

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|-------------------|----------|-----|
| web-0 | 1/1 | Running | 0 | 4m |
| web-1 | 1/1 | Running | 0 | 4m |
| web-2 | 0/1 | ContainerCreating | 0 | 11s |
| web-2 | 1/1 | Running | 0 | 18s |

Get the Pod's container image:

```
kubectl get pod web-2 --template '{{range $i, $c := .spec.containers}}{{ $c.image}}{{end}}'
```

```
registry.k8s.io/nginx-slim:0.8
```

Notice that, even though the update strategy is RollingUpdate the StatefulSet restored the Pod with the original container image. This is because the ordinal of the Pod is less than the partition specified by the updateStrategy.

Rolling out a canary

You're now going to try a [canary rollout](#) of that staged change.

You can roll out a canary (to test the modified template) by decrementing the partition you specified [above](#).

Patch the StatefulSet to decrement the partition:

```
# The value of "partition" should match the highest existing ordinal for
# the StatefulSet
kubectl patch statefulset web -p '{"spec":{"updateStrategy":
{"type":"RollingUpdate","rollingUpdate":{"partition":2}}}]'
```

```
statefulset.apps/web patched
```

The control plane triggers replacement for web-2 (implemented by a graceful **delete** followed by creating a new Pod once the deletion is complete). Wait for the new web-2 Pod to be Running and Ready.

```
# This should already be running
kubectl get pod -l app=nginx --watch
```

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|-------------------|----------|-----|
| web-0 | 1/1 | Running | 0 | 4m |
| web-1 | 1/1 | Running | 0 | 4m |
| web-2 | 0/1 | ContainerCreating | 0 | 11s |
| web-2 | 1/1 | Running | 0 | 18s |

Get the Pod's container:

```
kubectl get pod web-2 --template '{{range $i, $c := .spec.containers}}{{ $c.image}}{{end}}'
```

```
registry.k8s.io/nginx-slim:0.7
```

When you changed the partition, the StatefulSet controller automatically updated the web-2 Pod because the Pod's ordinal was greater than or equal to the partition.

Delete the web-1 Pod:

```
kubectl delete pod web-1
```

```
pod "web-1" deleted
```

Wait for the web-1 Pod to be Running and Ready.

```
# This should already be running
kubectl get pod -l app=nginx --watch
```

The output is similar to:

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|-------------------|----------|-----|
| web-0 | 1/1 | Running | 0 | 6m |
| web-1 | 0/1 | Terminating | 0 | 6m |
| web-2 | 1/1 | Running | 0 | 2m |
| web-1 | 0/1 | Terminating | 0 | 6m |
| web-1 | 0/1 | Terminating | 0 | 6m |
| web-1 | 0/1 | Terminating | 0 | 6m |
| web-1 | 0/1 | Pending | 0 | 0s |
| web-1 | 0/1 | Pending | 0 | 0s |
| web-1 | 0/1 | ContainerCreating | 0 | 0s |
| web-1 | 1/1 | Running | 0 | 18s |

Get the web-1 Pod's container image:

```
kubectl get pod web-1 --template '{{range $i, $c := .spec.containers}}{{ $c.image}}{{end}}'
```

```
registry.k8s.io/nginx-slim:0.8
```

web-1 was restored to its original configuration because the Pod's ordinal was less than the partition. When a partition is specified, all Pods with an ordinal that is greater than or equal to the partition will be updated when the StatefulSet's `.spec.template` is updated. If a Pod that has an ordinal less than the partition is deleted or otherwise terminated, it will be restored to its original configuration.

Phased roll outs

You can perform a phased roll out (e.g. a linear, geometric, or exponential roll out) using a partitioned rolling update in a similar manner to how you rolled out a [canary](#). To perform a phased roll out, set the partition to the ordinal at which you want the controller to pause the update.

The partition is currently set to 2. Set the partition to 0:

```
kubectl patch statefulset web -p '{"spec":{"updateStrategy":  
{"type":"RollingUpdate","rollingUpdate":{"partition":0}}}}'
```

```
statefulset.apps/web patched
```

Wait for all of the Pods in the StatefulSet to become Running and Ready.

```
# This should already be running
kubectl get pod -l app=nginx --watch
```

The output is similar to:

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|-------------------|----------|-----|
| web-0 | 1/1 | Running | 0 | 3m |
| web-1 | 0/1 | ContainerCreating | 0 | 11s |
| web-2 | 1/1 | Running | 0 | 2m |
| web-1 | 1/1 | Running | 0 | 18s |
| web-0 | 1/1 | Terminating | 0 | 3m |
| web-0 | 1/1 | Terminating | 0 | 3m |
| web-0 | 0/1 | Terminating | 0 | 3m |
| web-0 | 0/1 | Terminating | 0 | 3m |
| web-0 | 0/1 | Terminating | 0 | 3m |
| web-0 | 0/1 | Terminating | 0 | 3m |
| web-0 | 0/1 | Pending | 0 | 0s |
| web-0 | 0/1 | Pending | 0 | 0s |
| web-0 | 0/1 | ContainerCreating | 0 | 0s |
| web-0 | 1/1 | Running | 0 | 3s |

Get the container image details for the Pods in the StatefulSet:

```
for p in 0 1 2; do kubectl get pod "web-$p" --template '{{range $i, $c := .spec.containers}}
{{$c.image}}{{end}}'; echo; done
```

```
registry.k8s.io/nginx-slim:0.7
registry.k8s.io/nginx-slim:0.7
registry.k8s.io/nginx-slim:0.7
```

By moving the partition to 0, you allowed the StatefulSet to continue the update process.

OnDelete

You select this update strategy for a StatefulSet by setting the `.spec.template.updateStrategy.type` to `OnDelete`.

Patch the web StatefulSet to use the `OnDelete` update strategy:

```
kubectl patch statefulset web -p '{"spec":{"updateStrategy":{"type":"OnDelete"}}}'
```

```
statefulset.apps/web patched
```

When you select this update strategy, the StatefulSet controller does not automatically update Pods when a modification is made to the StatefulSet's `.spec.template` field. You need to manage the rollout yourself - either manually, or using separate automation.

Deleting StatefulSets

StatefulSet supports both *non-cascading* and *cascading* deletion. In a non-cascading **delete**, the StatefulSet's Pods are not deleted when the StatefulSet is deleted. In a cascading **delete**, both the StatefulSet and its Pods are deleted.

Read [Use Cascading Deletion in a Cluster](#) to learn about cascading deletion generally.

Non-cascading delete

In one terminal window, watch the Pods in the StatefulSet.

```
# End this watch when there are no Pods for the StatefulSet
kubectl get pods --watch -l app=nginx
```

Use [kubectl delete](#) to delete the StatefulSet. Make sure to supply the `--cascade=orphan` parameter to the command. This parameter tells Kubernetes to only delete the StatefulSet, and to **not** delete any of its Pods.

```
kubectl delete statefulset web --cascade=orphan
```

```
statefulset.apps "web" deleted
```

Get the Pods, to examine their status:

```
kubectl get pods -l app=nginx
```

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|---------|----------|-----|
| web-0 | 1/1 | Running | 0 | 6m |
| web-1 | 1/1 | Running | 0 | 7m |
| web-2 | 1/1 | Running | 0 | 5m |

Even though web has been deleted, all of the Pods are still Running and Ready. Delete web-0:

```
kubectl delete pod web-0
```

```
pod "web-0" deleted
```

Get the StatefulSet's Pods:

```
kubectl get pods -l app=nginx
```

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|---------|----------|-----|
| web-1 | 1/1 | Running | 0 | 10m |
| web-2 | 1/1 | Running | 0 | 7m |

As the web StatefulSet has been deleted, web-0 has not been relaunched.

In one terminal, watch the StatefulSet's Pods.

```
# Leave this watch running until the next time you start a watch
kubectl get pods --watch -l app=nginx
```

In a second terminal, recreate the StatefulSet. Note that, unless you deleted the nginx Service (which you should not have), you will see an error indicating that the Service already exists.

```
kubectl apply -f https://k8s.io/examples/application/web/web.yaml
```

```
statefulset.apps/web created
service/nginx unchanged
```

Ignore the error. It only indicates that an attempt was made to create the *nginx* headless Service even though that Service already exists.

Examine the output of the `kubectl get` command running in the first terminal.

```
# This should already be running
kubectl get pods --watch -l app=nginx
```

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|---------|----------|-----|
| web-1 | 1/1 | Running | 0 | 16m |
| web-2 | 1/1 | Running | 0 | 2m |

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|-------------------|----------|-----|
| web-0 | 0/1 | Pending | 0 | 0s |
| web-0 | 0/1 | Pending | 0 | 0s |
| web-0 | 0/1 | ContainerCreating | 0 | 0s |
| web-0 | 1/1 | Running | 0 | 18s |
| web-2 | 1/1 | Terminating | 0 | 3m |
| web-2 | 0/1 | Terminating | 0 | 3m |
| web-2 | 0/1 | Terminating | 0 | 3m |
| web-2 | 0/1 | Terminating | 0 | 3m |

When the web StatefulSet was recreated, it first relaunched web-0. Since web-1 was already Running and Ready, when web-0 transitioned to Running and Ready, it adopted this Pod. Since you recreated the StatefulSet with replicas equal to 2, once web-0 had been recreated, and once web-1 had been determined to already be Running and Ready, web-2 was terminated.

Now take another look at the contents of the `index.html` file served by the Pods' web servers:

```
for i in 0 1; do kubectl exec -i -t "web-$i" -- curl http://localhost/; done
```

```
web-0
web-1
```

Even though you deleted both the StatefulSet and the web-0 Pod, it still serves the hostname originally entered into its `index.html` file. This is because the StatefulSet never deletes the PersistentVolumes associated with a Pod. When you recreated the StatefulSet and it relaunched web-0, its original PersistentVolume was remounted.

Cascading delete

In one terminal window, watch the Pods in the StatefulSet.

```
# Leave this running until the next page section
kubectl get pods --watch -l app=nginx
```

In another terminal, delete the StatefulSet again. This time, omit the `--cascade=orphan` parameter.

```
kubectl delete statefulset web
```

```
statefulset.apps "web" deleted
```

Examine the output of the `kubectl get` command running in the first terminal, and wait for all of the Pods to transition to Terminating.

```
# This should already be running
kubectl get pods --watch -l app=nginx
```

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|---------|----------|-----|
| web-0 | 1/1 | Running | 0 | 11m |
| web-1 | 1/1 | Running | 0 | 27m |

| NAME | READY | STATUS | RESTARTS | AGE |
|-------|-------|-------------|----------|-----|
| web-0 | 1/1 | Terminating | 0 | 12m |
| web-1 | 1/1 | Terminating | 0 | 29m |
| web-0 | 0/1 | Terminating | 0 | 12m |
| web-0 | 0/1 | Terminating | 0 | 12m |
| web-0 | 0/1 | Terminating | 0 | 12m |
| web-1 | 0/1 | Terminating | 0 | 29m |
| web-1 | 0/1 | Terminating | 0 | 29m |
| web-1 | 0/1 | Terminating | 0 | 29m |

As you saw in the [Scaling Down](#) section, the Pods are terminated one at a time, with respect to the reverse order of their ordinal indices. Before terminating a Pod, the StatefulSet controller waits for the Pod's successor to be completely terminated.

Note:

Although a cascading delete removes a StatefulSet together with its Pods, the cascade does **not** delete the headless Service associated with the StatefulSet. You must delete the nginx Service manually.

```
kubectl delete service nginx
```

```
service "nginx" deleted
```

Recreate the StatefulSet and headless Service one more time:

```
kubectl apply -f https://k8s.io/examples/application/web/web.yaml
```

```
service/nginx created
statefulset.apps/web created
```

When all of the StatefulSet's Pods transition to Running and Ready, retrieve the contents of their index.html files:

```
for i in 0 1; do kubectl exec -i -t "web-$i" -- curl http://localhost/; done
```

```
web-0
web-1
```

Even though you completely deleted the StatefulSet, and all of its Pods, the Pods are recreated with their PersistentVolumes mounted, and web-0 and web-1 continue to serve their hostnames.

Finally, delete the nginx Service...

```
kubectl delete service nginx
```

```
service "nginx" deleted
```

...and the web StatefulSet:

```
kubectrl delete statefulset web
```

```
statefulset "web" deleted
```

Pod management policy

For some distributed systems, the StatefulSet ordering guarantees are unnecessary and/or undesirable. These systems require only uniqueness and identity.

You can specify a [Pod management policy](#) to avoid this strict ordering; either OrderedReady (the default), or Parallel.

OrderedReady Pod management

OrderedReady pod management is the default for StatefulSets. It tells the StatefulSet controller to respect the ordering guarantees demonstrated above.

Use this when your application requires or expects that changes, such as rolling out a new version of your application, happen in the strict order of the ordinal (pod number) that the StatefulSet provides. In other words, if you have Pods app-0, app-1 and app-2, Kubernetes will update app-0 first and check it. Once the checks are good, Kubernetes updates app-1 and finally app-2.

If you added two more Pods, Kubernetes would set up app-3 and wait for that to become healthy before deploying app-4.

Because this is the default setting, you've already practised using it.

Parallel Pod management

The alternative, Parallel pod management, tells the StatefulSet controller to launch or terminate all Pods in parallel, and not to wait for Pods to become Running and Ready or completely terminated prior to launching or terminating another Pod.

The Parallel pod management option only affects the behavior for scaling operations. Updates are not affected; Kubernetes still rolls out changes in order. For this tutorial, the application is very simple: a webserver that tells you its hostname (because this is a StatefulSet, the hostname for each Pod is different and predictable).

[application/web/web-parallel.yaml](#)

```
apiVersion: v1
kind: Service
metadata:
  name: nginx
  labels:
    app: nginx
spec:
  ports:
    - port: 80
    name: web
```

```

clusterIP: None
selector:
  app: nginx
---
apiVersion: apps/v1
kind: StatefulSet
metadata:
  name: web
spec:
  serviceName: "nginx"
  podManagementPolicy: "Parallel"
  replicas: 2
  selector:
    matchLabels:
      app: nginx
  template:
    metadata:
      labels:
        app: nginx
    spec:
      containers:
        - name: nginx
          image: registry.k8s.io/nginx-slim:0.8
          ports:
            - containerPort: 80
              name: web
          volumeMounts:
            - name: www
              mountPath: /usr/share/nginx/html
      volumeClaimTemplates:
        - metadata:
            name: www
          spec:
            accessModes: [ "ReadWriteOnce" ]
            resources:
              requests:
                storage: 1Gi

```

This manifest is identical to the one you downloaded above except that the `.spec.podManagementPolicy` of the web StatefulSet is set to Parallel.

In one terminal, watch the Pods in the StatefulSet.

```
# Leave this watch running until the end of the section
kubectl get pod -l app=nginx --watch
```

In another terminal, reconfigure the StatefulSet for Parallel Pod management:

```
kubectl apply -f https://k8s.io/examples/application/web/web-parallel.yaml
```

```
service/nginx updated
statefulset.apps/web updated
```

Keep the terminal open where you're running the watch. In another terminal window, scale the StatefulSet:

```
kubectl scale statefulset/web --replicas=5
```

```
statefulset.apps/web scaled
```

Examine the output of the terminal where the `kubectl get` command is running. It may look something like

```
web-3    0/1    Pending 0    0s
web-3    0/1    Pending 0    0s
web-3    0/1    Pending 0    7s
web-3    0/1    ContainerCreating 0    7s
web-2    0/1    Pending 0    0s
web-4    0/1    Pending 0    0s
web-2    1/1    Running 0    8s
web-4    0/1    ContainerCreating 0    4s
web-3    1/1    Running 0    26s
web-4    1/1    Running 0    2s
```

The StatefulSet launched three new Pods, and it did not wait for the first to become Running and Ready prior to launching the second and third Pods.

This approach is useful if your workload has a stateful element, or needs Pods to be able to identify each other with predictable naming, and especially if you sometimes need to provide a lot more capacity quickly. If this simple web service for the tutorial suddenly got an extra 1,000,000 requests per minute then you would want to run some more Pods - but you also would not want to wait for each new Pod to launch. Starting the extra Pods in parallel cuts the time between requesting the extra capacity and having it available for use.

Cleaning up

You should have two terminals open, ready for you to run `kubectl` commands as part of cleanup.

```
kubectl delete sts web
# sts is an abbreviation for statefulset
```

You can watch `kubectl get` to see those Pods being deleted.

```
# end the watch when you've seen what you need to
kubectl get pod -l app=nginx --watch
```

```
web-3    1/1    Terminating 0    9m
web-2    1/1    Terminating 0    9m
web-3    1/1    Terminating 0    9m
web-2    1/1    Terminating 0    9m
web-1    1/1    Terminating 0    44m
web-0    1/1    Terminating 0    44m
web-0    0/1    Terminating 0    44m
web-3    0/1    Terminating 0    9m
web-2    0/1    Terminating 0    9m
```

| | | | | |
|-------|-----|-------------|---|-----|
| web-1 | 0/1 | Terminating | 0 | 44m |
| web-0 | 0/1 | Terminating | 0 | 44m |
| web-2 | 0/1 | Terminating | 0 | 9m |
| web-2 | 0/1 | Terminating | 0 | 9m |
| web-2 | 0/1 | Terminating | 0 | 9m |
| web-1 | 0/1 | Terminating | 0 | 44m |
| web-1 | 0/1 | Terminating | 0 | 44m |
| web-1 | 0/1 | Terminating | 0 | 44m |
| web-0 | 0/1 | Terminating | 0 | 44m |
| web-0 | 0/1 | Terminating | 0 | 44m |
| web-0 | 0/1 | Terminating | 0 | 44m |
| web-3 | 0/1 | Terminating | 0 | 9m |
| web-3 | 0/1 | Terminating | 0 | 9m |
| web-3 | 0/1 | Terminating | 0 | 9m |

During deletion, a StatefulSet removes all Pods concurrently; it does not wait for a Pod's ordinal successor to terminate prior to deleting that Pod.

Close the terminal where the `kubectl get` command is running and delete the `nginx` Service:

```
kubectl delete svc nginx
```

Delete the persistent storage media for the PersistentVolumes used in this tutorial.

```
kubectl get pvc
```

| NAME | STATUS | VOLUME | CAPACITY | ACCESS MODES |
|--------------|--------|--|----------|--------------|
| STORAGECLASS | AGE | | | |
| www-web-0 | Bound | pvc-2bf00408-d366-4a12-bad0-1869c65d0bee | 1Gi | RWO |

```

```
persistentvolumeclaim "www-web-0" deleted  
persistentvolumeclaim "www-web-1" deleted  
persistentvolumeclaim "www-web-2" deleted  
persistentvolumeclaim "www-web-3" deleted  
persistentvolumeclaim "www-web-4" deleted
```

```
kubectl get pvc
```

No resources found in default namespace.

Note:

You also need to delete the persistent storage media for the PersistentVolumes used in this tutorial. Follow the necessary steps, based on your environment, storage configuration, and provisioning method, to ensure that all storage is reclaimed.

Example: Deploying WordPress and MySQL with Persistent Volumes

This tutorial shows you how to deploy a WordPress site and a MySQL database using Minikube. Both applications use PersistentVolumes and PersistentVolumeClaims to store data.

A [PersistentVolume](#) (PV) is a piece of storage in the cluster that has been manually provisioned by an administrator, or dynamically provisioned by Kubernetes using a [StorageClass](#). A [PersistentVolumeClaim](#) (PVC) is a request for storage by a user that can be fulfilled by a PV. PersistentVolumes and PersistentVolumeClaims are independent from Pod lifecycles and preserve data through restarting, rescheduling, and even deleting Pods.

Warning:

This deployment is not suitable for production use cases, as it uses single instance WordPress and MySQL Pods. Consider using [WordPress Helm Chart](#) to deploy WordPress in production.

Note:

The files provided in this tutorial are using GA Deployment APIs and are specific to Kubernetes version 1.9 and later. If you wish to use this tutorial with an earlier version of Kubernetes, please update the API version appropriately, or reference earlier versions of this tutorial.

Objectives

- Create PersistentVolumeClaims and PersistentVolumes
- Create a kustomization.yaml with
 - a Secret generator
 - MySQL resource configs
 - WordPress resource configs
- Apply the kustomization directory by `kubectl apply -k ./`

- Clean up

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To check the version, enter `kubectl version`.

The example shown on this page works with kubectl 1.27 and above.

Download the following configuration files:

1. [mysql-deployment.yaml](#)
2. [wordpress-deployment.yaml](#)

Create PersistentVolumeClaims and PersistentVolumes

MySQL and Wordpress each require a PersistentVolume to store data. Their PersistentVolumeClaims will be created at the deployment step.

Many cluster environments have a default StorageClass installed. When a StorageClass is not specified in the PersistentVolumeClaim, the cluster's default StorageClass is used instead.

When a PersistentVolumeClaim is created, a PersistentVolume is dynamically provisioned based on the StorageClass configuration.

Warning:

In local clusters, the default StorageClass uses the `hostPath` provisioner. `hostPath` volumes are only suitable for development and testing. With `hostPath` volumes, your data lives in `/tmp` on the node the Pod is scheduled onto and does not move between nodes. If a Pod dies and gets scheduled to another node in the cluster, or the node is rebooted, the data is lost.

Note:

If you are bringing up a cluster that needs to use the `hostPath` provisioner, the `--enable-hostpath-provisioner` flag must be set in the controller-manager component.

Note:

If you have a Kubernetes cluster running on Google Kubernetes Engine, please follow [this guide](#).

Create a kustomization.yaml

Add a Secret generator

A [Secret](#) is an object that stores a piece of sensitive data like a password or key. Since 1.14, kubectl supports the management of Kubernetes objects using a kustomization file. You can create a Secret by generators in kustomization.yaml.

Add a Secret generator in kustomization.yaml from the following command. You will need to replace YOUR_PASSWORD with the password you want to use.

```
cat <<EOF >./kustomization.yaml
secretGenerator:
- name: mysql-pass
  literals:
  - password=YOUR_PASSWORD
EOF
```

Add resource configs for MySQL and WordPress

The following manifest describes a single-instance MySQL Deployment. The MySQL container mounts the PersistentVolume at /var/lib/mysql. The MYSQL_ROOT_PASSWORD environment variable sets the database password from the Secret.

[application/wordpress/mysql-deployment.yaml](#)

```
apiVersion: v1
kind: Service
metadata:
  name: wordpress-mysql
  labels:
    app: wordpress
spec:
  ports:
    - port: 3306
  selector:
    app: wordpress
    tier: mysql
  clusterIP: None
---
apiVersion: v1
kind: PersistentVolumeClaim
metadata:
  name: mysql-pv-claim
  labels:
    app: wordpress
spec:
  accessModes:
    - ReadWriteOnce
  resources:
    requests:
      storage: 20Gi
```

```

---
apiVersion: apps/v1
kind: Deployment
metadata:
  name: wordpress-mysql
  labels:
    app: wordpress
spec:
  selector:
    matchLabels:
      app: wordpress
      tier: mysql
  strategy:
    type: Recreate
  template:
    metadata:
      labels:
        app: wordpress
        tier: mysql
    spec:
      containers:
        - image: mysql:8.0
          name: mysql
          env:
            - name: MYSQL_ROOT_PASSWORD
              valueFrom:
                secretKeyRef:
                  name: mysql-pass
                  key: password
            - name: MYSQL_DATABASE
              value: wordpress
            - name: MYSQL_USER
              value: wordpress
            - name: MYSQL_PASSWORD
              valueFrom:
                secretKeyRef:
                  name: mysql-pass
                  key: password
          ports:
            - containerPort: 3306
              name: mysql
          volumeMounts:
            - name: mysql-persistent-storage
              mountPath: /var/lib/mysql
      volumes:
        - name: mysql-persistent-storage
          persistentVolumeClaim:
            claimName: mysql-pv-claim

```

The following manifest describes a single-instance WordPress Deployment. The WordPress container mounts the PersistentVolume at `/var/www/html` for website data files. The `WORDPRESS_DB_HOST` environment variable sets the name of the MySQL Service defined

above, and WordPress will access the database by Service. The WORDPRESS_DB_PASSWORD environment variable sets the database password from the Secret kustomize generated.

[application/wordpress/wordpress-deployment.yaml](#)

```
apiVersion: v1
kind: Service
metadata:
  name: wordpress
  labels:
    app: wordpress
spec:
  ports:
    - port: 80
  selector:
    app: wordpress
    tier: frontend
  type: LoadBalancer
---
apiVersion: v1
kind: PersistentVolumeClaim
metadata:
  name: wp-pv-claim
  labels:
    app: wordpress
spec:
  accessModes:
    - ReadWriteOnce
  resources:
    requests:
      storage: 20Gi
---
apiVersion: apps/v1
kind: Deployment
metadata:
  name: wordpress
  labels:
    app: wordpress
spec:
  selector:
    matchLabels:
      app: wordpress
      tier: frontend
  strategy:
    type: Recreate
  template:
    metadata:
      labels:
        app: wordpress
        tier: frontend
    spec:
      containers:
        - image: wordpress:6.2.1-apache
```

```

name: wordpress
env:
- name: WORDPRESS_DB_HOST
  value: wordpress-mysql
- name: WORDPRESS_DB_PASSWORD
  valueFrom:
    secretKeyRef:
      name: mysql-pass
      key: password
- name: WORDPRESS_DB_USER
  value: wordpress
ports:
- containerPort: 80
  name: wordpress
volumeMounts:
- name: wordpress-persistent-storage
  mountPath: /var/www/html
volumes:
- name: wordpress-persistent-storage
  persistentVolumeClaim:
    claimName: wp-pv-claim

```

1. Download the MySQL deployment configuration file.

```
curl -LO https://k8s.io/examples/application/wordpress/mysql-deployment.yaml
```

2. Download the WordPress configuration file.

```
curl -LO https://k8s.io/examples/application/wordpress/wordpress-deployment.yaml
```

3. Add them to kustomization.yaml file.

```

cat <<EOF >>./kustomization.yaml
resources:
- mysql-deployment.yaml
- wordpress-deployment.yaml
EOF

```

Apply and Verify

The kustomization.yaml contains all the resources for deploying a WordPress site and a MySQL database. You can apply the directory by

```
kubectl apply -k ./
```

Now you can verify that all objects exist.

1. Verify that the Secret exists by running the following command:

```
kubectl get secrets
```

The response should be like this:

| NAME | TYPE | DATA | AGE |
|-----------------------|--------|------|-----|
| mysql-pass-c57bb4t7mf | Opaque | 1 | 9s |

2. Verify that a PersistentVolume got dynamically provisioned.

```
kubectl get pvc
```

Note:

It can take up to a few minutes for the PVs to be provisioned and bound.

The response should be like this:

| NAME | STATUS | VOLUME | CAPACITY | ACCESS MODES |
|----------------|----------|--|----------|--------------|
| STORAGECLASS | AGE | | | |
| mysql-pv-claim | Bound | pvc-8cbd7b2e-4044-11e9-b2bb-42010a800002 | 20Gi | |
| RWO | standard | 77s | | |
| wp-pv-claim | Bound | pvc-8cd0df54-4044-11e9-b2bb-42010a800002 | 20Gi | |
| RWO | standard | 77s | | |

3. Verify that the Pod is running by running the following command:

```
kubectl get pods
```

Note:

It can take up to a few minutes for the Pod's Status to be RUNNING.

The response should be like this:

| NAME | READY | STATUS | RESTARTS | AGE |
|----------------------------------|-------|---------|----------|-----|
| wordpress-mysql-1894417608-x5dzt | 1/1 | Running | 0 | 40s |

4. Verify that the Service is running by running the following command:

```
kubectl get services wordpress
```

The response should be like this:

| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE |
|-----------|--------------|------------|-------------|--------------|-----|
| wordpress | LoadBalancer | 10.0.0.89 | <pending> | 80:32406/TCP | 4m |

Note:

Minikube can only expose Services through NodePort. The EXTERNAL-IP is always pending.

5. Run the following command to get the IP Address for the WordPress Service:

```
minikube service wordpress --url
```

The response should be like this:

```
http://1.2.3.4:32406
```

- Copy the IP address, and load the page in your browser to view your site.
6. You should see the WordPress set up page similar to the following screenshot.

Warning:

Do not leave your WordPress installation on this page. If another user finds it, they can set up a website on your instance and use it to serve malicious content.

Either install WordPress by creating a username and password or delete your instance.

Cleaning up

1. Run the following command to delete your Secret, Deployments, Services and PersistentVolumeClaims:

```
kubectrl delete -k ./
```

What's next

- Learn more about [Introspection and Debugging](#)
- Learn more about [Jobs](#)
- Learn more about [Port Forwarding](#)
- Learn how to [Get a Shell to a Container](#)

Example: Deploying Cassandra with a StatefulSet

This tutorial shows you how to run [Apache Cassandra](#) on Kubernetes. Cassandra, a database, needs persistent storage to provide data durability (application *state*). In this example, a custom Cassandra seed provider lets the database discover new Cassandra instances as they join the Cassandra cluster.

StatefulSets make it easier to deploy stateful applications into your Kubernetes cluster. For more information on the features used in this tutorial, see [StatefulSet](#).

Note:

Cassandra and Kubernetes both use the term *node* to mean a member of a cluster. In this tutorial, the Pods that belong to the StatefulSet are Cassandra nodes and are members of the Cassandra cluster (called a *ring*). When those Pods run in your Kubernetes cluster, the Kubernetes control plane schedules those Pods onto Kubernetes [Nodes](#).

When a Cassandra node starts, it uses a *seed list* to bootstrap discovery of other nodes in the ring. This tutorial deploys a custom Cassandra seed provider that lets the database discover new Cassandra Pods as they appear inside your Kubernetes cluster.

Objectives

- Create and validate a Cassandra headless [Service](#).
- Use a [StatefulSet](#) to create a Cassandra ring.
- Validate the StatefulSet.

- Modify the StatefulSet.
- Delete the StatefulSet and its [Pods](#).

Before you begin

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

To complete this tutorial, you should already have a basic familiarity with [Pods](#), [Services](#), and [StatefulSets](#).

Additional Minikube setup instructions

Caution:

[Minikube](#) defaults to 2048MB of memory and 2 CPU. Running Minikube with the default resource configuration results in insufficient resource errors during this tutorial. To avoid these errors, start Minikube with the following settings:

```
minikube start --memory 5120 --cpus=4
```

Creating a headless Service for Cassandra

In Kubernetes, a [Service](#) describes a set of [Pods](#) that perform the same task.

The following Service is used for DNS lookups between Cassandra Pods and clients within your cluster:

[application/cassandra/cassandra-service.yaml](#)

```
apiVersion: v1
kind: Service
metadata:
  labels:
    app: cassandra
    name: cassandra
spec:
  clusterIP: None
  ports:
    - port: 9042
  selector:
    app: cassandra
```

Create a Service to track all Cassandra StatefulSet members from the cassandra-service.yaml file:

```
kubectl apply -f https://k8s.io/examples/application/cassandra/cassandra-service.yaml
```

Validating (optional)

Get the Cassandra Service.

```
kubectl get svc cassandra
```

The response is

| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE |
|-----------|-----------|------------|-------------|----------|-----|
| cassandra | ClusterIP | None | <none> | 9042/TCP | 45s |

If you don't see a Service named cassandra, that means creation failed. Read [Debug Services](#) for help troubleshooting common issues.

Using a StatefulSet to create a Cassandra ring

The StatefulSet manifest, included below, creates a Cassandra ring that consists of three Pods.

Note:

This example uses the default provisioner for Minikube. Please update the following StatefulSet for the cloud you are working with.

[application/cassandra/cassandra-statefulset.yaml](#)

```
apiVersion: apps/v1
kind: StatefulSet
metadata:
  name: cassandra
  labels:
    app: cassandra
spec:
  serviceName: cassandra
  replicas: 3
  selector:
    matchLabels:
      app: cassandra
  template:
    metadata:
      labels:
        app: cassandra
    spec:
      terminationGracePeriodSeconds: 1800
      containers:
        - name: cassandra
          image: gcr.io/google-samples/cassandra:v13
          imagePullPolicy: Always
          ports:
            - containerPort: 7000
              name: intra-node
            - containerPort: 7001
              name: tls-intra-node
            - containerPort: 7199
```

```

    name: jmx
  - containerPort: 9042
    name: cql
resources:
  limits:
    cpu: "500m"
    memory: 1Gi
  requests:
    cpu: "500m"
    memory: 1Gi
securityContext:
  capabilities:
    add:
      - IPC_LOCK
lifecycle:
  preStop:
    exec:
      command:
        - /bin/sh
        - -c
        - nodetool drain
env:
  - name: MAX_HEAP_SIZE
    value: 512M
  - name: HEAP_NEWSIZE
    value: 100M
  - name: CASSANDRA_SEEDS
    value: "cassandra-0.cassandra.default.svc.cluster.local"
  - name: CASSANDRA_CLUSTER_NAME
    value: "K8Demo"
  - name: CASSANDRA_DC
    value: "DC1-K8Demo"
  - name: CASSANDRA_RACK
    value: "Rack1-K8Demo"
  - name: POD_IP
    valueFrom:
      fieldRef:
        fieldPath: status.podIP
readinessProbe:
  exec:
    command:
      - /bin/bash
      - -c
      - /ready-probe.sh
  initialDelaySeconds: 15
  timeoutSeconds: 5
# These volume mounts are persistent. They are like inline claims,
# but not exactly because the names need to match exactly one of
# the stateful pod volumes.
volumeMounts:
  - name: cassandra-data
    mountPath: /cassandra_data
# These are converted to volume claims by the controller

```

```
# and mounted at the paths mentioned above.
# do not use these in production until ssd GCEPersistentDisk or other ssd pd
volumeClaimTemplates:
- metadata:
  name: cassandra-data
spec:
  accessModes: [ "ReadWriteOnce" ]
  storageClassName: fast
  resources:
    requests:
      storage: 1Gi
---
kind: StorageClass
apiVersion: storage.k8s.io/v1
metadata:
  name: fast
provisioner: k8s.io/minikube-hostpath
parameters:
  type: pd-ssd
```

Create the Cassandra StatefulSet from the `cassandra-statefulset.yaml` file:

```
# Use this if you are able to apply cassandra-statefulset.yaml unmodified
kubectl apply -f https://k8s.io/examples/application/cassandra/cassandra-statefulset.yaml
```

If you need to modify `cassandra-statefulset.yaml` to suit your cluster, download <https://k8s.io/examples/application/cassandra/cassandra-statefulset.yaml> and then apply that manifest, from the folder you saved the modified version into:

```
# Use this if you needed to modify cassandra-statefulset.yaml locally
kubectl apply -f cassandra-statefulset.yaml
```

Validating the Cassandra StatefulSet

1. Get the Cassandra StatefulSet:

```
kubectl get statefulset cassandra
```

The response should be similar to:

| NAME | DESIRED | CURRENT | AGE |
|-----------|---------|---------|-----|
| cassandra | 3 | 0 | 13s |

The StatefulSet resource deploys Pods sequentially.

2. Get the Pods to see the ordered creation status:

```
kubectl get pods -l="app=cassandra"
```

The response should be similar to:

| NAME | READY | STATUS | RESTARTS | AGE |
|-------------|-------|-------------------|----------|-----|
| cassandra-0 | 1/1 | Running | 0 | 1m |
| cassandra-1 | 0/1 | ContainerCreating | 0 | 8s |

It can take several minutes for all three Pods to deploy. Once they are deployed, the same command returns output similar to:

| NAME | READY | STATUS | RESTARTS | AGE |
|-------------|-------|---------|----------|-----|
| cassandra-0 | 1/1 | Running | 0 | 10m |
| cassandra-1 | 1/1 | Running | 0 | 9m |
| cassandra-2 | 1/1 | Running | 0 | 8m |

3. Run the Cassandra [nodetool](#) inside the first Pod, to display the status of the ring.

```
kubectrl exec -it cassandra-0 -- nodetool status
```

The response should look something like:

```
Datacenter: DC1-K8Demo
=====
Status=Up/Down
|/ State=Normal/Leaving/Joining/Moving
-- Address    Load      Tokens     Owns (effective)  Host ID                               Rack
UN 172.17.0.5  83.57 KiB  32         74.0%             e2dd09e6-d9d3-477e-96c5-45094c08db0f  Rack1-K8Demo
UN 172.17.0.4  101.04 KiB 32         58.8%             f89d6835-3a42-4419-92b3-0e62cae1479c  Rack1-K8Demo
UN 172.17.0.6  84.74 KiB  32         67.1%             a6a1e8c2-3dc5-4417-b1a0-26507af2aaad  Rack1-K8Demo
```

Modifying the Cassandra StatefulSet

Use `kubectrl edit` to modify the size of a Cassandra StatefulSet.

1. Run the following command:

```
kubectrl edit statefulset cassandra
```

This command opens an editor in your terminal. The line you need to change is the `replicas` field. The following sample is an excerpt of the StatefulSet file:

```
# Please edit the object below. Lines beginning with a '#' will be ignored,
# and an empty file will abort the edit. If an error occurs while saving this file will be
# reopened with the relevant failures.
#
apiVersion: apps/v1
kind: StatefulSet
metadata:
  creationTimestamp: 2016-08-13T18:40:58Z
  generation: 1
  labels:
    app: cassandra
    name: cassandra
    namespace: default
  resourceVersion: "323"
  uid: 7a219483-6185-11e6-a910-42010a8a0fc0
```

```
spec:
  replicas: 3
```

2. Change the number of replicas to 4, and then save the manifest.

The StatefulSet now scales to run with 4 Pods.

3. Get the Cassandra StatefulSet to verify your change:

```
kubectl get statefulset cassandra
```

The response should be similar to:

| NAME | DESIRED | CURRENT | AGE |
|-----------|---------|---------|-----|
| cassandra | 4 | 4 | 36m |

Cleaning up

Deleting or scaling a StatefulSet down does not delete the volumes associated with the StatefulSet. This setting is for your safety because your data is more valuable than automatically purging all related StatefulSet resources.

Warning:

Depending on the storage class and reclaim policy, deleting the *PersistentVolumeClaims* may cause the associated volumes to also be deleted. Never assume you'll be able to access data if its volume claims are deleted.

1. Run the following commands (chained together into a single command) to delete everything in the Cassandra StatefulSet:

```
grace=$(kubectl get pod cassandra-0 -o=jsonpath='{.spec.terminationGracePeriodSeconds}') \
&& kubectl delete statefulset -l app=cassandra \
&& echo "Sleeping ${grace} seconds" 1>&2 \
&& sleep $grace \
&& kubectl delete persistentvolumeclaim -l app=cassandra
```

2. Run the following command to delete the Service you set up for Cassandra:

```
kubectl delete service -l app=cassandra
```

Cassandra container environment variables

The Pods in this tutorial use the gcr.io/google-samples/cassandra:v13 image from Google's [container registry](#). The Docker image above is based on [debian-base](#) and includes OpenJDK 8.

This image includes a standard Cassandra installation from the Apache Debian repo. By using environment variables you can change values that are inserted into `cassandra.yaml`.

| Environment variable | Default value |
|------------------------|----------------|
| CASSANDRA_CLUSTER_NAME | 'Test Cluster' |

| Environment variable | Default value |
|-----------------------|---------------|
| CASSANDRA_NUM_TOKENS | 32 |
| CASSANDRA_RPC_ADDRESS | 0.0.0.0 |

What's next

- Learn how to [Scale a StatefulSet](#).
- Learn more about the [KubernetesSeedProvider](#)
- See more custom [Seed Provider Configurations](#)

Running ZooKeeper, A Distributed System Coordinator

This tutorial demonstrates running [Apache Zookeeper](#) on Kubernetes using [StatefulSets](#), [PodDisruptionBudgets](#), and [PodAntiAffinity](#).

Before you begin

Before starting this tutorial, you should be familiar with the following Kubernetes concepts:

- [Pods](#)
- [Cluster DNS](#)
- [Headless Services](#)
- [PersistentVolumes](#)
- [PersistentVolume Provisioning](#)
- [StatefulSets](#)
- [PodDisruptionBudgets](#)
- [PodAntiAffinity](#)
- [kubectl CLI](#)

You must have a cluster with at least four nodes, and each node requires at least 2 CPUs and 4 GiB of memory. In this tutorial you will cordon and drain the cluster's nodes. **This means that the cluster will terminate and evict all Pods on its nodes, and the nodes will temporarily become unschedulable.** You should use a dedicated cluster for this tutorial, or you should ensure that the disruption you cause will not interfere with other tenants.

This tutorial assumes that you have configured your cluster to dynamically provision PersistentVolumes. If your cluster is not configured to do so, you will have to manually provision three 20 GiB volumes before starting this tutorial.

Objectives

After this tutorial, you will know the following.

- How to deploy a ZooKeeper ensemble using StatefulSet.
- How to consistently configure the ensemble.
- How to spread the deployment of ZooKeeper servers in the ensemble.

- How to use `PodDisruptionBudgets` to ensure service availability during planned maintenance.

ZooKeeper

[Apache ZooKeeper](#) is a distributed, open-source coordination service for distributed applications. ZooKeeper allows you to read, write, and observe updates to data. Data are organized in a file system like hierarchy and replicated to all ZooKeeper servers in the ensemble (a set of ZooKeeper servers). All operations on data are atomic and sequentially consistent. ZooKeeper ensures this by using the [Zab](#) consensus protocol to replicate a state machine across all servers in the ensemble.

The ensemble uses the Zab protocol to elect a leader, and the ensemble cannot write data until that election is complete. Once complete, the ensemble uses Zab to ensure that it replicates all writes to a quorum before it acknowledges and makes them visible to clients. Without respect to weighted quorums, a quorum is a majority component of the ensemble containing the current leader. For instance, if the ensemble has three servers, a component that contains the leader and one other server constitutes a quorum. If the ensemble can not achieve a quorum, the ensemble cannot write data.

ZooKeeper servers keep their entire state machine in memory, and write every mutation to a durable WAL (Write Ahead Log) on storage media. When a server crashes, it can recover its previous state by replaying the WAL. To prevent the WAL from growing without bound, ZooKeeper servers will periodically snapshot them in memory state to storage media. These snapshots can be loaded directly into memory, and all WAL entries that preceded the snapshot may be discarded.

Creating a ZooKeeper ensemble

The manifest below contains a [Headless Service](#), a [Service](#), a [PodDisruptionBudget](#), and a [StatefulSet](#).

[application/zookeeper/zookeeper.yaml](#)

```
apiVersion: v1
kind: Service
metadata:
  name: zk-hs
  labels:
    app: zk
spec:

  name: server
- containerPort: 3888
  name: leader-election
command:
- sh
- -c
- "start-zookeeper \
  --servers=3 \
  --data_dir=/var/lib/zookeeper/data \
  --data_log_dir=/var/lib/zookeeper/data/log \
  --conf_dir=/opt/zookeeper/conf \
  --client_port=2181 \
  --election_port=3888 \
  --server_port=2888 \
  --tick_time=2000 \
  --init_limit=10 \
  --sync_limit=5 \
  --heap=512M \
  --max_client_cnxns=60 \
  --snap_retain_count=3 \
  --purge_interval=12 \
  --max_session_timeout=40000 \
  --min_session_timeout=4000 \
  --log_level=INFO"
readinessProbe:
  exec:
    command:
      - sh
      - -c
      - "zookeeper-ready 2181"
  initialDelaySeconds: 10
  timeoutSeconds: 5
livenessProbe:
  exec:
    command:
      - sh
      - -c
      - "zookeeper-ready 2181"
  initialDelaySeconds: 10
  timeoutSeconds: 5
volumeMounts:
- name: datadir
  mountPath: /var/lib/zookeeper
securityContext:
  runAsUser: 1000
```

```

    fsGroup: 1000
  volumeClaimTemplates:
  - metadata:
    name: datadir
    spec:
    accessModes: [ "ReadWriteOnce" ]
    resources:
    requests:
    storage: 10Gi

```

Open a terminal, and use the [kubectl apply](#) command to create the manifest.

```
kubectl apply -f https://k8s.io/examples/application/zookeeper/zookeeper.yaml
```

This creates the zk-hs Headless Service, the zk-cs Service, the zk-pdb PodDisruptionBudget, and the zk StatefulSet.

```

service/zk-hs created
service/zk-cs created
poddisruptionbudget.policy/zk-pdb created
statefulset.apps/zk created

```

Use [kubectl get](#) to watch the StatefulSet controller create the StatefulSet's Pods.

```
kubectl get pods -w -l app=zk
```

Once the zk-2 Pod is Running and Ready, use CTRL-C to terminate kubectl.

| NAME | READY | STATUS | RESTARTS | AGE |
|------|-------|-------------------|----------|-----|
| zk-0 | 0/1 | Pending | 0 | 0s |
| zk-0 | 0/1 | Pending | 0 | 0s |
| zk-0 | 0/1 | ContainerCreating | 0 | 0s |
| zk-0 | 0/1 | Running | 0 | 19s |
| zk-0 | 1/1 | Running | 0 | 40s |
| zk-1 | 0/1 | Pending | 0 | 0s |
| zk-1 | 0/1 | Pending | 0 | 0s |
| zk-1 | 0/1 | ContainerCreating | 0 | 0s |
| zk-1 | 0/1 | Running | 0 | 18s |
| zk-1 | 1/1 | Running | 0 | 40s |
| zk-2 | 0/1 | Pending | 0 | 0s |
| zk-2 | 0/1 | Pending | 0 | 0s |
| zk-2 | 0/1 | ContainerCreating | 0 | 0s |
| zk-2 | 0/1 | Running | 0 | 19s |
| zk-2 | 1/1 | Running | 0 | 40s |

The StatefulSet controller creates three Pods, and each Pod has a container with a [ZooKeeper](#) server.

Facilitating leader election

Because there is no terminating algorithm for electing a leader in an anonymous network, Zab requires explicit membership configuration to perform leader election. Each server in the ensemble needs to have a unique identifier, all servers need to know the global set of identifiers, and each identifier needs to be associated with a network address.

Use [kubectl exec](#) to get the hostnames of the Pods in the zk StatefulSet.

```
for i in 0 1 2; do kubectl exec zk-$i -- hostname; done
```

The StatefulSet controller provides each Pod with a unique hostname based on its ordinal index. The hostnames take the form of <statefulset name>-<ordinal index>. Because the replicas field of the zk StatefulSet is set to 3, the Set's controller creates three Pods with their hostnames set to zk-0, zk-1, and zk-2.

```
zk-0
zk-1
zk-2
```

The servers in a ZooKeeper ensemble use natural numbers as unique identifiers, and store each server's identifier in a file called myid in the server's data directory.

To examine the contents of the myid file for each server use the following command.

```
for i in 0 1 2; do echo "myid zk-$i"; kubectl exec zk-$i -- cat /var/lib/zookeeper/data/myid; done
```

Because the identifiers are natural numbers and the ordinal indices are non-negative integers, you can generate an identifier by adding 1 to the ordinal.

```
myid zk-0
1
myid zk-1
2
myid zk-2
3
```

To get the Fully Qualified Domain Name (FQDN) of each Pod in the zk StatefulSet use the following command.

```
for i in 0 1 2; do kubectl exec zk-$i -- hostname -f; done
```

The zk-hs Service creates a domain for all of the Pods, zk-hs.default.svc.cluster.local.

```
zk-0.zk-hs.default.svc.cluster.local
zk-1.zk-hs.default.svc.cluster.local
zk-2.zk-hs.default.svc.cluster.local
```

The A records in [Kubernetes DNS](#) resolve the FQDNs to the Pods' IP addresses. If Kubernetes reschedules the Pods, it will update the A records with the Pods' new IP addresses, but the A records names will not change.

ZooKeeper stores its application configuration in a file named zoo.cfg. Use kubectl exec to view the contents of the zoo.cfg file in the zk-0 Pod.

```
kubectl exec zk-0 -- cat /opt/zookeeper/conf/zoo.cfg
```

In the server.1, server.2, and server.3 properties at the bottom of the file, the 1, 2, and 3 correspond to the identifiers in the ZooKeeper servers' myid files. They are set to the FQDNs for the Pods in the zk StatefulSet.

```
clientPort=2181
dataDir=/var/lib/zookeeper/data
dataLogDir=/var/lib/zookeeper/log
tickTime=2000
initLimit=10
syncLimit=2000
maxClientCnxns=60
minSessionTimeout= 4000
maxSessionTimeout= 40000
autopurge.snapRetainCount=3
autopurge.purgeInterval=0
server.1=zk-0.zk-hs.default.svc.cluster.local:2888:3888
server.2=zk-1.zk-hs.default.svc.cluster.local:2888:3888
server.3=zk-2.zk-hs.default.svc.cluster.local:2888:3888
```

Achieving consensus

Consensus protocols require that the identifiers of each participant be unique. No two participants in the Zab protocol should claim the same unique identifier. This is necessary to allow the processes in the system to agree on which processes have committed which data. If two Pods are launched with the same ordinal, two ZooKeeper servers would both identify themselves as the same server.

```
kubectll get pods -w -l app=zk
```

| NAME | READY | STATUS | RESTARTS | AGE |
|------|-------|-------------------|----------|-----|
| zk-0 | 0/1 | Pending | 0 | 0s |
| zk-0 | 0/1 | Pending | 0 | 0s |
| zk-0 | 0/1 | ContainerCreating | 0 | 0s |
| zk-0 | 0/1 | Running | 0 | 19s |
| zk-0 | 1/1 | Running | 0 | 40s |
| zk-1 | 0/1 | Pending | 0 | 0s |
| zk-1 | 0/1 | Pending | 0 | 0s |
| zk-1 | 0/1 | ContainerCreating | 0 | 0s |
| zk-1 | 0/1 | Running | 0 | 18s |
| zk-1 | 1/1 | Running | 0 | 40s |
| zk-2 | 0/1 | Pending | 0 | 0s |
| zk-2 | 0/1 | Pending | 0 | 0s |
| zk-2 | 0/1 | ContainerCreating | 0 | 0s |
| zk-2 | 0/1 | Running | 0 | 19s |
| zk-2 | 1/1 | Running | 0 | 40s |

The A records for each Pod are entered when the Pod becomes Ready. Therefore, the FQDNs of the ZooKeeper servers will resolve to a single endpoint, and that endpoint will be the unique ZooKeeper server claiming the identity configured in its myid file.

```
zk-0.zk-hs.default.svc.cluster.local
zk-1.zk-hs.default.svc.cluster.local
zk-2.zk-hs.default.svc.cluster.local
```

This ensures that the servers properties in the ZooKeepers' zoo.cfg files represents a correctly configured ensemble.

```
server.1=zk-0.zk-hs.default.svc.cluster.local:2888:3888
server.2=zk-1.zk-hs.default.svc.cluster.local:2888:3888
server.3=zk-2.zk-hs.default.svc.cluster.local:2888:3888
```

When the servers use the Zab protocol to attempt to commit a value, they will either achieve consensus and commit the value (if leader election has succeeded and at least two of the Pods are Running and Ready), or they will fail to do so (if either of the conditions are not met). No state will arise where one server acknowledges a write on behalf of another.

Sanity testing the ensemble

The most basic sanity test is to write data to one ZooKeeper server and to read the data from another.

The command below executes the `zkCli.sh` script to write `world` to the path `/hello` on the `zk-0` Pod in the ensemble.

```
kubectrl exec zk-0 -- zkCli.sh create /hello world
```

WATCHER::

```
WatchedEvent state:SyncConnected type:None path:null
Created /hello
```

To get the data from the `zk-1` Pod use the following command.

```
kubectrl exec zk-1 -- zkCli.sh get /hello
```

The data that you created on `zk-0` is available on all the servers in the ensemble.

WATCHER::

```
WatchedEvent state:SyncConnected type:None path:null
world
cZxid = 0x100000002
ctime = Thu Dec 08 15:13:30 UTC 2016
mZxid = 0x100000002
mtime = Thu Dec 08 15:13:30 UTC 2016
pZxid = 0x100000002
cversion = 0
dataVersion = 0
aclVersion = 0
ephemeralOwner = 0x0
dataLength = 5
numChildren = 0
```

Providing durable storage

As mentioned in the [ZooKeeper Basics](#) section, ZooKeeper commits all entries to a durable WAL, and periodically writes snapshots in memory state, to storage media. Using WALs to provide durability is a common technique for applications that use consensus protocols to achieve a replicated state machine.

Use the [kubectl delete](#) command to delete the zk StatefulSet.

```
kubectl delete statefulset zk
```

```
statefulset.apps "zk" deleted
```

Watch the termination of the Pods in the StatefulSet.

```
kubectl get pods -w -l app=zk
```

When zk-0 is fully terminated, use CTRL-C to terminate kubectl.

```
zk-2  1/1  Terminating  0    9m
zk-0  1/1  Terminating  0   11m
zk-1  1/1  Terminating  0   10m
zk-2  0/1  Terminating  0    9m
zk-2  0/1  Terminating  0    9m
zk-2  0/1  Terminating  0    9m
zk-1  0/1  Terminating  0   10m
zk-1  0/1  Terminating  0   10m
zk-1  0/1  Terminating  0   10m
zk-0  0/1  Terminating  0   11m
zk-0  0/1  Terminating  0   11m
zk-0  0/1  Terminating  0   11m
```

Reapply the manifest in zookeeper.yaml.

```
kubectl apply -f https://k8s.io/examples/application/zookeeper/zookeeper.yaml
```

This creates the zk StatefulSet object, but the other API objects in the manifest are not modified because they already exist.

Watch the StatefulSet controller recreate the StatefulSet's Pods.

```
kubectl get pods -w -l app=zk
```

Once the zk-2 Pod is Running and Ready, use CTRL-C to terminate kubectl.

| NAME | READY | STATUS | RESTARTS | AGE |
|------|-------|-------------------|----------|-----|
| zk-0 | 0/1 | Pending | 0 | 0s |
| zk-0 | 0/1 | Pending | 0 | 0s |
| zk-0 | 0/1 | ContainerCreating | 0 | 0s |
| zk-0 | 0/1 | Running | 0 | 19s |
| zk-0 | 1/1 | Running | 0 | 40s |
| zk-1 | 0/1 | Pending | 0 | 0s |
| zk-1 | 0/1 | Pending | 0 | 0s |
| zk-1 | 0/1 | ContainerCreating | 0 | 0s |
| zk-1 | 0/1 | Running | 0 | 18s |
| zk-1 | 1/1 | Running | 0 | 40s |
| zk-2 | 0/1 | Pending | 0 | 0s |
| zk-2 | 0/1 | Pending | 0 | 0s |
| zk-2 | 0/1 | ContainerCreating | 0 | 0s |
| zk-2 | 0/1 | Running | 0 | 19s |
| zk-2 | 1/1 | Running | 0 | 40s |

Use the command below to get the value you entered during the [sanity test](#), from the zk-2 Pod.

```
kubectl exec zk-2 zkCli.sh get /hello
```

Even though you terminated and recreated all of the Pods in the zk StatefulSet, the ensemble still serves the original value.

WATCHER::

```
WatchedEvent state:SyncConnected type:None path:null
world
cZxid = 0x1000000002
ctime = Thu Dec 08 15:13:30 UTC 2016
mZxid = 0x1000000002
mtime = Thu Dec 08 15:13:30 UTC 2016
pZxid = 0x1000000002
cversion = 0
dataVersion = 0
aclVersion = 0
ephemeralOwner = 0x0
dataLength = 5
numChildren = 0
```

The volumeClaimTemplates field of the zk StatefulSet's spec specifies a PersistentVolume provisioned for each Pod.

```
volumeClaimTemplates:
- metadata:
  name: datadir
  annotations:
    volume.alpha.kubernetes.io/storage-class: anything
  spec:
    accessModes: [ "ReadWriteOnce" ]
    resources:
      requests:
        storage: 20Gi
```

The StatefulSet controller generates a PersistentVolumeClaim for each Pod in the StatefulSet.

Use the following command to get the StatefulSet's PersistentVolumeClaims.

```
kubectl get pvc -l app=zk
```

When the StatefulSet recreated its Pods, it remounts the Pods' PersistentVolumes.

| NAME | STATUS | VOLUME | CAPACITY | ACCESSMODES | AGE |
|--------------|--------|--|----------|-------------|-----|
| datadir-zk-0 | Bound | pvc-bed742cd-bcb1-11e6-994f-42010a800002 | 20Gi | RWO | 1h |
| datadir-zk-1 | Bound | pvc-bedd27d2-bcb1-11e6-994f-42010a800002 | 20Gi | RWO | 1h |
| datadir-zk-2 | Bound | pvc-bee0817e-bcb1-11e6-994f-42010a800002 | 20Gi | RWO | 1h |

The volumeMounts section of the StatefulSet's container template mounts the PersistentVolumes in the ZooKeeper servers' data directories.

```
volumeMounts:
- name: datadir
  mountPath: /var/lib/zookeeper
```

When a Pod in the zk StatefulSet is (re)scheduled, it will always have the same PersistentVolume mounted to the ZooKeeper server's data directory. Even when the Pods are rescheduled, all the writes made to the ZooKeeper servers' WALs, and all their snapshots, remain durable.

Ensuring consistent configuration

As noted in the [Facilitating Leader Election](#) and [Achieving Consensus](#) sections, the servers in a ZooKeeper ensemble require consistent configuration to elect a leader and form a quorum. They also require consistent configuration of the Zab protocol in order for the protocol to work correctly over a network. In our example we achieve consistent configuration by embedding the configuration directly into the manifest.

Get the zk StatefulSet.

```
kubectrl get sts zk -o yaml
```

```
...
command:
  - sh
  - -c
  - "start-zookeeper \
    --servers=3 \
    --data_dir=/var/lib/zookeeper/data \
    --data_log_dir=/var/lib/zookeeper/data/log \
    --conf_dir=/opt/zookeeper/conf \
    --client_port=2181 \
    --election_port=3888 \
    --server_port=2888 \
    --tick_time=2000 \
    --init_limit=10 \
    --sync_limit=5 \
    --heap=512M \
    --max_client_cnxns=60 \
    --snap_retain_count=3 \
    --purge_interval=12 \
    --max_session_timeout=40000 \
    --min_session_timeout=4000 \
    --log_level=INFO"
...
```

The command used to start the ZooKeeper servers passed the configuration as command line parameter. You can also use environment variables to pass configuration to the ensemble.

Configuring logging

One of the files generated by the zkGenConfig.sh script controls ZooKeeper's logging. ZooKeeper uses [Log4j](#), and, by default, it uses a time and size based rolling file appender for its logging configuration.

Use the command below to get the logging configuration from one of Pods in the zk StatefulSet.

```
kubectl exec zk-0 cat /usr/etc/zookeeper/log4j.properties
```

The logging configuration below will cause the ZooKeeper process to write all of its logs to the standard output file stream.

```
zookeeper.root.logger=CONSOLE
zookeeper.console.threshold=INFO
log4j.rootLogger=${zookeeper.root.logger}
log4j.appender.CONSOLE=org.apache.log4j.ConsoleAppender
log4j.appender.CONSOLE.Threshold=${zookeeper.console.threshold}
log4j.appender.CONSOLE.layout=org.apache.log4j.PatternLayout
log4j.appender.CONSOLE.layout.ConversionPattern=%d{ISO8601} [myid:%X{myid}] - %-5p [%t:
%C{1}@%L] - %m%n
```

This is the simplest possible way to safely log inside the container. Because the applications write logs to standard out, Kubernetes will handle log rotation for you. Kubernetes also implements a sane retention policy that ensures application logs written to standard out and standard error do not exhaust local storage media.

Use [kubectl logs](#) to retrieve the last 20 log lines from one of the Pods.

```
kubectl logs zk-0 --tail 20
```

You can view application logs written to standard out or standard error using `kubectl logs` and from the Kubernetes Dashboard.

```

```

Kubernetes integrates with many logging solutions. You can choose a logging solution that best fits your cluster and applications. For cluster-level logging and aggregation, consider deploying a [sidecar container](#) to rotate and ship your logs.

Configuring a non-privileged user

The best practices to allow an application to run as a privileged user inside of a container are a matter of debate. If your organization requires that applications run as a non-privileged user you can use a [SecurityContext](#) to control the user that the entry point runs as.

The zk StatefulSet's Pod template contains a SecurityContext.

```

securityContext:
  runAsUser: 1000
  fsGroup: 1000

```

In the Pods' containers, UID 1000 corresponds to the zookeeper user and GID 1000 corresponds to the zookeeper group.

Get the ZooKeeper process information from the zk-0 Pod.

```
kubectl exec zk-0 -- ps -elf
```

As the runAsUser field of the securityContext object is set to 1000, instead of running as root, the ZooKeeper process runs as the zookeeper user.

```

F S UID      PID PPID C PRI NI ADDR SZ WCHAN  STIME TTY      TIME CMD
4 S zookeep+  1   0  0  80  0 - 1127 -   20:46 ?      00:00:00 sh -c zkGenConfig.sh &&
zkServer.sh start-foreground
0 S zookeep+ 27   1  0  80  0 - 1155556 - 20:46 ?      00:00:19 /usr/lib/jvm/java-8-openjdk-
amd64/bin/java -Dzookeeper.log.dir=/var/log/zookeeper -
Dzookeeper.root.logger=INFO,CONSOLE -cp /usr/bin/../build/classes:/usr/bin/../build/lib/*.jar:/
usr/bin/../share/zookeeper/zookeeper-3.4.9.jar:/usr/bin/../share/zookeeper/slf4j-

```

```
log4j12-1.6.1.jar:/usr/bin/../../share/zookeeper/slf4j-api-1.6.1.jar:/usr/bin/../../share/zookeeper/netty-3.10.5.Final.jar:/usr/bin/../../share/zookeeper/log4j-1.2.16.jar:/usr/bin/../../share/zookeeper/jline-0.9.94.jar:/usr/bin/../../src/java/lib/*.jar:/usr/bin/../../etc/zookeeper: -Xmx2G -Xms2G -Dcom.sun.management.jmxremote -Dcom.sun.management.jmxremote.local.only=false org.apache.zookeeper.server.quorum.QuorumPeerMain /usr/bin/../../etc/zookeeper/zoo.cfg
```

By default, when the Pod's PersistentVolumes is mounted to the ZooKeeper server's data directory, it is only accessible by the root user. This configuration prevents the ZooKeeper process from writing to its WAL and storing its snapshots.

Use the command below to get the file permissions of the ZooKeeper data directory on the zk-0 Pod.

```
kubectl exec -ti zk-0 -- ls -ld /var/lib/zookeeper/data
```

Because the fsGroup field of the securityContext object is set to 1000, the ownership of the Pods' PersistentVolumes is set to the zookeeper group, and the ZooKeeper process is able to read and write its data.

```
drwxr-sr-x 3 zookeeper zookeeper 4096 Dec  5 20:45 /var/lib/zookeeper/data
```

Managing the ZooKeeper process

The [ZooKeeper documentation](#) mentions that "You will want to have a supervisory process that manages each of your ZooKeeper server processes (JVM)." Utilizing a watchdog (supervisory process) to restart failed processes in a distributed system is a common pattern. When deploying an application in Kubernetes, rather than using an external utility as a supervisory process, you should use Kubernetes as the watchdog for your application.

Updating the ensemble

The zk StatefulSet is configured to use the RollingUpdate update strategy.

You can use kubectl patch to update the number of cpus allocated to the servers.

```
kubectl patch sts zk --type='json' -p='[{"op": "replace", "path": "/spec/template/spec/containers/0/resources/requests/cpu", "value": "0.3"}]'
```

```
statefulset.apps/zk patched
```

Use kubectl rollout status to watch the status of the update.

```
kubectl rollout status sts/zk
```

```
waiting for statefulset rolling update to complete 0 pods at revision zk-5db4499664...
Waiting for 1 pods to be ready...
Waiting for 1 pods to be ready...
waiting for statefulset rolling update to complete 1 pods at revision zk-5db4499664...
Waiting for 1 pods to be ready...
Waiting for 1 pods to be ready...
waiting for statefulset rolling update to complete 2 pods at revision zk-5db4499664...
Waiting for 1 pods to be ready...
```

```
Waiting for 1 pods to be ready...
statefulset rolling update complete 3 pods at revision zk-5db4499664...
```

This terminates the Pods, one at a time, in reverse ordinal order, and recreates them with the new configuration. This ensures that quorum is maintained during a rolling update.

Use the `kubectl rollout history` command to view a history of previous configurations.

```
kubectl rollout history sts/zk
```

The output is similar to this:

```
statefulsets "zk"
REVISION
1
2
```

Use the `kubectl rollout undo` command to roll back the modification.

```
kubectl rollout undo sts/zk
```

The output is similar to this:

```
statefulset.apps/zk rolled back
```

Handling process failure

[Restart Policies](#) control how Kubernetes handles process failures for the entry point of the container in a Pod. For Pods in a StatefulSet, the only appropriate RestartPolicy is Always, and this is the default value. For stateful applications you should **never** override the default policy.

Use the following command to examine the process tree for the ZooKeeper server running in the zk-0 Pod.

```
kubectl exec zk-0 -- ps -ef
```

The command used as the container's entry point has PID 1, and the ZooKeeper process, a child of the entry point, has PID 27.

```
UID      PID  PPID  C  STIME TTY      TIME CMD
zookeeper+  1    0  0 15:03 ?        00:00:00 sh -c zkGenConfig.sh && zkServer.sh start-foreground
zookeeper+  27   1  0 15:03 ?        00:00:03 /usr/lib/jvm/java-8-openjdk-amd64/bin/java -
Dzookeeper.log.dir=/var/log/zookeeper -Dzookeeper.root.logger=INFO,CONSOLE -cp /usr/
bin/./build/classes:/usr/bin/./build/lib/*:./share/zookeeper/zookeeper-3.4.9.jar:/usr/
bin/./share/zookeeper/slf4j-log4j12-1.6.1.jar:/usr/bin/./share/zookeeper/slf4j-api-1.6.1.jar:/usr/
bin/./share/zookeeper/netty-3.10.5.Final.jar:/usr/bin/./share/zookeeper/log4j-1.2.16.jar:/usr/
bin/./share/zookeeper/jline-0.9.94.jar:/usr/bin/./src/java/lib/*:./etc/zookeeper: -
Xmx2G -Xms2G -Dcom.sun.management.jmxremote -
Dcom.sun.management.jmxremote.local.only=false
org.apache.zookeeper.server.quorum.QuorumPeerMain /usr/bin/./etc/zookeeper/zoo.cfg
```

In another terminal watch the Pods in the zk StatefulSet with the following command.

```
kubectl get pod -w -l app=zk
```

In another terminal, terminate the ZooKeeper process in Pod zk-0 with the following command.

```
kubectrl exec zk-0 -- pkill java
```

The termination of the ZooKeeper process caused its parent process to terminate. Because the RestartPolicy of the container is Always, it restarted the parent process.

| NAME | READY | STATUS | RESTARTS | AGE |
|------|-------|---------|----------|-----|
| zk-0 | 1/1 | Running | 0 | 21m |
| zk-1 | 1/1 | Running | 0 | 20m |
| zk-2 | 1/1 | Running | 0 | 19m |

| NAME | READY | STATUS | RESTARTS | AGE |
|------|-------|---------|----------|-----|
| zk-0 | 0/1 | Error | 0 | 29m |
| zk-0 | 0/1 | Running | 1 | 29m |
| zk-0 | 1/1 | Running | 1 | 29m |

If your application uses a script (such as zkServer.sh) to launch the process that implements the application's business logic, the script must terminate with the child process. This ensures that Kubernetes will restart the application's container when the process implementing the application's business logic fails.

Testing for liveness

Configuring your application to restart failed processes is not enough to keep a distributed system healthy. There are scenarios where a system's processes can be both alive and unresponsive, or otherwise unhealthy. You should use liveness probes to notify Kubernetes that your application's processes are unhealthy and it should restart them.

The Pod template for the zk StatefulSet specifies a liveness probe.

```
livenessProbe:
  exec:
    command:
      - sh
      - -c
      - "zookeeper-ready 2181"
  initialDelaySeconds: 15
  timeoutSeconds: 5
```

The probe calls a bash script that uses the ZooKeeper ruok four letter word to test the server's health.

```
OK=$(echo ruok | nc 127.0.0.1 $1)
if [ "$OK" == "imok" ]; then
  exit 0
else
  exit 1
fi
```

In one terminal window, use the following command to watch the Pods in the zk StatefulSet.

```
kubectrl get pod -w -l app=zk
```

In another window, using the following command to delete the `zookeeper-ready` script from the file system of Pod `zk-0`.

```
kubectrl exec zk-0 -- rm /opt/zookeeper/bin/zookeeper-ready
```

When the liveness probe for the ZooKeeper process fails, Kubernetes will automatically restart the process for you, ensuring that unhealthy processes in the ensemble are restarted.

```
kubectrl get pod -w -l app=zk
```

| NAME | READY | STATUS | RESTARTS | AGE |
|------|-------|---------|----------|-----|
| zk-0 | 1/1 | Running | 0 | 1h |
| zk-1 | 1/1 | Running | 0 | 1h |
| zk-2 | 1/1 | Running | 0 | 1h |

| NAME | READY | STATUS | RESTARTS | AGE |
|------|-------|---------|----------|-----|
| zk-0 | 0/1 | Running | 0 | 1h |
| zk-0 | 0/1 | Running | 1 | 1h |
| zk-0 | 1/1 | Running | 1 | 1h |

Testing for readiness

Readiness is not the same as liveness. If a process is alive, it is scheduled and healthy. If a process is ready, it is able to process input. Liveness is a necessary, but not sufficient, condition for readiness. There are cases, particularly during initialization and termination, when a process can be alive but not ready.

If you specify a readiness probe, Kubernetes will ensure that your application's processes will not receive network traffic until their readiness checks pass.

For a ZooKeeper server, liveness implies readiness. Therefore, the readiness probe from the `zookeeper.yaml` manifest is identical to the liveness probe.

```
readinessProbe:
  exec:
    command:
      - sh
      - -c
      - "zookeeper-ready 2181"
  initialDelaySeconds: 15
  timeoutSeconds: 5
```

Even though the liveness and readiness probes are identical, it is important to specify both. This ensures that only healthy servers in the ZooKeeper ensemble receive network traffic.

Tolerating Node failure

ZooKeeper needs a quorum of servers to successfully commit mutations to data. For a three server ensemble, two servers must be healthy for writes to succeed. In quorum based systems, members are deployed across failure domains to ensure availability. To avoid an outage, due to the loss of an individual machine, best practices preclude co-locating multiple instances of the application on the same machine.

By default, Kubernetes may co-locate Pods in a StatefulSet on the same node. For the three server ensemble you created, if two servers are on the same node, and that node fails, the clients of your ZooKeeper service will experience an outage until at least one of the Pods can be rescheduled.

You should always provision additional capacity to allow the processes of critical systems to be rescheduled in the event of node failures. If you do so, then the outage will only last until the Kubernetes scheduler reschedules one of the ZooKeeper servers. However, if you want your service to tolerate node failures with no downtime, you should set `podAntiAffinity`.

Use the command below to get the nodes for Pods in the `zk` StatefulSet.

```
for i in 0 1 2; do kubectl get pod zk-$i --template {{.spec.nodeName}}; echo ""; done
```

All of the Pods in the `zk` StatefulSet are deployed on different nodes.

```
kubernetes-node-cxpk
kubernetes-node-a5aq
kubernetes-node-2g2d
```

This is because the Pods in the `zk` StatefulSet have a `PodAntiAffinity` specified.

```
affinity:
  podAntiAffinity:
    requiredDuringSchedulingIgnoredDuringExecution:
      - labelSelector:
          matchExpressions:
            - key: "app"
              operator: In
              values:
                - zk
        topologyKey: "kubernetes.io/hostname"
```

The `requiredDuringSchedulingIgnoredDuringExecution` field tells the Kubernetes Scheduler that it should never co-locate two Pods which have `app` label as `zk` in the domain defined by the `topologyKey`. The `topologyKey` `kubernetes.io/hostname` indicates that the domain is an individual node. Using different rules, labels, and selectors, you can extend this technique to spread your ensemble across physical, network, and power failure domains.

Surviving maintenance

In this section you will cordon and drain nodes. If you are using this tutorial on a shared cluster, be sure that this will not adversely affect other tenants.

The previous section showed you how to spread your Pods across nodes to survive unplanned node failures, but you also need to plan for temporary node failures that occur due to planned maintenance.

Use this command to get the nodes in your cluster.

```
kubectl get nodes
```

This tutorial assumes a cluster with at least four nodes. If the cluster has more than four, use [kubectl cordon](#) to cordon all but four nodes. Constraining to four nodes will ensure Kubernetes

encounters affinity and PodDisruptionBudget constraints when scheduling zookeeper Pods in the following maintenance simulation.

```
kubectcl cordon <node-name>
```

Use this command to get the zk-pdb PodDisruptionBudget.

```
kubectcl get pdb zk-pdb
```

The max-unavailable field indicates to Kubernetes that at most one Pod from zk StatefulSet can be unavailable at any time.

| NAME | MIN-AVAILABLE | MAX-UNAVAILABLE | ALLOWED-DISRUPTIONS | AGE |
|--------|---------------|-----------------|---------------------|-----|
| zk-pdb | N/A | 1 | 1 | |

In one terminal, use this command to watch the Pods in the zk StatefulSet.

```
kubectcl get pods -w -l app=zk
```

In another terminal, use this command to get the nodes that the Pods are currently scheduled on.

```
for i in 0 1 2; do kubectcl get pod zk-$i --template {{.spec.nodeName}}; echo ""; done
```

The output is similar to this:

```
kubernetes-node-pb41
kubernetes-node-ixsl
kubernetes-node-i4c4
```

Use [kubectcl drain](#) to cordon and drain the node on which the zk-0 Pod is scheduled.

```
kubectcl drain $(kubectcl get pod zk-0 --template {{.spec.nodeName}}) --ignore-daemonsets --force
--delete-emptydir-data
```

The output is similar to this:

```
node "kubernetes-node-pb41" cordoned

WARNING: Deleting pods not managed by ReplicationController, ReplicaSet, Job, or
DaemonSet: fluentd-cloud-logging-kubernetes-node-pb41, kube-proxy-kubernetes-node-pb41;
Ignoring DaemonSet-managed pods: node-problem-detector-v0.1-o5elz
pod "zk-0" deleted
node "kubernetes-node-pb41" drained
```

As there are four nodes in your cluster, kubectcl drain, succeeds and the zk-0 is rescheduled to another node.

| NAME | READY | STATUS | RESTARTS | AGE |
|------|-------|---------|----------|-----|
| zk-0 | 1/1 | Running | 2 | 1h |
| zk-1 | 1/1 | Running | 0 | 1h |
| zk-2 | 1/1 | Running | 0 | 1h |

| NAME | READY | STATUS | RESTARTS | AGE |
|------|-------|-------------|----------|-----|
| zk-0 | 1/1 | Terminating | 2 | 2h |
| zk-0 | 0/1 | Terminating | 2 | 2h |

| | | | | |
|------|-----|-------------------|---|-----|
| zk-0 | 0/1 | Terminating | 2 | 2h |
| zk-0 | 0/1 | Terminating | 2 | 2h |
| zk-0 | 0/1 | Pending | 0 | 0s |
| zk-0 | 0/1 | Pending | 0 | 0s |
| zk-0 | 0/1 | ContainerCreating | 0 | 0s |
| zk-0 | 0/1 | Running | 0 | 51s |
| zk-0 | 1/1 | Running | 0 | 1m |

Keep watching the StatefulSet's Pods in the first terminal and drain the node on which zk-1 is scheduled.

```
kubectldrain $(kubectldget pod zk-1 --template {{.spec.nodeName}}) --ignore-daemonsets --force
--delete-emptydir-data
```

The output is similar to this:

```
"kubernetes-node-ixsl" cordoned
WARNING: Deleting pods not managed by ReplicationController, ReplicaSet, Job, or
DaemonSet: fluentd-cloud-logging-kubernetes-node-ixsl, kube-proxy-kubernetes-node-ixsl;
Ignoring DaemonSet-managed pods: node-problem-detector-v0.1-voc74
pod "zk-1" deleted
node "kubernetes-node-ixsl" drained
```

The zk-1 Pod cannot be scheduled because the zk StatefulSet contains a PodAntiAffinity rule preventing co-location of the Pods, and as only two nodes are schedulable, the Pod will remain in a Pending state.

```
kubectldget pods -w -l app=zk
```

The output is similar to this:

| NAME | READY | STATUS | RESTARTS | AGE |
|------|-------|---------|----------|-----|
| zk-0 | 1/1 | Running | 2 | 1h |
| zk-1 | 1/1 | Running | 0 | 1h |
| zk-2 | 1/1 | Running | 0 | 1h |

| NAME | READY | STATUS | RESTARTS | AGE |
|------|-------|-------------------|----------|-----|
| zk-0 | 1/1 | Terminating | 2 | 2h |
| zk-0 | 0/1 | Terminating | 2 | 2h |
| zk-0 | 0/1 | Terminating | 2 | 2h |
| zk-0 | 0/1 | Terminating | 2 | 2h |
| zk-0 | 0/1 | Pending | 0 | 0s |
| zk-0 | 0/1 | Pending | 0 | 0s |
| zk-0 | 0/1 | ContainerCreating | 0 | 0s |
| zk-0 | 0/1 | Running | 0 | 51s |
| zk-0 | 1/1 | Running | 0 | 1m |
| zk-1 | 1/1 | Terminating | 0 | 2h |
| zk-1 | 0/1 | Terminating | 0 | 2h |
| zk-1 | 0/1 | Terminating | 0 | 2h |
| zk-1 | 0/1 | Terminating | 0 | 2h |
| zk-1 | 0/1 | Pending | 0 | 0s |
| zk-1 | 0/1 | Pending | 0 | 0s |

Continue to watch the Pods of the StatefulSet, and drain the node on which zk-2 is scheduled.

```
kubectldrain $(kubectldget pod zk-2 --template {{.spec.nodeName}}) --ignore-daemonsets --force
--delete-emptydir-data
```

The output is similar to this:

```
node "kubernetes-node-i4c4" cordoned
```

```
WARNING: Deleting pods not managed by ReplicationController, ReplicaSet, Job, or
DaemonSet: fluentd-cloud-logging-kubernetes-node-i4c4, kube-proxy-kubernetes-node-i4c4;
Ignoring DaemonSet-managed pods: node-problem-detector-v0.1-dyrog
WARNING: Ignoring DaemonSet-managed pods: node-problem-detector-v0.1-dyrog; Deleting
pods not managed by ReplicationController, ReplicaSet, Job, or DaemonSet: fluentd-cloud-
logging-kubernetes-node-i4c4, kube-proxy-kubernetes-node-i4c4
There are pending pods when an error occurred: Cannot evict pod as it would violate the pod's
disruption budget.
pod/zk-2
```

Use CTRL-C to terminate kubectld.

You cannot drain the third node because evicting zk-2 would violate zk-budget. However, the node will remain cordoned.

Use zkCli.sh to retrieve the value you entered during the sanity test from zk-0.

```
kubectldexec zk-0 zkCli.sh get /hello
```

The service is still available because its PodDisruptionBudget is respected.

```
WatchedEvent state:SyncConnected type:None path:null
world
cZxid = 0x2000000002
ctime = Wed Dec 07 00:08:59 UTC 2016
mZxid = 0x2000000002
mtime = Wed Dec 07 00:08:59 UTC 2016
pZxid = 0x2000000002
cversion = 0
dataVersion = 0
aclVersion = 0
ephemeralOwner = 0x0
dataLength = 5
numChildren = 0
```

Use [kubectlduncordon](#) to uncordon the first node.

```
kubectlduncordon kubernetes-node-pb41
```

The output is similar to this:

```
node "kubernetes-node-pb41" uncordoned
```

zk-1 is rescheduled on this node. Wait until zk-1 is Running and Ready.

```
kubectldget pods -w -l app=zk
```

The output is similar to this:

| NAME | READY | STATUS | RESTARTS | AGE |
|------|-------|---------|----------|-----|
| zk-0 | 1/1 | Running | 2 | 1h |
| zk-1 | 1/1 | Running | 0 | 1h |
| zk-2 | 1/1 | Running | 0 | 1h |

| NAME | READY | STATUS | RESTARTS | AGE |
|------|-------|-------------------|----------|-----|
| zk-0 | 1/1 | Terminating | 2 | 2h |
| zk-0 | 0/1 | Terminating | 2 | 2h |
| zk-0 | 0/1 | Terminating | 2 | 2h |
| zk-0 | 0/1 | Terminating | 2 | 2h |
| zk-0 | 0/1 | Pending | 0 | 0s |
| zk-0 | 0/1 | Pending | 0 | 0s |
| zk-0 | 0/1 | ContainerCreating | 0 | 0s |
| zk-0 | 0/1 | Running | 0 | 51s |
| zk-0 | 1/1 | Running | 0 | 1m |
| zk-1 | 1/1 | Terminating | 0 | 2h |
| zk-1 | 0/1 | Terminating | 0 | 2h |
| zk-1 | 0/1 | Terminating | 0 | 2h |
| zk-1 | 0/1 | Terminating | 0 | 2h |
| zk-1 | 0/1 | Pending | 0 | 0s |
| zk-1 | 0/1 | Pending | 0 | 0s |
| zk-1 | 0/1 | Pending | 0 | 12m |
| zk-1 | 0/1 | ContainerCreating | 0 | 12m |
| zk-1 | 0/1 | Running | 0 | 13m |
| zk-1 | 1/1 | Running | 0 | 13m |

Attempt to drain the node on which zk-2 is scheduled.

```
kubectl drain $(kubectl get pod zk-2 --template {{.spec.nodeName}}) --ignore-daemonsets --force --delete-emptydir-data
```

The output is similar to this:

```
node "kubernetes-node-i4c4" already cordoned
WARNING: Deleting pods not managed by ReplicationController, ReplicaSet, Job, or
DaemonSet: fluentd-cloud-logging-kubernetes-node-i4c4, kube-proxy-kubernetes-node-i4c4;
Ignoring DaemonSet-managed pods: node-problem-detector-v0.1-dyrog
pod "heapster-v1.2.0-2604621511-wht1r" deleted
pod "zk-2" deleted
node "kubernetes-node-i4c4" drained
```

This time kubectl drain succeeds.

Uncordon the second node to allow zk-2 to be rescheduled.

```
kubectl uncordon kubernetes-node-ixsl
```

The output is similar to this:

```
node "kubernetes-node-ixsl" uncordoned
```

You can use kubectl drain in conjunction with PodDisruptionBudgets to ensure that your services remain available during maintenance. If drain is used to cordon nodes and evict pods prior to taking the node offline for maintenance, services that express a disruption budget will

have that budget respected. You should always allocate additional capacity for critical services so that their Pods can be immediately rescheduled.

Cleaning up

- Use `kubectl uncordon` to uncordon all the nodes in your cluster.
- You must delete the persistent storage media for the PersistentVolumes used in this tutorial. Follow the necessary steps, based on your environment, storage configuration, and provisioning method, to ensure that all storage is reclaimed.

Services

[Connecting Applications with Services](#)

[Using Source IP](#)

[Explore Termination Behavior for Pods And Their Endpoints](#)

Connecting Applications with Services

The Kubernetes model for connecting containers

Now that you have a continuously running, replicated application you can expose it on a network.

Kubernetes assumes that pods can communicate with other pods, regardless of which host they land on. Kubernetes gives every pod its own cluster-private IP address, so you do not need to explicitly create links between pods or map container ports to host ports. This means that containers within a Pod can all reach each other's ports on localhost, and all pods in a cluster can see each other without NAT. The rest of this document elaborates on how you can run reliable services on such a networking model.

This tutorial uses a simple nginx web server to demonstrate the concept.

Exposing pods to the cluster

We did this in a previous example, but let's do it once again and focus on the networking perspective. Create an nginx Pod, and note that it has a container port specification:

[service/networking/run-my-nginx.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
  name: my-nginx
spec:
  selector:
```

```
matchLabels:
  run: my-nginx
replicas: 2
template:
  metadata:
    labels:
      run: my-nginx
  spec:
    containers:
      - name: my-nginx
        image: nginx
        ports:
          - containerPort: 80
```

This makes it accessible from any node in your cluster. Check the nodes the Pod is running on:

```
kubectl apply -f ./run-my-nginx.yaml
kubectl get pods -l run=my-nginx -o wide
```

| NAME | READY | STATUS | RESTARTS | AGE | IP | NODE |
|---------------------------|-------|---------|----------|-----|------------|------------------------|
| my-nginx-3800858182-jr4a2 | 1/1 | Running | 0 | 13s | 10.244.3.4 | kubernetes-minion-905m |
| my-nginx-3800858182-kna2y | 1/1 | Running | 0 | 13s | 10.244.2.5 | kubernetes-minion-ljyd |

Check your pods' IPs:

```
kubectl get pods -l run=my-nginx -o custom-columns=POD_IP:.status.podIPs
POD_IP
[map[ip:10.244.3.4]]
[map[ip:10.244.2.5]]
```

You should be able to ssh into any node in your cluster and use a tool such as curl to make queries against both IPs. Note that the containers are *not* using port 80 on the node, nor are there any special NAT rules to route traffic to the pod. This means you can run multiple nginx pods on the same node all using the same containerPort, and access them from any other pod or node in your cluster using the assigned IP address for the pod. If you want to arrange for a specific port on the host Node to be forwarded to backing Pods, you can - but the networking model should mean that you do not need to do so.

You can read more about the [Kubernetes Networking Model](#) if you're curious.

Creating a Service

So we have pods running nginx in a flat, cluster wide, address space. In theory, you could talk to these pods directly, but what happens when a node dies? The pods die with it, and the ReplicaSet inside the Deployment will create new ones, with different IPs. This is the problem a Service solves.

A Kubernetes Service is an abstraction which defines a logical set of Pods running somewhere in your cluster, that all provide the same functionality. When created, each Service is assigned a unique IP address (also called clusterIP). This address is tied to the lifespan of the Service, and

will not change while the Service is alive. Pods can be configured to talk to the Service, and know that communication to the Service will be automatically load-balanced out to some pod that is a member of the Service.

You can create a Service for your 2 nginx replicas with `kubectl expose`:

```
kubectl expose deployment/my-nginx
```

```
service/my-nginx exposed
```

This is equivalent to `kubectl apply -f` the following yaml:

[service/networking/nginx-svc.yaml](#)

```
apiVersion: v1
kind: Service
metadata:
  name: my-nginx
  labels:
    run: my-nginx
spec:
  ports:
    - port: 80
      protocol: TCP
  selector:
    run: my-nginx
```

This specification will create a Service which targets TCP port 80 on any Pod with the `run: my-nginx` label, and expose it on an abstracted Service port (`targetPort`: is the port the container accepts traffic on, `port`: is the abstracted Service port, which can be any port other pods use to access the Service). View [Service](#) API object to see the list of supported fields in service definition. Check your Service:

```
kubectl get svc my-nginx
```

| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE |
|----------|-----------|--------------|-------------|---------|-----|
| my-nginx | ClusterIP | 10.0.162.149 | <none> | 80/TCP | 21s |

As mentioned previously, a Service is backed by a group of Pods. These Pods are exposed through [EndpointSlices](#). The Service's selector will be evaluated continuously and the results will be POSTed to an EndpointSlice that is connected to the Service using [labels](#). When a Pod dies, it is automatically removed from the EndpointSlices that contain it as an endpoint. New Pods that match the Service's selector will automatically get added to an EndpointSlice for that Service. Check the endpoints, and note that the IPs are the same as the Pods created in the first step:

```
kubectl describe svc my-nginx
```

```
Name:          my-nginx
Namespace:     default
Labels:        run=my-nginx
Annotations:   <none>
Selector:      run=my-nginx
Type:          ClusterIP
```

```
IP Family Policy: SingleStack
IP Families:      IPv4
IP:              10.0.162.149
IPs:             10.0.162.149
Port:            <unset> 80/TCP
TargetPort:      80/TCP
Endpoints:       10.244.2.5:80,10.244.3.4:80
Session Affinity: None
Events:          <none>
```

```
kubectl get endpointslices -l kubernetes.io/service-name=my-nginx
```

| NAME | ADDRESSTYPE | PORTS | ENDPOINTS | AGE |
|----------------|-------------|-------|-----------------------|-----|
| my-nginx-7vzhx | IPv4 | 80 | 10.244.2.5,10.244.3.4 | 21s |

You should now be able to curl the nginx Service on `<CLUSTER-IP>:<PORT>` from any node in your cluster. Note that the Service IP is completely virtual, it never hits the wire. If you're curious about how this works you can read more about the [service proxy](#).

Accessing the Service

Kubernetes supports 2 primary modes of finding a Service - environment variables and DNS. The former works out of the box while the latter requires the [CoreDNS cluster addon](#).

Note:

If the service environment variables are not desired (because possible clashing with expected program ones, too many variables to process, only using DNS, etc) you can disable this mode by setting the `enableServiceLinks` flag to false on the [pod spec](#).

Environment Variables

When a Pod runs on a Node, the kubelet adds a set of environment variables for each active Service. This introduces an ordering problem. To see why, inspect the environment of your running nginx Pods (your Pod name will be different):

```
kubectl exec my-nginx-3800858182-jr4a2 -- printenv | grep SERVICE
```

```
KUBERNETES_SERVICE_HOST=10.0.0.1
KUBERNETES_SERVICE_PORT=443
KUBERNETES_SERVICE_PORT_HTTPS=443
```

Note there's no mention of your Service. This is because you created the replicas before the Service. Another disadvantage of doing this is that the scheduler might put both Pods on the same machine, which will take your entire Service down if it dies. We can do this the right way by killing the 2 Pods and waiting for the Deployment to recreate them. This time the Service exists *before* the replicas. This will give you scheduler-level Service spreading of your Pods (provided all your nodes have equal capacity), as well as the right environment variables:

```
kubectl scale deployment my-nginx --replicas=0; kubectl scale deployment my-nginx --replicas=2;
```

```
kubectrl get pods -l run=my-nginx -o wide
```

| NAME | READY | STATUS | RESTARTS | AGE | IP | NODE |
|---------------------------------------|-------|---------|----------|-----|------------|--------------------|
| my-nginx-3800858182-e9ihh-ljyd | 1/1 | Running | 0 | 5s | 10.244.2.7 | kubernetes-minion- |
| my-nginx-3800858182-j4rm4-minion-905m | 1/1 | Running | 0 | 5s | 10.244.3.8 | kubernetes- |

You may notice that the pods have different names, since they are killed and recreated.

```
kubectrl exec my-nginx-3800858182-e9ihh -- printenv | grep SERVICE
```

```
KUBERNETES_SERVICE_PORT=443
MY_NGINX_SERVICE_HOST=10.0.162.149
KUBERNETES_SERVICE_HOST=10.0.0.1
MY_NGINX_SERVICE_PORT=80
KUBERNETES_SERVICE_PORT_HTTPS=443
```

DNS

Kubernetes offers a DNS cluster addon Service that automatically assigns dns names to other Services. You can check if it's running on your cluster:

```
kubectrl get services kube-dns --namespace=kube-system
```

| NAME | TYPE | CLUSTER-IP | EXTERNAL-IP | PORT(S) | AGE |
|----------|-----------|------------|-------------|---------------|-----|
| kube-dns | ClusterIP | 10.0.0.10 | <none> | 53/UDP,53/TCP | 8m |

The rest of this section will assume you have a Service with a long lived IP (my-nginx), and a DNS server that has assigned a name to that IP. Here we use the CoreDNS cluster addon (application name kube-dns), so you can talk to the Service from any pod in your cluster using standard methods (e.g. `gethostbyname()`). If CoreDNS isn't running, you can enable it referring to the [CoreDNS README](#) or [Installing CoreDNS](#). Let's run another curl application to test this:

```
kubectrl run curl --image=radial/busyboxplus:curl -i --tty --rm
```

Waiting for pod default/curl-131556218-9fnch to be running, status is Pending, pod ready: false
Hit enter for command prompt

Then, hit enter and run `nslookup my-nginx`:

```
[ root@curl-131556218-9fnch:/ ]$ nslookup my-nginx
Server: 10.0.0.10
Address 1: 10.0.0.10

Name: my-nginx
Address 1: 10.0.162.149
```

Securing the Service

Till now we have only accessed the nginx server from within the cluster. Before exposing the Service to the internet, you want to make sure the communication channel is secure. For this, you will need:

- Self signed certificates for https (unless you already have an identity certificate)
- An nginx server configured to use the certificates
- A [secret](#) that makes the certificates accessible to pods

You can acquire all these from the [nginx https example](#). This requires having go and make tools installed. If you don't want to install those, then follow the manual steps later. In short:

```
make keys KEY=/tmp/nginx.key CERT=/tmp/nginx.crt
kubectl create secret tls nginxsecret --key /tmp/nginx.key --cert /tmp/nginx.crt
```

```
secret/nginxsecret created
```

```
kubectl get secrets
```

| NAME | TYPE | DATA | AGE |
|-------------|-------------------|------|-----|
| nginxsecret | kubernetes.io/tls | 2 | 1m |

And also the configmap:

```
kubectl create configmap nginxconfigmap --from-file=default.conf
```

You can find an example for default.conf in [the Kubernetes examples project repo](#).

```
configmap/nginxconfigmap created
```

```
kubectl get configmaps
```

| NAME | DATA | AGE |
|----------------|------|------|
| nginxconfigmap | 1 | 114s |

You can view the details of the nginxconfigmap ConfigMap using the following command:

```
kubectl describe configmap nginxconfigmap
```

The output is similar to:

```
Name:      nginxconfigmap
Namespace: default
Labels:    <none>
Annotations: <none>

Data
====
default.conf:
----
server {
    listen 80 default_server;
    listen [::]:80 default_server ipv6only=on;
```

```

listen 443 ssl;

root /usr/share/nginx/html;
index index.html;

server_name localhost;
ssl_certificate /etc/nginx/ssl/tls.crt;
ssl_certificate_key /etc/nginx/ssl/tls.key;

location / {
    try_files $uri $uri/ =404;
}
}

```

BinaryData

====

Events: <none>

Following are the manual steps to follow in case you run into problems running make (on windows for example):

```

# Create a public private key pair
openssl req -x509 -nodes -days 365 -newkey rsa:2048 -keyout /d/tmp/nginx.key -out /d/tmp/nginx.crt -subj "/CN=my-nginx/O=my-nginx"
# Convert the keys to base64 encoding
cat /d/tmp/nginx.crt | base64
cat /d/tmp/nginx.key | base64

```

Use the output from the previous commands to create a yaml file as follows. The base64 encoded value should all be on a single line.

```

apiVersion: "v1"
kind: "Secret"
metadata:
  name: "nginxsecret"
  namespace: "default"
type: kubernetes.io/tls
data:
  tls.crt: "LS0tLS1CRUdJTiBDRVJUSUZJQ0FURS0tLS0tCk1JSURlekNDQWdlZ0F3SUJBZ0lKQUp5M3lQK0pzMlplJTUEwR0NTcUdTSWlZRFFFQkJRUVFNQ1l4RVRBUEJnTIYKQkFNVENHNW5hVzU0YzNaak1SRXdEd1lEVlFRS0V3aHVVaMmx1ZUhOMll6QWVGdzB4TnpFd01qWXdOekEzTVRKYQpGdzB4T0RFd01qWXdOekEzTVRKYU1DWXhFVEFQQmdOVk1BTVRDRzVuYVc1NGMzWm1pNUkV3RHdZRFZRUUtFd2h1CloybHVlSE4yWXPdQ0FTSXdeUUVlKS29aSWWh2Y05BUUVCQlFBRGdnRVB BRENDQVFvQ2dnRUJBSjFhSU1SOVdWM0IKMlZlQlRMRmtobDRONXljMEJxYUhlQktMSnJMcY8vdzZhU3hRS29GbHlJSU94NGUrMlN5ajBFcndCLzlyTnBwbQppeW1CL3JkRldkOXg5UWWhBQUxCZkVaTmNiV3NsTVFVcnhBZW50VWt1dk1vLzgvMHRpbGhjc3paenJEYVJ4NEo5Ci82UVRtVVI3a0ZTWUpOWTVQZkR3cGc3dlVvaDZmZ1Voam92VG42eHNVR0M2QURVODBpNXFlZWWhNeVI1N2lmU2YKNHJpaXdlY3hnL3lZR1JBRS9mRTRqakxCdmdONjc2SU90S01rZXV3R0ljNDFhd05tNnNTS2RqYUNGeGpYSnZaZQp2by9kTlEyYHhHWCTKT2l3SEhXbXNhdGp4WTRaNVk3R1ZoK0QrWnYvcW1mMFgvdVY0Rmo1NzV3ajFMWVBocWtsCmdhSXZYRyt4U1FVQ0F3RUFBYU5RTUU0d0hRWURWUjBPQkJZRUZPNG9OWWk3YXc1OUlsYkROMzhIYkduYnhFVjcKT"

Gc9Ci0tLS0tRU5EIFBSSVZBVEUgS0VZLS0tLS0K"
```

Now create the secrets using the file:

```
kubectl apply -f nginxsecrets.yaml
kubectl get secrets
```

| NAME | TYPE | DATA | AGE |
|-------------|-------------------|------|-----|
| nginxsecret | kubernetes.io/tls | 2 | 1m |

Now modify your nginx replicas to start an https server using the certificate in the secret, and the Service, to expose both ports (80 and 443):

[service/networking/nginx-secure-app.yaml](#)

```
apiVersion: v1
kind: Service
metadata:
  name: my-nginx
  labels:
    run: my-nginx
spec:
  type: NodePort
  ports:
    - port: 8080
      targetPort: 80
      protocol: TCP
      name: http
    - port: 443
      protocol: TCP
      name: https
  selector:
    run: my-nginx
---
apiVersion: apps/v1
kind: Deployment
metadata:
  name: my-nginx
spec:
  selector:
    matchLabels:
      run: my-nginx
  replicas: 1
  template:
    metadata:
      labels:
        run: my-nginx
    spec:
      volumes:
        - name: secret-volume
          secret:
            secretName: nginxsecret
        - name: configmap-volume
          configMap:
            name: nginxconfigmap
      containers:
        - name: nginxhttps
          image: bprashanth/nginxhttps:1.0
          ports:
            - containerPort: 443
            - containerPort: 80
          volumeMounts:
            - mountPath: /etc/nginx/ssl
              name: secret-volume
            - mountPath: /etc/nginx/conf.d
              name: configmap-volume
```

Noteworthy points about the nginx-secure-app manifest:

- It contains both Deployment and Service specification in the same file.
- The [nginx server](#) serves HTTP traffic on port 80 and HTTPS traffic on 443, and nginx Service exposes both ports.
- Each container has access to the keys through a volume mounted at /etc/nginx/ssl. This is set up *before* the nginx server is started.

```
kubectl delete deployments,svc my-nginx; kubectl create -f ./nginx-secure-app.yaml
```

At this point you can reach the nginx server from any node.

```
kubectl get pods -l run=my-nginx -o custom-columns=POD_IP:.status.podIPs
POD_IP
[map[ip:10.244.3.5]]
```

```
node $ curl -k https://10.244.3.5
...
<h1>Welcome to nginx!</h1>
```

Note how we supplied the `-k` parameter to curl in the last step, this is because we don't know anything about the pods running nginx at certificate generation time, so we have to tell curl to ignore the CName mismatch. By creating a Service we linked the CName used in the certificate with the actual DNS name used by pods during Service lookup. Let's test this from a pod (the same secret is being reused for simplicity, the pod only needs nginx.crt to access the Service):

[service/networking/curlpod.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
  name: curl-deployment
spec:
  selector:
    matchLabels:
      app: curlpod
  replicas: 1
  template:
    metadata:
      labels:
        app: curlpod
    spec:
      volumes:
        - name: secret-volume
          secret:
            secretName: nginxsecret
      containers:
        - name: curlpod
          command:
            - sh
            - -c
            - while true; do sleep 1; done
          image: radial/busyboxplus:curl
          volumeMounts:
```

```
- mountPath: /etc/nginx/ssl
  name: secret-volume
```

```
kubectl apply -f ./curlpod.yaml
kubectl get pods -l app=curlpod
```

NAME	READY	STATUS	RESTARTS	AGE
curl-deployment-1515033274-1410r	1/1	Running	0	1m

```
kubectl exec curl-deployment-1515033274-1410r -- curl https://my-nginx --cacert /etc/nginx/ssl/
tls.crt
```

```
...
<title>Welcome to nginx!</title>
...
```

Exposing the Service

For some parts of your applications you may want to expose a Service onto an external IP address. Kubernetes supports two ways of doing this: NodePorts and LoadBalancers. The Service created in the last section already used NodePort, so your nginx HTTPS replica is ready to serve traffic on the internet if your node has a public IP.

```
kubectl get svc my-nginx -o yaml | grep nodePort -C 5
uid: 07191fb3-f61a-11e5-8ae5-42010af00002
```

```
spec:
  clusterIP: 10.0.162.149
  ports:
  - name: http
    nodePort: 31704
    port: 8080
    protocol: TCP
    targetPort: 80
  - name: https
    nodePort: 32453
    port: 443
    protocol: TCP
    targetPort: 443
  selector:
    run: my-nginx
```

```
kubectl get nodes -o yaml | grep ExternalIP -C 1
```

```
- address: 104.197.41.11
  type: ExternalIP
  allocatable:
```

```
--
```

```
- address: 23.251.152.56
  type: ExternalIP
  allocatable:
```

```
...
```

```
$ curl https://<EXTERNAL-IP>:<NODE-PORT> -k
```

```
...
<h1>Welcome to nginx!</h1>
```

Let's now recreate the Service to use a cloud load balancer. Change the Type of my-nginx Service from NodePort to LoadBalancer:

```
kubectl edit svc my-nginx
kubectl get svc my-nginx
```

NAME	TYPE	CLUSTER-IP	EXTERNAL-IP	PORT(S)	AGE
my-nginx	LoadBalancer	10.0.162.149	xx.xxx.xxx.xxx	8080:30163/TCP	21s

```
curl https://<EXTERNAL-IP> -k
...
<title>Welcome to nginx!</title>
```

The IP address in the EXTERNAL-IP column is the one that is available on the public internet. The CLUSTER-IP is only available inside your cluster/private cloud network.

Note that on AWS, type LoadBalancer creates an ELB, which uses a (long) hostname, not an IP. It's too long to fit in the standard kubectl get svc output, in fact, so you'll need to do kubectl describe service my-nginx to see it. You'll see something like this:

```
kubectl describe service my-nginx
...
LoadBalancer Ingress: a320587ffd19711e5a37606cf4a74574-1142138393.us-
east-1.elb.amazonaws.com
...
```

Using Source IP

Applications running in a Kubernetes cluster find and communicate with each other, and the outside world, through the Service abstraction. This document explains what happens to the source IP of packets sent to different types of Services, and how you can toggle this behavior according to your needs.

Before you begin

Terminology

This document makes use of the following terms:

[NAT](#)

Network address translation

[Source NAT](#)

Replacing the source IP on a packet; in this page, that usually means replacing with the IP address of a node.

[Destination NAT](#)

Replacing the destination IP on a packet; in this page, that usually means replacing with the IP address of a [Pod](#)

VIP

A virtual IP address, such as the one assigned to every [Service](#) in Kubernetes

kube-proxy

A network daemon that orchestrates Service VIP management on every node

Prerequisites

You need to have a Kubernetes cluster, and the kubectl command-line tool must be configured to communicate with your cluster. It is recommended to run this tutorial on a cluster with at least two nodes that are not acting as control plane hosts. If you do not already have a cluster, you can create one by using [minikube](#) or you can use one of these Kubernetes playgrounds:

- [Killercodea](#)
- [Play with Kubernetes](#)

The examples use a small nginx webserver that echoes back the source IP of requests it receives through an HTTP header. You can create it as follows:

Note:

The image in the following command only runs on AMD64 architectures.

```
kubectl create deployment source-ip-app --image=registry.k8s.io/echoserver:1.4
```

The output is:

```
deployment.apps/source-ip-app created
```

Objectives

- Expose a simple application through various types of Services
- Understand how each Service type handles source IP NAT
- Understand the tradeoffs involved in preserving source IP

Source IP for Services with Type=ClusterIP

Packets sent to ClusterIP from within the cluster are never source NAT'd if you're running kube-proxy in [iptables mode](#), (the default). You can query the kube-proxy mode by fetching `http://localhost:10249/proxyMode` on the node where kube-proxy is running.

```
kubectl get nodes
```

The output is similar to this:

NAME	STATUS	ROLES	AGE	VERSION
kubernetes-node-6jst	Ready	<none>	2h	v1.13.0
kubernetes-node-cx31	Ready	<none>	2h	v1.13.0
kubernetes-node-jj1t	Ready	<none>	2h	v1.13.0

Get the proxy mode on one of the nodes (kube-proxy listens on port 10249):

```
# Run this in a shell on the node you want to query.  
curl http://localhost:10249/proxyMode
```

The output is:

```
iptables
```

You can test source IP preservation by creating a Service over the source IP app:

```
kubectcl expose deployment source-ip-app --name=clusterip --port=80 --target-port=8080
```

The output is:

```
service/clusterip exposed
```

```
kubectcl get svc clusterip
```

The output is similar to:

NAME	TYPE	CLUSTER-IP	EXTERNAL-IP	PORT(S)	AGE
clusterip	ClusterIP	10.0.170.92	<none>	80/TCP	51s

And hitting the ClusterIP from a pod in the same cluster:

```
kubectcl run busybox -it --image=busybox:1.28 --restart=Never --rm
```

The output is similar to this:

Waiting for pod default/busybox to be running, status is Pending, pod ready: false
If you don't see a command prompt, try pressing enter.

You can then run a command inside that Pod:

```
# Run this inside the terminal from "kubectcl run"  
ip addr
```

```
1: lo: <LOOPBACK,UP,LOWER_UP> mtu 65536 qdisc noqueue  
    link/loopback 00:00:00:00:00:00 brd 00:00:00:00:00:00  
    inet 127.0.0.1/8 scope host lo  
        valid_lft forever preferred_lft forever  
    inet6 ::1/128 scope host  
        valid_lft forever preferred_lft forever  
3: eth0: <BROADCAST,MULTICAST,UP,LOWER_UP> mtu 1460 qdisc noqueue  
    link/ether 0a:58:0a:f4:03:08 brd ff:ff:ff:ff:ff:ff  
    inet 10.244.3.8/24 scope global eth0  
        valid_lft forever preferred_lft forever  
    inet6 fe80::188a:84ff:feb0:26a5/64 scope link  
        valid_lft forever preferred_lft forever
```

...then use wget to query the local webserver

```
# Replace "10.0.170.92" with the IPv4 address of the Service named "clusterip"  
wget -qO - 10.0.170.92
```

```
CLIENT VALUES:
client_address=10.244.3.8
command=GET
...
```

The `client_address` is always the client pod's IP address, whether the client pod and server pod are in the same node or in different nodes.

Source IP for Services with `Type=NodePort`

Packets sent to Services with [Type=NodePort](#) are source NAT'd by default. You can test this by creating a NodePort Service:

```
kubectl expose deployment source-ip-app --name=nodeport --port=80 --target-port=8080 --type=NodePort
```

The output is:

```
service/nodeport exposed
```

```
NODEPORT=$(kubectl get -o jsonpath="{.spec.ports[0].nodePort}" services nodeport)
NODES=$(kubectl get nodes -o jsonpath='{ $.items[*].status.addresses[? (@.type=="InternalIP")].address }')
```

If you're running on a cloud provider, you may need to open up a firewall-rule for the `nodes:nodeport` reported above. Now you can try reaching the Service from outside the cluster through the node port allocated above.

```
for node in $NODES; do curl -s $node:$NODEPORT | grep -i client_address; done
```

The output is similar to:

```
client_address=10.180.1.1
client_address=10.240.0.5
client_address=10.240.0.3
```

Note that these are not the correct client IPs, they're cluster internal IPs. This is what happens:

- Client sends packet to `node2:nodePort`
- `node2` replaces the source IP address (SNAT) in the packet with its own IP address
- `node2` replaces the destination IP on the packet with the pod IP
- packet is routed to node 1, and then to the endpoint
- the pod's reply is routed back to `node2`
- the pod's reply is sent back to the client

Visually:

[source IP nodeport figure 01](#)

Figure. Source IP `Type=NodePort` using SNAT

To avoid this, Kubernetes has a feature to [preserve the client source IP](#). If you set `service.spec.externalTrafficPolicy` to the value `Local`, kube-proxy only proxies proxy requests to local endpoints, and does not forward traffic to other nodes. This approach preserves the

original source IP address. If there are no local endpoints, packets sent to the node are dropped, so you can rely on the correct source-ip in any packet processing rules you might apply a packet that make it through to the endpoint.

Set the `service.spec.externalTrafficPolicy` field as follows:

```
kubectl patch svc nodeport -p '{"spec":{"externalTrafficPolicy":"Local"}}'
```

The output is:

```
service/nodeport patched
```

Now, re-run the test:

```
for node in $NODES; do curl --connect-timeout 1 -s $node:$NODEPORT | grep -i  
client_address; done
```

The output is similar to:

```
client_address=198.51.100.79
```

Note that you only got one reply, with the *right* client IP, from the one node on which the endpoint pod is running.

This is what happens:

- client sends packet to `node2:nodePort`, which doesn't have any endpoints
- packet is dropped
- client sends packet to `node1:nodePort`, which *does* have endpoints
- node1 routes packet to endpoint with the correct source IP

Visually:

source IP nodeport figure 02

Figure. Source IP `Type=NodePort` preserves client source IP address

Source IP for Services with `Type=LoadBalancer`

Packets sent to Services with `Type=LoadBalancer` are source NAT'd by default, because all schedulable Kubernetes nodes in the Ready state are eligible for load-balanced traffic. So if packets arrive at a node without an endpoint, the system proxies it to a node *with* an endpoint, replacing the source IP on the packet with the IP of the node (as described in the previous section).

You can test this by exposing the `source-ip-app` through a load balancer:

```
kubectl expose deployment source-ip-app --name=loadbalancer --port=80 --target-port=8080 --  
type=LoadBalancer
```

The output is:

```
service/loadbalancer exposed
```

Print out the IP addresses of the Service:

```
kubectl get svc loadbalancer
```

The output is similar to this:

NAME	TYPE	CLUSTER-IP	EXTERNAL-IP	PORT(S)	AGE
loadbalancer	LoadBalancer	10.0.65.118	203.0.113.140	80/TCP	5m

Next, send a request to this Service's external-ip:

```
curl 203.0.113.140
```

The output is similar to this:

```
CLIENT VALUES:
client_address=10.240.0.5
...
```

However, if you're running on Google Kubernetes Engine/GCE, setting the same `service.spec.externalTrafficPolicy` field to `Local` forces nodes *without* Service endpoints to remove themselves from the list of nodes eligible for loadbalanced traffic by deliberately failing health checks.

Visually:

Source IP with `externalTrafficPolicy`

You can test this by setting the annotation:

```
kubectl patch svc loadbalancer -p '{"spec":{"externalTrafficPolicy":"Local"}}'
```

You should immediately see the `service.spec.healthCheckNodePort` field allocated by Kubernetes:

```
kubectl get svc loadbalancer -o yaml | grep -i healthCheckNodePort
```

The output is similar to this:

```
healthCheckNodePort: 32122
```

The `service.spec.healthCheckNodePort` field points to a port on every node serving the health check at `/healthz`. You can test this:

```
kubectl get pod -o wide -l app=source-ip-app
```

The output is similar to this:

NAME	READY	STATUS	RESTARTS	AGE	IP	NODE
source-ip-app-826191075-qehz4	1/1	Running	0	20h	10.180.1.136	kubernetes-node-6jst

Use `curl` to fetch the `/healthz` endpoint on various nodes:

```
# Run this locally on a node you choose
curl localhost:32122/healthz
```

1 Service Endpoints found

On a different node you might get a different result:

```
# Run this locally on a node you choose
curl localhost:32122/healthz
```

No Service Endpoints Found

A controller running on the [control plane](#) is responsible for allocating the cloud load balancer. The same controller also allocates HTTP health checks pointing to this port/path on each node. Wait about 10 seconds for the 2 nodes without endpoints to fail health checks, then use curl to query the IPv4 address of the load balancer:

```
curl 203.0.113.140
```

The output is similar to this:

```
CLIENT VALUES:
client_address=198.51.100.79
...
```

Cross-platform support

Only some cloud providers offer support for source IP preservation through Services with Type=LoadBalancer. The cloud provider you're running on might fulfill the request for a loadbalancer in a few different ways:

1. With a proxy that terminates the client connection and opens a new connection to your nodes/endpoints. In such cases the source IP will always be that of the cloud LB, not that of the client.
2. With a packet forwarder, such that requests from the client sent to the loadbalancer VIP end up at the node with the source IP of the client, not an intermediate proxy.

Load balancers in the first category must use an agreed upon protocol between the loadbalancer and backend to communicate the true client IP such as the HTTP [Forwarded](#) or [X-FORWARDED-FOR](#) headers, or the [proxy protocol](#). Load balancers in the second category can leverage the feature described above by creating an HTTP health check pointing at the port stored in the service.spec.healthCheckNodePort field on the Service.

Cleaning up

Delete the Services:

```
kubectl delete svc -l app=source-ip-app
```

Delete the Deployment, ReplicaSet and Pod:

```
kubectl delete deployment source-ip-app
```

Explore Termination Behavior for Pods And Their Endpoints

Once you connected your Application with Service following steps like those outlined in [Connecting Applications with Services](#), you have a continuously running, replicated application, that is exposed on a network. This tutorial helps you look at the termination flow for Pods and to explore ways to implement graceful connection draining.

Termination process for Pods and their endpoints

There are often cases when you need to terminate a Pod - be it for upgrade or scale down. In order to improve application availability, it may be important to implement a proper active connections draining.

This tutorial explains the flow of Pod termination in connection with the corresponding endpoint state and removal by using a simple nginx web server to demonstrate the concept.

Example flow with endpoint termination

The following is the example of the flow described in the [Termination of Pods](#) document.

Let's say you have a Deployment containing of a single nginx replica (just for demonstration purposes) and a Service:

[service/pod-with-graceful-termination.yaml](#)

```
apiVersion: apps/v1
kind: Deployment
metadata:
  name: nginx-deployment
  labels:
    app: nginx
spec:
  replicas: 1
  selector:
    matchLabels:
      app: nginx
  template:
    metadata:
      labels:
        app: nginx
    spec:
      terminationGracePeriodSeconds: 120 # extra long grace period
      containers:
```

```

- name: nginx
  image: nginx:latest
  ports:
  - containerPort: 80
  lifecycle:
    preStop:
      exec:
        # Real life termination may take any time up to terminationGracePeriodSeconds.
        # In this example - just hang around for at least the duration of
        terminationGracePeriodSeconds,
        # at 120 seconds container will be forcibly terminated.
        # Note, all this time nginx will keep processing requests.
        command: [
          "/bin/sh", "-c", "sleep 180"
        ]

```

[service/explore-graceful-termination-nginx.yaml](#)

```

apiVersion: v1
kind: Service
metadata:
  name: nginx-service
spec:
  selector:
    app: nginx
  ports:
  - protocol: TCP
    port: 80
    targetPort: 80

```

Now create the Deployment Pod and Service using the above files:

```

kubectl apply -f pod-with-graceful-termination.yaml
kubectl apply -f explore-graceful-termination-nginx.yaml

```

Once the Pod and Service are running, you can get the name of any associated EndpointSlices:

```

kubectl get endpointslice

```

The output is similar to this:

NAME	ADDRESSTYPE	PORTS	ENDPOINTS	AGE
nginx-service-6tjbr	IPv4	80	10.12.1.199,10.12.1.201	22m

You can see its status, and validate that there is one endpoint registered:

```

kubectl get endpointslices -o json -l kubernetes.io/service-name=nginx-service

```

The output is similar to this:

```

{
  "addressType": "IPv4",
  "apiVersion": "discovery.k8s.io/v1",
  "endpoints": [

```

```
{
  "addresses": [
    "10.12.1.201"
  ],
  "conditions": {
    "ready": true,
    "serving": true,
    "terminating": false
  }
}
```

Now let's terminate the Pod and validate that the Pod is being terminated respecting the graceful termination period configuration:

```
kubectl delete pod nginx-deployment-7768647bf9-b4b9s
```

All pods:

```
kubectl get pods
```

The output is similar to this:

NAME	READY	STATUS	RESTARTS	AGE
nginx-deployment-7768647bf9-b4b9s	1/1	Terminating	0	4m1s
nginx-deployment-7768647bf9-rkxlw	1/1	Running	0	8s

You can see that the new pod got scheduled.

While the new endpoint is being created for the new Pod, the old endpoint is still around in the terminating state:

```
kubectl get endpointslice -o json nginx-service-6tjbr
```

The output is similar to this:

```
{
  "addressType": "IPv4",
  "apiVersion": "discovery.k8s.io/v1",
  "endpoints": [
    {
      "addresses": [
        "10.12.1.201"
      ],
      "conditions": {
        "ready": false,
        "serving": true,
        "terminating": true
      },
      "nodeName": "gke-main-default-pool-dca1511c-d17b",
      "targetRef": {
        "kind": "Pod",
        "name": "nginx-deployment-7768647bf9-b4b9s",
        "namespace": "default",
        "uid": "66fa831c-7eb2-407f-bd2c-f96dfe841478"
      },
      "zone": "us-central1-c"
    }
  ]
}
```

```
},
{
  "addresses": [
    "10.12.1.202"
  ],
  "conditions": {
    "ready": true,
    "serving": true,
    "terminating": false
  },
  "nodeName": "gke-main-default-pool-dca1511c-d17b",
  "targetRef": {
    "kind": "Pod",
    "name": "nginx-deployment-7768647bf9-rkxlw",
    "namespace": "default",
    "uid": "722b1cbe-dcd7-4ed4-8928-4a4d0e2bbe35"
  },
  "zone": "us-central1-c"
}
```

This allows applications to communicate their state during termination and clients (such as load balancers) to implement a connections draining functionality. These clients may detect terminating endpoints and implement a special logic for them.

In Kubernetes, endpoints that are terminating always have their ready status set as false. This needs to happen for backward compatibility, so existing load balancers will not use it for regular traffic. If traffic draining on terminating pod is needed, the actual readiness can be checked as a condition serving.

When Pod is deleted, the old endpoint will also be deleted.
